## LIFE SUPPORT POLICY

NATIONAL'S PRODUCTS ARE NOT AUTHORIZED FOR USE AS CRITICAL COMPONENTS IN LIFE SUPPORT DEVICES OR SYSTEMS WITHOUT THE EXPRESS WRITTEN APPROVAL OF THE PRESIDENT OF NATIONAL SEMICONDUCTOR CORPORATION. As used herein:

1. Life support devices or systems are devices or systems which, (a) are intended for surgical implant into the body, or (b) support or sustain life, and whose failure to perform, when properly used in accordance with instructions for use provided in the labeling, can be reasonably expected to result in a significant injury to the user.
2. A critical component is any component of a life support device or system whose failure to perform can be reasonably expected to cause the failure of the life support device or system, or to affect its safety or effectiveness.

**National Semiconductor Corporation** 2900 Semiconductor Drive, P.O. Box 58090, Santa Clara, California 95052-8090 1-800-272-9959 TWX (910) 339-9240

National does not assume any responsibility for use of any circuitry described, no circuit patent licenses are implied, and National reserves the right, at any time without notice, to change said circuitry or specifications.

## Product Status Definitions

### Definition of Terms

Data Sheet Identification	Product Status	Definition
<b>Advance Information</b>	Formative or In Design	This data sheet contains the design specifications for product development. Specifications may change in any manner without notice.
<b>Preliminary</b>	First Production	This data sheet contains preliminary data, and supplementary data will be published at a later date. National Semiconductor Corporation reserves the right to make changes at any time without notice in order to improve design and supply the best possible product.
<b>No Identification Noted</b>	Full Production	This data sheet contains final specifications. National Semiconductor Corporation reserves the right to make changes at any time without notice in order to improve design and supply the best possible product.
<b>Obsolete</b>	Not In Production	This data sheet contains specifications on a product that has been discontinued by National Semiconductor Corporation. The data sheet is printed for reference information only.

National Semiconductor Corporation reserves the right to make changes without further notice to any products herein to improve reliability, function or design. National does not assume any liability arising out of the application or use of any product or circuit described herein; neither does it convey any license under its patent rights, nor the rights of others.

## An Introduction to Local Area Network (LAN) Standards and an Overview of National Semiconductor Products

Note: See Glossary for Definitions of the various main organizations.

TL/F/11257-1

**FIGURE 1. National Semiconductor's Participation In Industry Standards Committees**

### PRO-ACTIVE COMMUNICATIONS STANDARDS INVOLVEMENT

Standards are important in the development and growth of the communications industry. Several international committees and organizations define and promote standards to ensure interoperability and interconnectivity among multiple vendors' products.

National Semiconductor takes an active part in the development and definition of these standards (see Figure 1) and

produces a wide range of products that meet and exceed the requirements of these standards.

National's data communications portfolio includes complete silicon solutions for IEEE 802.3 4th Edition Ethernet, IEEE 802.3u Fast Ethernet, and ANSI X3T9.5 FDDI applications—the broadest portfolio in the industry. See Table I for a protocol characteristics summary.

**TABLE I. Key Characteristics of Popular LAN Protocols**

Characteristic	Ethernet	Fast Ethernet	FDDI
<b>Bandwidth</b>	10 Mbps	100 Mbps	100 Mbps
<b>Topology</b>	Bus, Star	Star	Dual Ring, Star
<b>Media</b>	Twisted Pair, Coax Optical Fiber	Twisted Pair Optical Fiber	Optical Fiber Twisted Pair
<b>Network Access</b>	CSMA/CD	CSMA/CD	Timed-Token-Passing
<b>Frame Size (bytes)</b>	1,500	1,500	4,500
<b>Encoding</b>	Manchester	4B/5B, MLT3	4B /5B
<b>Max. No. Nodes</b>	1,024	1,024	1000
<b>Distance (nodes)</b>	2.8 km	200m	2-3 km
<b>Max. Network Span</b>	2.8 km	2 km	200 km

**TABLE II. IEEE 802.3 Physical Layer Specifications, 10 Mbps Ethernet**

Parameter	10BASE5	10BASE2	10BASE-T
<b>Designator</b>	Thick Coax	Thin Coax	Twisted Pair
<b>Segment Length</b>	500 Meters	185 Meters	100 Meters Nominal
<b>Topology</b>	Bus (Multi-Point)	Bus (Multi-Point)	Star (Point-to-Point)
<b>Cable Type</b>	0.4" Diam. 50 $\Omega$ , Double Shield Coax (RG11)	0.2" Diam. 50 $\Omega$ , Single Shield Coax (RG58)	24 Gauge, 100 $\Omega$ Twisted Pair
<b>Connection</b>	Precision TAP	BNC "T"	8-Pin, RJ-45

**ETHERNET: IEEE 802.3 4th EDITION**

Ethernet is the most widely installed LAN standard for connecting personal computers and workstations with information resources, servers and other peripherals.

The 10 Mbps Ethernet CSMA/CD (Carrier Sense Multiple Access with Collision Detection) protocol defines how a node will gain access to the network. The node first monitors the media to ensure that no transmissions are in progress (Carrier Sense). The node may then decide to transmit (Multiple Access). If more than one node decides to transmit simultaneously, then a collision will occur.

All nodes must be able to detect this condition (Collision Detection), stop their transmissions, and retry after a random period of time.

**Physical Layer Specifications**

Physical Layer Specifications define various media and topology options. Current specifications include 10BASE5, which defines the use of thick, double-shielded coax in a bus configuration; 10BASE2, which defines the use of thin coax in a bus configuration; 10BASE-T, which defines the use of unshielded twisted pair cable in a star configuration; and 10BASE-F, which defines the use of optical fiber in a star configuration. Table II summarizes the specifications for the coax and twisted pair cables.

Because of its topology, 10BASE-T Ethernet LANs require both nodes and hubs or repeaters to extend the signals around the network. Network management becomes an issue or requirement in 10BASE-T as well. The IEEE 802.3 Repeater Specification defines basic, mandatory and optional management attributes to ensure interoperability in repeaters.

**Comprehensive Ethernet Solutions**

National's Ethernet products are grouped into four families: Network Interface Controllers (NIC Family); Systems Oriented Network Interface Controllers (SONIC™ Family); Physical Layers and Encoders/Decoders (PHYs and ENDECs Family); and Repeater Interface Controllers (RIC™ Family).

The NIC Family of 8/16-bit controllers provides value-based solutions for the node environment and designs. It consists of the DP8390 NIC, DP83901 SNIC™, DP83902 ST-NIC™, and DP83905 AT/LANTIC™. All are based on the industry standard DP8390 NIC core. The AT/LANTIC, the most highly integrated of the family, has an AT Bus Interface and twisted pair transceiver integrated on-chip making it well suited for motherboard designs. The ST-NIC also has an integrated twisted pair transceiver, but has no on-chip bus interface making it ideal for specialty I/O applications, such as PCMCIA, and non-AT buses. The SNIC provides a MAC and ENDEC only. The NIC is only a MAC.

The SONIC Family of 16/32-bit controllers provides full performance solutions for nodes and interconnect products. It consists of the DP83932 SONIC, DP83934 SONIC-T, and DP83916 SONIC-I6. The SONIC is appropriate for 16- and

32-bit Ethernet network nodes and bridges for any of the standard media choices. The SONIC-T is ideal for 10BASE-T networks due to its integrated twisted pair transceiver. The SONIC-16 is for 16-bit designs using the standard media choices.

The PHYs and ENDECs consist of separate physical layer transceivers and encoder/decoders. The DP8392 CTI™ is the industry's most reliable and most popular transceiver. It is often used in Media Access Units.

The RIC Family of repeater devices offers solutions for both high and low end hubs. The DP83950 RIC provides full management capabilities for large, multi-port, expandable hubs while the DP83955/56 LERIC™ offers limited management for small, basic functionality hubs.

More detailed information, including specific datasheets and application notes for these products, are included in Sections 1-4 of this book.

**FAST ETHERNET: IEEE 802.3u**

Fast Ethernet is another LAN standard that is similar to ordinary Ethernet, but ten times faster: 100 Mbps rather than 10 Mbps. Like ordinary Ethernet, it uses CSMA/CD and offers a choice of cable types.

**Physical Layer Specifications**

The current Physical Layer Specifications for Fast Ethernet include 100BASE-TX, which defines the use of two unshielded twisted pair cables; 100BASE-FX, which defines the use of optical fiber; and 100BASE-T4, which defines the use of four unshielded twisted pair cables. These cabling options operate in a star (point-to-point) configuration. Table III summarizes these Physical Layer Specifications.

**Comprehensive Fast Ethernet Solutions**

National's Fast Ethernet products provide a wide range of support for implementation of Fast Ethernet LAN's.

The DP83223 TWISTER™ High Speed Networking Transceiver Device is a twisted pair transceiver designed to operate in either a Fast Ethernet 100BASE-TX or FDDI LAN environment.

The DP83840 Ethernet Physical Layer is a device designed for easy implementation of Ethernet or Fast Ethernet using unshielded, shielded, or fiber optic cables.

The DP83810 Ethernet Controller for the Peripheral Component Interconnect Local Bus provides an Ethernet or Fast Ethernet interface for computer systems using the PCI Local Bus. For Fast Ethernet applications, it provides a complete solution when used with the DP83840 Ethernet Physical Layer and the DP83223 High Speed Networking Transceiver.

The DP83856 Repeater Information Base, used together with one or more DP83850 Repeater Interface Controller devices, simplifies the design of managed multipoint Fast Ethernet repeaters. Each DP83850 directly supports up to 12 network connections.

TABLE III. IEEE 802.3u Physical Layer Specifications, 100 Mbps Ethernet

Parameter	100BASE-TX	100BASE-FX	100BASE-T4
<b>Designator</b>	Twisted Pair	Fiber	Twisted Pair
<b>Segment Length</b>	100 Meters	114 Meters*	100 Meters
<b>Topology</b>	Star (Point-to-Point)	Star (Point-to-Point)	Star (Point-to-Point)
<b>Required Cabling</b>	2 Twisted Pairs	1 Multi-Mode Fiber or 2 Single-Made Fibers	4 Twisted Pairs
<b>Cable Quality</b>	Category 5 Unshielded Twisted Pair (UTP) or Shielded Twisted Pair (STP)	N/A	Category 3, 4 or 5 Unshielded Twisted Pair (UTP)
<b>Cable Type</b>	24 Gauge 100Ω UTP or 150Ω STP	62.5/125 μm Multi-Mode or Single-Mode Fiber	24 Gauge, 100Ω UTP
<b>Connection</b>	8-pin, RJ-45 (for UTP) or 9-pin, D8-9 (for STP)	Low Cost Fiber Optical Interface Connector (duplex SC), Media Interface Connector (MIC), or Optical Medium Connector Plug and Socket (ST)	8-pin, RJ-45

\*100BASE-FX segment length is limited by the collision domain of Ethernet. Longer segment lengths (i.e., 2 km or greater) are possible when used with switched Ethernet devices.

**FDDI (Fiber Distributed Data Interface): ANSI X3T9.5**

Fiber Distributed Data Interface (FDDI) is a 100 Mbps networking standard that uses a token passing access method and dual rings of optical fiber or twisted pair cable.

Like Token Ring, FDDI utilizes a ring topology. However, FDDI has a dual-ring configuration providing greater fault tolerance and redundancy. Timed-token-passing for FDDI works in a manner similar to token-passing for Token Ring. The standard defines fiber as the physical media, but a low cost physical media specification is in development to standardize the use of shielded and unshielded twisted pair media.

Originally used for backbone applications to connect multiple islands of lower speed LANs, FDDI has since migrated to the desktop. The inherent management capabilities and use of fiber offers a means with which to expand networks in a controlled manner. The use of twisted pair media for FDDI products provides a cost-effective means of bringing high-speed networking to the desktop.

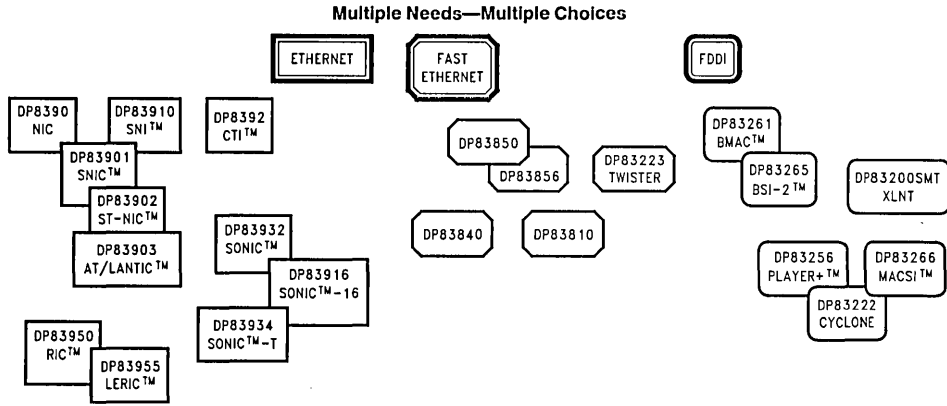

National's FDDI DP83200 Series portfolio consists of a two chip set, a five chip set, and a MLT-3/NRZI transceiver for UTP/STP cabling. A brief overview of these products is included in Section 6 for your reference. More detailed infor-

mation is available in the 1995 FDDI Databook or through your local National Semiconductor Sales Office.

**National's Commitment to Networking Standards**

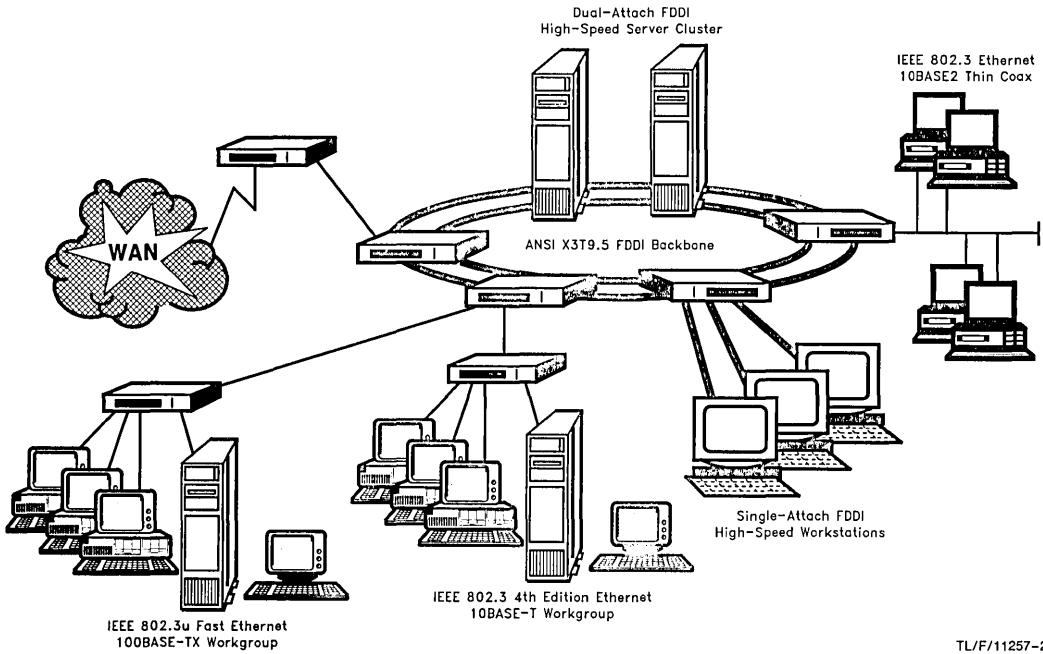

In support of current networking standards, National Semiconductor provides an extensive selection of networking silicon for Ethernet, Fast Ethernet, and FDDI. Comprehensive evaluation platforms, demonstration software, application notes, and system briefs are also available to provide network product designers and manufactures optimal flexibility and ease of product development for today's networking needs.

National Semiconductor's active involvement in the development of communications standards and experience as a LAN user have resulted in the availability of a broad range of silicon solutions for the networking market. National understands the importance of preserving investments in existing standards while balancing participation in the innovation and development of emerging networking standards such as isochronous Ethernet, ATM, and FDDI-II. With continuing efforts on standards committees, product innovation, and market leadership, National is dedicated to serving the networking needs today and in the future.

## DP83907 AT/LANTIC™ II

### General Description

The DP83907 Twisted-Pair Enhanced Coaxial Network Interface Controller is a CMOS VLSI device designed for easy implementation of CSMA/CD local area networks.

Unique to the DP83907 is the integration of the entire bus interface for PCAT ISA (Industry Standard Architecture) bus based systems. Hardware and software selectable options allow the DP83907's bus interface to be configured in the same manner as an NE2000 Architecture. All bus drivers and control logic are integrated to reduce board cost and area.

Supported network interfaces include 10BASE5 or 10BASE2 Ethernet via an external transceiver connected to its AUI port, and Twisted-pair Ethernet® (10BASE-T) using the on-board transceiver. The DP83907 provides the Ethernet Media Access Control (MAC), Encode-Decode (ENDEC) with an AUI interface, and 10BASE-T transceiver functions in accordance with the IEEE 802.3 standards.

The DP83907's integrated 10BASE-T transceiver fully complies with the IEEE standard. This functional block incorporates the receiver, transmitter, collision, heartbeat, loop-back, jabber, and link integrity blocks as defined in the standard. The transceiver when combined with equalization resistors, transmit/receive filters, and pulse transformers provides a complete physical interface from the DP83907's ENDEC module and the twisted pair medium. (continued)

### Features

- Controller and integrated bus interface solution for IEEE 802.3, 10BASE5, 10BASE2, and 10BASE-T
- Software compatible with industry standard Ethernet Adapters: Novell®'s NE2000
- No external bus logic or drivers needed
- Supports jumpered or jumperless configuration
- Provides EEPROM interface for non-volatile storage of configuration data, user-defined data and Ethernet Physical Address
- Allows in-situ programming of EEPROM
- Integrated controller, ENDEC, and transceiver
- Full IEEE 802.3 compliant AUI interface
- Single 5V supply

#### 10BASE-T TRANSCIEVER MODULE:

- Integrates transceiver functionality
- Transmitter and receiver functions
- Collision detect, heartbeat and jabber
- Selectable link integrity test or link disable
- Polarity Detection/Correction
- Auto switch
- On chip filter

#### ENDEC MODULE:

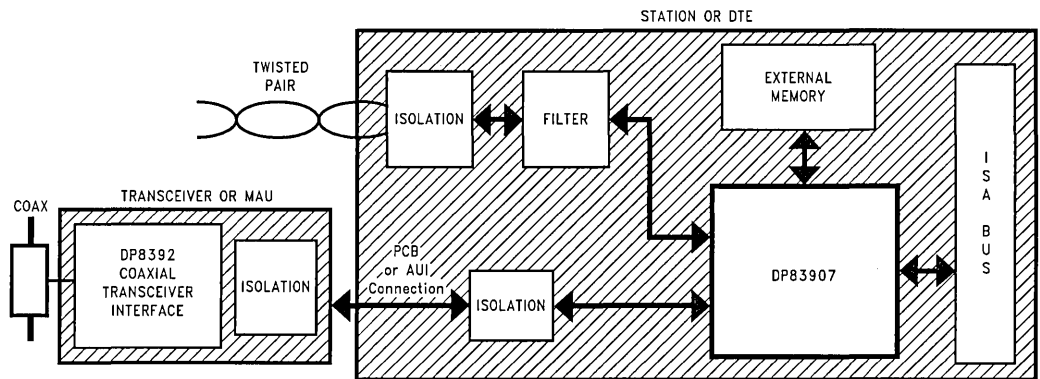

- 10 Mbit/s Manchester encoding/decoding
- Squelch on receive and collision pairs

#### MAC/CONTROLLER MODULE:

- Software compatible with DP8390, DP83901, DP83902
- Efficient buffer management implementation

#### IN-CIRCUIT TEST

## 1.0 System Diagram

TL/F/12082-1

## General Description (Continued)

The integrated ENDEC module allows Manchester encoding and decoding via a differential transceiver and phase lock loop decoder at 10 Mbit/sec. Also included are a collision detect translator and diagnostic loopback capability. The ENDEC module interfaces directly to the transceiver module, and also provides a fully IEEE compliant AUI (Attachment Unit Interface) for connection to other media transceivers.

The Media Access Control function which is provided by the Network Interface Control module (NIC) provides simple and efficient packet transmission and reception control by means of off-board memory which can be accessed through an I/O port.

The DP83907 provides a comprehensive solution for 10BASE-T IEEE 802.3 networks. Due to the inherent constraints of CMOS processing, isolation is required at the AUI differential signal interface for 10BASE5 and 10BASE2 applications.

## 2.0 Pin Description

Pin No.	Pin Name	Type	Description
<b>ISA BUS INTERFACE PINS</b>			
119–127, 132	SA0–SA9	I TTL	<b>LATCHED ADDRESS BUS:</b> Low-order 10 bits of the system's latched 20-bit address bus. These bits are used to decode accesses to the DP83907's I/O map.
1–7	SA13–SA19	I TTL	<b>LATCHED ADDRESS BUS:</b> 7 bits of the system's latched 20-bit address bus that are used to decode accesses to the DP83907's boot PROM.
10, 11	$\overline{\text{SMRD}}$ , $\overline{\text{SMWR}}$	I TTL	<b>BOOT PROM STROBES:</b> These inputs are used to access the BOOT PROM.
15, 16, 18 19, 21, 22 24, 25, 98 99, 101, 102, 104, 105, 107, 108	SD0–SD7 SD8–SD15	I/O 3ST	<b>SYSTEM DATA BUS:</b> 16-bit system data bus. Used to transfer data between the system and the DP83907.
118	$\overline{\text{IOCS16}}$	O OCH	<b>16 BIT I/O TRANSFER:</b> This signal indicates that the DP83907 is responding to a 16-bit I/O access by driving 16 bits of data on the bus.
9	$\overline{\text{IOWR}}$	I TTL	<b>I/O WRITE STROBE:</b> Strobe from system to write to the DP83907's I/O map.
8	$\overline{\text{IORD}}$	I TTL	<b>I/O READ STROBE:</b> Strobe from system to read from the DP83907's I/O map.
30	RESET	I TTL	<b>RESET:</b> This signal is output by the system to reset all devices on the bus.
13	CHRDY	O OCH	<b>CHANNEL READY:</b> This signal is used to insert wait states into system accesses.
12	AEN	I TTL	<b>DMA ACTIVE:</b> This signal indicates that the systems DMA has control of the bus.
29, 111, 112, 114, 115, 128 129, 130	IRQ3, 4, 5, 9, 10, 11, 12, 15	O 3ST	<b>INTERRUPT REQUEST:</b> The operation of these outputs is determined by Configuration Register A.

**Note:** Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3ST = TRI-STATE® Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type	Description
<b>NETWORK INTERFACE PINS</b>			
44-47	TxOd+, TXO-, TXO+ TXOd-	O TPI	<b>TWISTED PAIR TRANSMIT OUTPUTS:</b> These high drive CMOS level outputs are resistively combined external to the chip to produce a differential output signal with equalization to compensate for Intersymbol Interference (ISI) on the twisted pair medium.
42, 43	RXI+, RXI-	I TPI	<b>TWISTED PAIR RECEIVE INPUTS:</b> These inputs feed a differential amplifier which passes valid data to the ENDEC module.
33, 34	TX- TX+	O AUI	<b>AUI TRANSMIT OUTPUT:</b> Differential driver which sends the encoded data to the transceiver.
36, 37	RX- RX+	I AUI	<b>AUI RECEIVE INPUT:</b> Differential receive input pair from the transceiver.
38, 39	CD- CD+	I AUI	<b>AUI COLLISION INPUT:</b> Differential collision pair input from the transceiver.
55	ACT_led	O LED	<b>ACTIVITY:</b> An open-drain active low output. It is asserted for approximately 50 ms whenever the DP83907 transmits or receives data in either AUI or TPI modes.
56	COL_led	O LED	<b>COLLISION:</b> An open-drain active low output. It is asserted for approximately 50 ms whenever the DP83907 detects a collision in either either AUI or TPI modes.
54	GDLNK_led	O LED	<b>GOOD LINK:</b> An open-drain active low output. This pin operates as an output to display link integrity status if this function has not been disabled by the GDLNK bit in Configuration Register B. This output is off if the DP83907 is in AUI mode or if link testing is enabled and the link integrity is bad (i.e., the twisted pair link has been broken). This output is on if the DP83907 is in Twisted Pair interface (TPI) mode, link integrity checking is enabled and the link integrity is good (i.e., the twisted pair link has <b>not</b> been broken) or if the link testing is disabled.
53	REQ	I	<b>EQUALIZATION RESISTOR:</b> A resistor can be connected from this pin to GND or V <sub>CC</sub> to change the equalization of the TP output.
52	RTX	I	<b>TRANSMIT LEVEL RESISTOR:</b> A resistor can be connected from this pin to GND or V <sub>CC</sub> to change the TP output amplitude level.
59	X1 (OSCIN)	I XTAL	<b>CRYSTAL ON EXTERNAL OSCILLATOR INPUT</b>
58	X2 (OSCOU)	O XTAL	<b>CRYSTAL FEEDBACK OUTPUT:</b> Used in crystal connections only. Should be left unconnected when using an oscillator module.
31	THIN	O DCDC	<b>THIN CABLE:</b> This output is high if DP83907 is configured for thin cable. It can be used to enable the DC-DC converter required by the thin Ethernet configuration.

**Note:** Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3ST = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type	Description
<b>EXTERNAL MEMORY SUPPORT</b>			
87-94	MSD0-7 or CA0-7 or DO, DI, SK	I/O-I-O MOS	<b>MEMORY SUPPORT DATA BUS—CONFIGURATION REGISTER A INPUT: EEPROM SIGNALS:</b> MSD0-7: When RESET is inactive these pins are used to access external memory and boot PROM. CA0-7: When RESET is active Configuration Register A is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0. DO, DI, SK: When RESET goes from an active to an inactive level DP83907 will read the contents of a serial EEPROM, using these signals, and load the contents into internal registers. These internal registers are mapped into the space taken up by the PROM in the NE2000 Architecture. After the EEPROM read operation has completed these pins will revert to MSD0-2 (D0 = MSD0, DI = MSD1, SK = MSD2).
77-82 85, 86	MSD8-15 or CB0-7	I/O-I MOS	<b>MEMORY SUPPORT DATA BUS—CONFIGURATION REGISTER B INPUT:</b> MSD8-15: When RESET is inactive these pins are used to access external memory. CB0-7: When RESET is active Configuration Register B is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0.
60-67	MSA1-8 or CC0-7	O-I MOS	<b>MEMORY SUPPORT ADDRESS BUS—CONFIGURATION REGISTER C INPUT:</b> MSA1-8: When RESET is inactive these pins drive the memory support address bus. CC0-7: When RESET is active Configuration Register C is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0.
68, 69 71-73	MSA9-13 or DWID, EECONFIG and SIG 5-7	O-I MOS	<b>MEMORY SUPPORT ADDRESS BUS—DWID, EECONFIG AND SIGNATURE REGISTER:</b> MSA9-13: When RESET is inactive these pins drive the memory support address bus. DWID (MSA9): When RESET is active this input specifies whether the DP83907 is interfacing to an 8-bit or 16-bit ISA bus. If the user puts an external pull-up on this pin then the bus is considered to be 16-bit. If the pin is left unconnected then the bus is considered to be 8-bit. EECONFIG(MSA10): When RESET is active this input specifies whether the DP83907 loads the configuration from an EEPROM or from the MSD0-15 and MSA1-8 pins. If the user puts an external pull-up on this pin then configuration data is loaded from the EEPROM. If the pin is left unconnected then configuration data is loaded from the memory support bus. SIG 5-7(MSA11-13): When RESET is active the most significant 3 bits of the signature register are loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0.
76	MSRD	O MOS	<b>MEMORY SUPPORT BUS READ:</b> Strobes data from the external RAM into the DP83907 via the memory support data bus.
74	MSWR	O MOS	<b>MEMORY SUPPORT BUS WRITE:</b> Strobes data from the DP83907 into the external RAM via the memory support data bus.

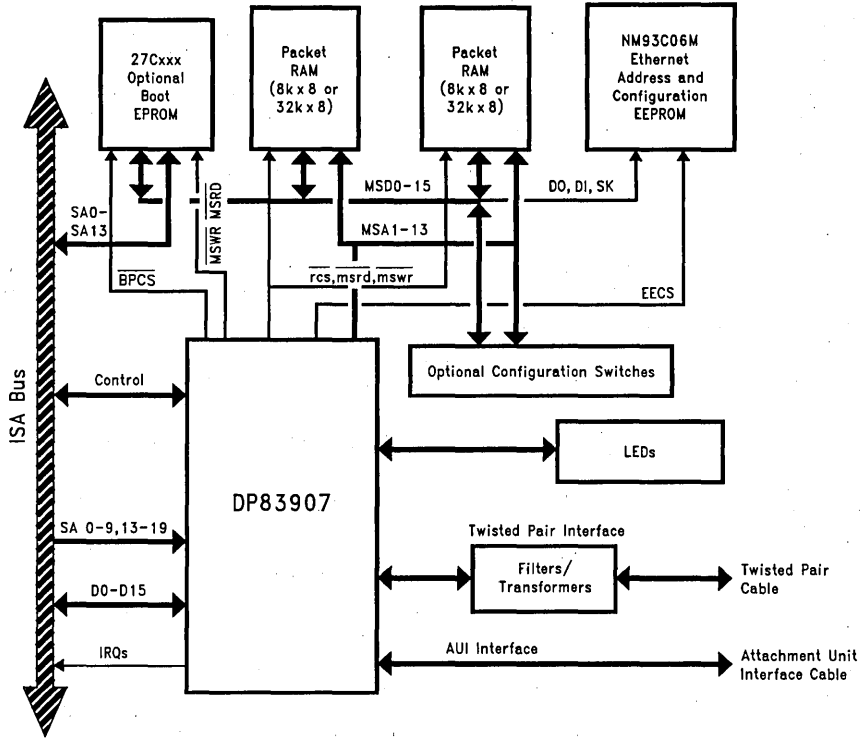

**Note:** Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3ST = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type	Description
<b>EXTERNAL MEMORY SUPPORT (Continued)</b>			
95	RCS	O MOS	<b>RAM CHIP SELECT:</b> Drives the chip select of the external RAM.
97	BPCS	O MOS	<b>BOOT PROM CHIP SELECT:</b> Selects the boot PROM on the memory support data bus. This is for READ only.
96	EECS	O MOS	<b>EEPROM CHIP SELECT:</b> Strobes data from the EEPROM onto the memory support data bus.
<b>POWER SUPPLY PINS</b>			
40	AV <sub>CC</sub>		<b>ANALOG 5V SUPPLY PIN:</b> This pin supplies 5V to the DP83907's analog circuitry. To maximize data recovery it is recommended that analog layout and decoupling rules be applied between this pin and AGND.
41	AGND		<b>ANALOG NEGATIVE (GROUND) SUPPLY PIN.</b>
35, 48	XV <sub>CC</sub> , TPV <sub>CC</sub>		<b>PHYSICAL MEDIA 5V SUPPLY PINS:</b> This pin supplies 5V to the DP83907's analog physical media interface circuitry.
32, 49	XGND, TPGND		<b>PHYSICAL MEDIA NEGATIVE (GROUND) SUPPLY PINS:</b> This pin is the ground to the DP83907's analog physical media interface circuitry.
26, 109	coreV <sub>CC</sub>		<b>POSITIVE 5V SUPPLY PINS:</b> These pins supply power to the DP83907.
27, 110	coreGND		<b>NEGATIVE (GROUND) SUPPLY PINS:</b> These are the supply pins for the DP83907. It is suggested that decoupling capacitors be connected between the V <sub>CC</sub> and GND pins. It is essential to provide a path to ground for the GND pins with the lowest possible impedance.
20, 70, 103	V <sub>CC</sub>		<b>POSITIVE 5V SUPPLY PINS:</b> These pins supply power to the DP83907 Output Drivers e.g., SD, MSD, MSA, Chip selects.
14, 17, 23, 28, 57, 75, 100, 106, 113, 116, 131	GND		<b>NEGATIVE (GROUND) SUPPLY PINS:</b> These are the supply pins for the DP83907 Drivers. It is suggested that decoupling capacitors be connected between the V <sub>CC</sub> and GND pins. It is essential to provide a path to ground for the GND pins with the lowest possible impedance.

**Note:** Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3ST = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

### 3.0 Simplified Application Diagram

TL/F/12082-3

### 3.0 Simplified Application Diagram (Continued)

FIGURE 1. Block Diagram of DP83907

TL/F/12082-4

## 4.0 Functional Description

The DP83907 is a highly integrated and configurable Ethernet controller making it suitable for most Ethernet applications. The DP83907 integrates the functions of the following blocks:

1. ISA Bus Interface containing all logic required to connect the DP8390 core to a packet buffer RAM and the ISA bus.
2. DP8390 Ethernet Controller Core and Media Access Control logic.
3. Media Interface which includes a TPI transceiver.

### 4.1 BUS INTERFACE BLOCK

The DP83907's Bus interface block provides the circuitry to interface the Ethernet controller logic and the external packet buffer RAM to an ISA (Industry Standard Architecture)

Bus. The bus interface provides an NE2000 Architecture compatible I/O port architecture, supporting both 8-bit and 16-bit wide ISA Bus slots.

#### DETERMINING 8-BIT OR 16-BIT WIDE DATA

DP83907 can treat the system data bus and all internal data busses as 8 bits or 16 bits wide. 8-bit or 16-bit mode is determined by MSA9 at reset. For an adapter card this pin can be used to automatically detect if the card has been plugged into an 8-bit or 16-bit slot by connecting MSA9 via a 10 k $\Omega$  pull-up resistor to a V<sub>DD</sub> on the upper connector. It will be pulled high when plugged into a 16-bit slot, enabling 16-bit mode, and floating when plugged into an 8-bit slot. When floating the internal pull-down resistor will enable 8-bit mode.

## 4.0 Functional Description (Continued)

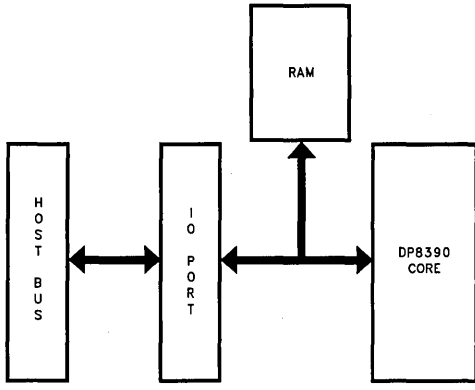

FIGURE 2. I/O Port

TL/F/12082-5

The DP83907's internal memory map is accessed one byte or word at a time, via a port within the systems I/O space. DP83907 is programmed by the user to control the transfers between its internal memory and the I/O port. The DP83907's internal registers and the memory access port are accessed within the system's I/O map. The address within this I/O map is, set by Configuration Register A.

### 16-BIT I/O PORT COMPATIBLE MODE I/O ADDRESS MAPPING

This mode is compatible with Novell's NE2000 Architecture. The base I/O address of DP83907 is configured by Configuration Register A (either upon power up or by software writing to this register). At the base I/O address the following structure appears.

FIGURE 3. I/O Port Mode Register I/O Map

The DP83907 register space within this area are 8 bits wide, but the data transfer port is 16 bits wide. The DP83907's registers can be programmed to control the passing of data between its internal memory and the data transfer port. By accessing the data transfer port (using I/O instructions) the user can transfer data to or from the DP83907's internal memory. The DP83907's internal memory map is as shown below.

	D15	D0
0000h	00	PROM
001Fh	Aliased PROM	
4000h	8k x 16 Buffer RAM	
7FFFh	8k x 16 Buffer RAM

0004h	00	E'net Address 2
0002h	00	E'net Address 1
0000h	00	E'net Address 0

(b)

FIGURE 4. a) NIC Core's 16-Bit Memory Map  
b) 16-Bit PROM Map

DP83907 has a 64k address range but only does partial decoding through this space. The PROM data is mirrored from all decodes up to 4000H and the entire map is repeated at 8000H. To access either the PROM or the RAM the user must initiate a Remote DMA transfer between the I/O port and memory.

### 4.0 Functional Description (Continued)

On a remote read the DP83907 moves data from its internal memory map to the I/O port and the host system reads it by using an "INW" or "INSW" instruction from the I/O address of the data transfer port. If the system attempts to read the port before DP83907 has written the next word of data to it DP83907 will insert wait states into the system cycle using the CHRDY line. DP83907 will not begin the next memory read until the previous word of data has been read.

On a remote write the system writes data to the I/O port, using an "OUTW" or "OUTSW" instruction, and DP83907 moves it to its buffer memory. If the system attempts to write to the port before DP83907 has moved the data to memory, DP83907 will insert wait states into the system cycle using the CHRDY line. DP83907 will not begin the next memory write until a new word has been written to the I/O port.

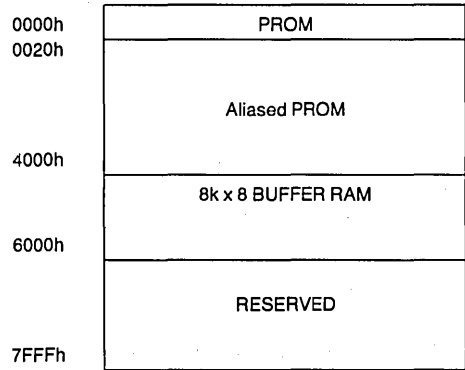

Addresses 00H to 1FH are specified as the PROM space for compatibility with the NE2000 Architecture. This is actually an array of 8-bit registers which are loaded from an external EEPROM after DP83907 is initialized by an ISA RESET. They should contain the same data as the PROM did in the NE2000 Architecture and in the same format. To transfer the data out the user must initiate a 16-bit DMA read transfer and discard the most significant byte of data on each transfer.

At address 00H of the PROM is a six byte Ethernet address for this node. The upper two addresses of the PROM store contain bytes which identify whether the DP83907 is in 8-bit or 16-bit mode. For 16-bit mode these bytes both contain the value 57H, for 8-bit mode they both contain 42H.

#### 8-BIT I/O PORT COMPATIBLE MODE

This mode is compatible with the 8-bit mode offered by Novells NE2000 Architecture. The NE2000 automatically detects whether it is in an 8-bit or 16-bit slot and configures itself appropriately. As explained in the previous paragraphs, the user can determine whether the board is in 8-bit or 16-bit mode by reading the PROM. In 8-bit mode only 8 Kbytes of RAM are addressable, as in the 8-bit mode of the NE2000 Architecture. The I/O map is the same as the 16-bit mode, the memory map is shown in *Figure 5*. Again the PROM has only a partial decode, so is mirrored at all addresses up to 4000H. The PROM still occupies 32 bytes of address space, although it only has 16 bytes of data, as the data at all odd address locations is merely a mirror of the data at the previous even address location.

A low cost card, using only one 8 Kbyte RAM, can be designed. If the function on MSA9 is left unconnected, then the DP83907 will always operate in 8-bit mode, regardless of the slot the board is in.

#### 4.2 POWER ON RESET OPERATION

The DP83907 configures itself after a Reset signal is applied. To be recognized as a valid Power-On-Reset the Reset signal must be active for at least 415  $\mu$ s. *Figure 6* shows how the RESET circuitry operates.

TL/F/12082-6

FIGURE 6. RESET Operation

## 4.0 Functional Description (Continued)

The ISA standard determines that within 500 ns of RESET going active all devices should enter the appropriate reset condition. The DP83907 will generate the internal signal  $I_{Oinactive}$  after RESET has been active for 400 ns, which will disable all outputs and cause RESET to be the only input monitored. The DP83907 will not respond to a RESET pulse of shorter duration than this. An internal timer continues to monitor the amount of time RESET is active. After 415  $\mu$ s it is considered a valid Power-On-Reset and an internal signal called RegLoad is generated.

When a Power-On-Reset occurs the DP83907 latches in the values on the configuration pins and uses these to configure the internal registers and options. Internally these pins contain pull-down resistors, which are enabled when  $I_{Oinactive}$  goes active. If any pins are unconnected they default to a logic zero. The internal pull-down resistor has a high resistance to allow the external pull-up resistors to be of a high value. This limits the current taken by the memory support bus. The suggested external resistor value is 10 k $\Omega$ . The configuration registers are loaded from the memory support bus when RESET goes inactive if RegLoad is active. The internal pull-down resistors are enabled onto the bus until RegLoad has gone inactive.

A Power-On-Reset also causes the DP83907 to load the internal PROM space from the EEPROM, which can take up to 320  $\mu$ s. This occurs after RegLoad has gone inactive. The DP83907 will be inaccessible during this time. If EECONFIG is held high the configuration data loaded on the falling edge of RESET will be overwritten with data read from the serial EEPROM. Regardless of the level on EECONFIG, the PROM space will always be loaded with data from the serial EEPROM during the time specified as EELoad.

### 4.3 EEPROM OPERATION

The DP83907 uses an NMC93C06, or another serial EEPROM with compatible timings. The NMC93C06 is a 256-bit device, arranged as 16 words by 16 bits wide. The programmed contents of the EEPROM is shown in *Figure 7*.

FIGURE 7. EEPROM Programming Map

### Mapping EEPROM into PROM Space

Data is read from the EEPROM at boot time and stored in registers within the DP83907. While this operation takes place the DP83907 can not be accessed by the system. These registers are mapped into the space traditionally occupied by the PROM in the NE2000

The user should program the EEPROM to contain the Ethernet address in the first six bytes and whatever is required in the next 8 bytes. The user should then program 5757H and 4242H into address 07h and 08h respectively. The DP83907 device driver may determine that this is a 16-bit board by checking this value.

The DP83907 reads the first 8 words from the EEPROM and maps them into the memory map at the appropriate address.

### In Circuit Programming the EEPROM

If the upper byte of address 0Fh in the EEPROM does not contain 073H then the DP83907 enters a mode that allows the EEPROM contents to be programmed. This can be used in production to program the EEPROM in-situ. By programming 073H into the uppermost byte the EEPROM is protected from future adaptation, except for configuration data which can always be modified.

If the EEPR bit of the Signature Register is low the EEPROM program mode may be entered. The EEPR bit is low if the EEPROM code is not programmed as 73H. In this mode, if the EELoad bit of Configuration Register B is set the user can directly control the EEPROM signals by writing to the Data Transfer Port. The user can write to the Data Transfer Port and the value on the SD3, SD2 and SD1 pins will be driven onto the EECS, SK and DI outputs. These outputs will be latched. The user can generate a clock on SK by repetitively writing 1 then 0 to the appropriate bit. This can be used to generate the EEPROM signals, as per the NM93C06 data sheet.

When the EEPROM has been programmed the user must give the DP83907 a reset signal to return to normal operation and to read in the new data.

### Storing and Loading Configuration from EEPROM

If the EECONFIG function on MSA10 is high during boot up the DP83907's configuration is read from the EEPROM, before the PROM data is read. The configuration data is stored within the upper two words of the EEPROM's address space. Configuration Registers A and B are located in the lower of these words, Register C in the lower byte of the upper word, as shown in *Figure 7*.

To write this configuration into the EEPROM the user must follow the routine specified in the pseudo code below. If the EEPROM code byte in the EEPROM is programmed as 73H the Configuration Registers may be written to in the EEPROM. This operation will work regardless of the level on EECONFIG. The EELoad bit of Configuration Register B being set starts the EEPROM write process. Care should be taken not to accidentally set the GDLink bit and therefore disable link integrity checking. The next 3 writes to this register load the values that will be stored in the configuration register (note that the last 2 of these writes do not have to follow the normal practice of preceding a write to this register with a read to this address). The DP83907 will then commence the EEPROM write. The write has been completed when the EELoad bit goes to zero. This loading process

## 4.0 Functional Description (Continued)

sure should be followed exactly and interrupts should be disabled until it has completed, to prevent any accidental accesses to the DP83907.

```

    WRITE(CONFIG_B, config_for_B);
    WRITE(CONFIG_B, config_for_C);
    while (value AND EELoad)
    {
        value = READ(CONFIG_B);
        WAIT();
    }
    ENABLE_INTERRUPTS();
}
```

### 4.4 JUMPERLESS OPERATION SUPPORT

One of the biggest problems in installing new adapters in a PC is not knowing the available resources within that machine. DP83907's software configuration overcomes that problem. The conflicts possible in the I/O base selection can be overcome by a special mode for software configuration of the I/O base address. By using this mode, and by using the configuration storage capability of the EEPROM, a fully software configurable design on the ISA bus can be realized without address conflict problems.

This mode is invoked by having the DP83907 default to jumperless software configuration option in the I/O base selection. This mode enables configuration register A to be mapped to address location 278H which is defined to be a printer port's data register. If software writes to this location four consecutive times, on the fourth write the DP83907 will load the data written into the I/O address bits of Configuration Register A. This data should set the I/O base address to a known conflict-free value. The DP83907 can now be configured and operated at the desired base I/O address. If desired, the configuration software could change the EEPROM content to the new values eliminating the need to reconfigure upon each power up. Alternately the software could leave the EEPROM alone and execute the configuration using the printer port's data register upon each power up. This configuration scheme will only work once after each power-up. Therefore the user can not enable the DP83907 from reserved mode, change it back into reserved mode and enable it again. A power-on reset must occur between the first time it is enabled from the reserved mode and the second.

### 4.5 ETHERNET CABLE CONFIGURATION

DP83907 offers the choice of all the possible Ethernet cabling options, that is Ethernet (10BASE5), Thin Ethernet (10BASE2) and Twisted-pair Ethernet (10BASE-T). The

type of cabling used is controlled by Configuration Register B. DP83907 also supplies a THIN output signal which can be used to disable/enable an external DC-DC converter which is required for 10BASE2.

### 4.6 INTERRUPT AND LED OPERATION

The DP83907 has only one Interrupt Mode. There are 8 possible interrupts. Configuration Register A controls which of the 8 interrupt lines are driven, the others are TRI-STATE. **The interrupt outputs should be connected to the following ISA Interrupt lines, in the order given, to maintain NE2000 Architecture compatibility: 3, 4, 5, 9, 10, 11, 12, 15.**

### 4.7 BOOT PROM OPERATION

The DP83907 supports an optional boot PROM, the address and size of which can be set in Configuration Register C. This boot PROM can be any 8-bit wide storage device implemented with a non-volatile technology. Write cycles to this device can be enabled and disabled by programming Configuration Register B. This can be used to prevent unwanted write cycles to certain devices, such as a Flash EEPROM. The DP83907 supplies the chip select to the device and buffers the data on to and from the ISA bus, so the memory support data bus should be connected to the boot PROM's data pins.

### 4.8 DP8390 CORE (NETWORK INTERFACE CONTROLLER)

The DP8390 Core logic, *Figure 12*, contains the Serializer/Deserializer which is controlled by the Protocol PLA, DMA Control, FIFO, Address Comparator and Multicast Hashing Register. The DP8390 core implements all of the IEEE 802.3 Media access control functions for the DP83907 and interfaces to the internal ENDEC (on the left of the block diagram) and to the Bus Interface and memory support bus via a number of address, data and control signals (the right side of the block diagram). The following sections describe the functions of the DP8390 core.

#### Receive Deserializer

The Receive Deserializer is activated when the input signal Carrier Sense is asserted to allow incoming bits to be shifted into the shift register by the receive clock. The serial receive data is also routed to the CRC generator/checker. The Receive Deserializer includes a synch detector which detects the SFD (Start of Frame Delimiter) to establish where byte boundaries within the serial bit stream are located. After every eight receive clocks, the byte wide data is transferred to the 16-byte FIFO and the Receive Byte Count is incremented. The first six bytes after the SFD are checked for valid comparison by the Address Recognition Logic. If the Address Recognition Logic does not recognize the packet, the FIFO is cleared.

#### CRC Generator/Checker

During transmission, the CRC logic generates a local CRC field for the transmitted bit sequence. The CRC encodes all fields after the SFD. The CRC is shifted out MSB first follow-

## 4.0 Functional Description (Continued)

FIGURE 12. DP8390 Core Simplified Block Diagram

TL/F/12082-7

ing the last transmit byte. During reception the CRC logic generates a CRC field from the incoming packet. This local CRC is serially compared to the incoming CRC appended to the end of the packet by the transmitting node. If the local and received CRC match, a specific pattern will be generated and decoded to indicate no data errors. Transmission errors result in different pattern and are detected, resulting in rejection of a packet.

### Transmit Serializer

The Transmit Serializer reads parallel data from the FIFO and serializes it for transmission. The serializer is clocked by the transmit clock generated internally. The serial data is also shifted into the CRC generator/checker. At the beginning of each transmission, the Preamble and SFD Generator append 62 bits of 1,0 preamble and a 1,1 synch pattern. After the last data byte of the packet has been serialized the 32-bit FCS (Frame Check Sequence) field is shifted directly out of the CRC generator. In the event of a collision the Preamble and SFD generator is used to generate a 32-bit JAM pattern of all 1's.

### Comparator-Address Recognition Logic

The address recognition logic compares the Destination Address Field (first 6 bytes of the received packet) to the Physical address registers stored in the Address Register Array.

If any one of the six bytes does not match the pre-programmed physical address, the Protocol Control Logic rejects the packet. All multicast destination addresses are filtered using a hashing technique. (See register description.) If the multicast address indexes a bit that has been set in the filter bit array of the Multicast Address Register Array the packet is accepted, otherwise it is rejected by the Protocol Control Logic. Each destination address is also checked for all 1's which is the reserved broadcast address.

### FIFO and Packet Data Operations

#### OVERVIEW

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the packet buffer memory, the DP83907 contains a 16-byte FIFO for buffering data between the media and the buffer RAM located on the memory support bus. The FIFO threshold is programmable. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory (via the memory bus). It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO under-run (or overrun) occurs.

## 4.0 Functional Description (Continued)

FIFO underruns or overruns are caused when a local DMA request is issued while an ISA bus access is current and the ISA cycle takes longer to complete than the local DMA's tolerable latency. This tolerable latency depends on the FIFO threshold, whether it is in byte or word wide mode and the speed of the DMA clock (BSCLK frequency). Note that this refers to standard ISA cycles, NOT those where the CHRDY is deasserted extending the cycle.

### FIFO THRESHOLD DETECTION

To assure that no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the  $n + 1$  byte has entered the FIFO; thus, with an 8 byte threshold, the DP83907 issues a request to the buffer RAM when the 9th byte has entered the FIFO, making the effective threshold 9 bytes. For Word Mode, the request is not generated until the  $n + 2$  bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to 8 byte threshold), a request to the buffer RAM is issued when the 10th byte has entered the FIFO, making the effective threshold 10 bytes.

### TOLERABLE LATENCY CALCULATION

To prevent a FIFO **overrun** a byte (or word) of data must be **removed** from the FIFO before the 13th byte is written. Therefore the worst case tolerable latency is the time from the effective threshold being reached to the time the 13th byte is written minus the time taken to load the first byte (or word) of data to the FIFO during a local DMA burst (8 BSCLKs).

$$\begin{aligned} \text{tolerable latency} &= ((\text{overrun} - \text{effective}) \text{ threshold} \\ &\quad \times \text{time to transfer byte on network}) \\ &\quad - \text{time to fill 1st FIFO location} \end{aligned}$$

For the case of a 4 word threshold using a 20 MHz BSCLK:

$$\begin{aligned} \text{tolerable latency} &= ((13 - 10) \times 800) - (8 \times 50) \text{ ns} \\ &= 2 \mu\text{s} \end{aligned}$$

To prevent a FIFO **underrun** a byte (or word) of data must be **added** to the FIFO before the last byte is removed. Therefore the worst case tolerable latency is the time from the effective threshold being reached to the time the last byte is removed minus the time taken to load the first byte (or word) of data to the FIFO during a local DMA burst (8 BSCLKs).

$$\begin{aligned} \text{tolerable latency} &= (\text{threshold} \\ &\quad \times \text{time to transfer byte on network}) \\ &\quad - \text{time to fill 1st FIFO location} \end{aligned}$$

For the case of a 4 word threshold using a 20 MHz BSCLK:

$$\begin{aligned} \text{tolerable latency} &= (4 \times 800) - (8 \times 50) \text{ ns} \\ &= 2.8 \mu\text{s} \end{aligned}$$

The worst case latency, either overrun or underrun, ultimately limits the overall latency that the DP83907 can tolerate. If the standard ISA cycles are shorter than the worst case latency, then no FIFO overruns or underruns will occur.

### BEGINNING OF RECEIVE

At the beginning or reception, the DP83907 stores the entire Address field of each incoming packet in the FIFO to deter-

mine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that a request to access the buffer RAM is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu\text{s}$ . This operation affects the bus latencies at 2 and 4 byte thresholds during the first receive request since the FIFO must be filled to 8 bytes (or 4 words) before issuing a request to the buffer RAM.

### END OF RECEIVE

When the end of a packet is detected by the ENDEC module, the DP83907 enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the 1st buffer. The DP83907 holds onto the memory bus for the entire sequence. The longest time that local DMA will hold the buffer RAM occurs when a packet ends just as the DP83907 performs its last FIFO burst. The DP83907, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completed by writing the header information to the buffer memory. The following steps occur during this sequence.

1. DP83907 issues request to access the RAM because the FIFO threshold has been reached.
2. During the burst, the packet ends, resulting in the request being extended.
3. DP83907 flushes remaining bytes from FIFO.
4. DP83907 performs internal processing to prepare for writing the header.
5. DP83907 writes 4-byte (2-word) header
6. DP83907 de-asserts access to the buffer RAM.

### BEGINNING OF TRANSMIT

Before transmitting, the DP83907 performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next request to the buffer RAM is not issued until after the DP83907 actually begins transmitting data, i.e., after SFD.

### READING THE FIFO

If the FIFO is read during normal operation the DP83907 will "hang" the ISA bus by deasserting CHRDY and never asserting it. The FIFO should only be read during loopback diagnostics.

### PROTOCOL PLA

The protocol PLA is responsible for implementing the IEEE 802.3 protocol, including collision recovery with random backoff. The Protocol PLA also formats packets during transmission and strips preamble and synch during reception.

### DMA AND BUFFER CONTROL LOGIC

The DMA and Buffer Control Logic is used to control two 16-bit DMA channels. During reception, the Local DMA stores packets in a receive buffer ring, located in buffer memory. During transmission the Local DMA uses programmed pointer and length registers to transfer a packet from local buffer memory to the FIFO.

## 4.0 Functional Description (Continued)

FIGURE 13. Twisted Pair Interface Module Block Diagram

TL/F/12082-8

A second DMA channel (Remote DMA) is used as a slave DMA to transfer data between the local buffer memory and the host system. The Local DMA and Remote DMA are internally arbitrated, with the Local DMA channel having highest priority. Both DMA channels use a common external bus clock to generate all required bus timing. External arbitration is performed with a standard bus request, bus acknowledge handshake protocol.

### 4.9 TWISTED PAIR INTERFACE MODULE

The TPI consists of five main logical functions:

- The Receiver/Smart Squelch, responsible for determining when valid data is present on the differential receive inputs (RXI $\pm$ ) and receiving the data.
- The Collision function checks for simultaneous transmission and reception of data on the TXO $\pm$  and RXI $\pm$  pins.
- The Link Detector/Generator checks the integrity of the cable connecting the two twisted pair MAUs.
- The Jabber disables the transmitter if it attempts to transmit a longer than legal packet.
- The TX Driver and Pre-emphasis transmits Manchester encoded data to the twisted pair network via the summing resistors and transformer/filter.

## 4.0 Functional Description (Continued)

### Receiver and Smart Squelch

The DP83907 implements an intelligent receive squelch on the RX1± differential inputs to ensure that impulse noise on the receive inputs will not be mistaken for a valid signal.

The squelch circuitry employs a combination of amplitude and timing measurements to determine the validity of data on the twisted pair inputs. There are two voltage level options for the smart squelch. One mode, 10BASE-T mode, uses levels that meet the 10BASE-T specification. The second mode, reduced squelch mode, uses a lower squelch threshold level, and can be used in longer cable applications where due to attenuation smaller signal levels may be present. The squelch level mode can be selected in the DP83907 configuration registers.

Figure 14 shows the operation of the smart squelch in 10BASE-T mode.

The signal at the start of packet is checked by the smart squelch and any pulses not exceeding the squelch level (either positive or negative, depending upon polarity) will be rejected. Once this first squelch level is overcome correctly the opposite squelch level must then be exceeded within 150 ns later. Finally the signal must exceed the original squelch level within a further 150 ns to ensure that the input waveform will not be rejected. The checking procedure results in the loss of typically three bits at the beginning of each packet.

Only after all these conditions have been satisfied will a control signal be generated to indicate to the remainder of the circuitry that valid data is present. At this time the smart squelch circuitry is reset.

In the reduced squelch mode the operation is identical except that the lower squelch levels shown in the figure are used.

Valid data is considered to be present until either squelch level has not been generated for a time longer than 150 ns, indicating End of Packet. Once good data has been detected the squelch levels are reduced to minimize the effect of noise causing premature End of Packet detection.

FIGURE 14. Twisted Pair Squelch Waveform

TL/F/12082-9

### Collision

A collision is detected by the TPI module when the receive and transmit channels are active simultaneously. If the TPI is receiving when a collision is detected it is reported to the controller immediately. If, however, the TPI is transmitting when a collision is detected the collision is not reported until seven bits have been received while in the collision state. This prevents a collision being reported incorrectly due to noise on the network. The signal to the controller remains for the duration of the collision.

Approximately 1  $\mu$ sec after the transmission of each packet a signal called the Signal Quality Error (SQE) consisting of typically 10 cycles of 10 MHz is generated. This 10 MHz signal, also called the Heartbeat, ensures the continued functioning of the collision circuitry.

### Link Detector/Generator

The link generator is a timer circuit that generates a link pulse as defined by the 10 Base-T specification that will be generated by the transmitter section. The pulse which is 100 ns wide is transmitted on the TXO+ output, every 16 ms, in the absence of transmit data.

The pulse is used to check the integrity of the connection to the remote MAU. The link detection circuit checks for valid pulses from the remote MAU and if valid link pulses are not received the link detector will disable the transmit, receive and collision detection functions.

The GDLNK output can directly drive a LED to show that there is a good twisted pair link. For normal conditions the LED will be on. The link integrity function can be disabled by setting the GDLNK bit of Configuration Register B.

### Jabber

The jabber timer monitors the transmitter and disables the transmission if the transmitter is active for greater than 26 ms. The transmitter is then disabled for the whole time that the Endec module's internal transmit enable is asserted. This signal has to be deasserted for approximately 750 ms (the unjab time) before the Jabber re-enables the transmit outputs.

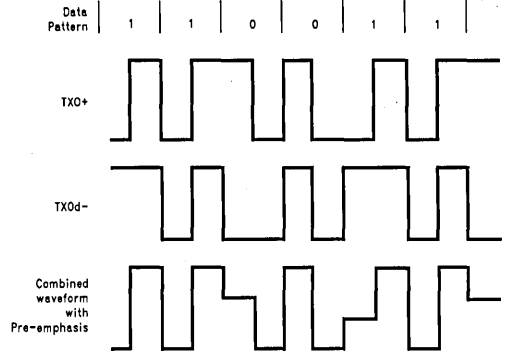

## 4.0 Functional Description (Continued)

### Transmitter

The transmitter consists of four signals, the true and complement Manchester encoded data (TXO±) and these signals delayed by 50 ns (TXOd±).

These four signals are resistively combined TXO+ with TXOd- and TXO- with TXOd+. This is known as digital pre-emphasis and is required to compensate for the twisted pair cable which acts like a low pass filter causing greater attenuation to the 10 MHz (50 ns) pulses of the Manchester encoded waveform than the 5 MHz (100 ns) pulses.

An example of how these signals are combined is shown in the following diagram.

TL/F/12082-10

FIGURE 15. Typical Summed Transmit Waveform

The signal with pre-emphasis shown above is generated by resistively combining TXO+ and TXOd-. This signal along with its complement is passed to the transmit filter.

TL/F/12082-11

FIGURE 16a. Circuitry to Connect DP83907 to Twisted Pair Cable with External Filter

## 4.0 Functional Description (Continued)

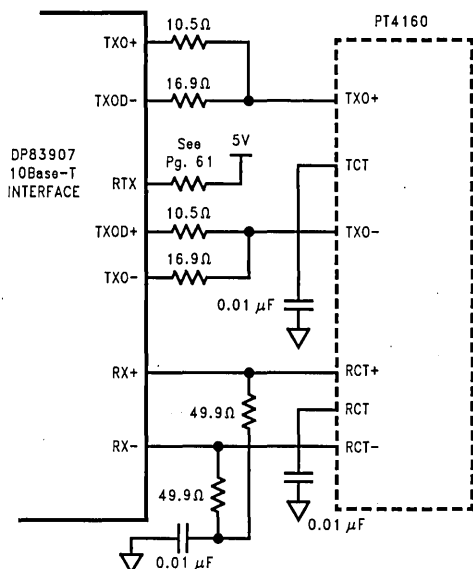

FIGURE 16b. Circuitry to Connect DP83907 to Twisted Pair Cable with Internal Filter

TL/F/12082-52

### On-Chip Filters

The on-chip filters are enabled via an external pull-up resistors on MSD<12> at configuration. Only an isolation transformer and impedance matching resistors are needed for the transmit and receive twisted pair interface.

### UTP/STP Function

The TPI transceiver supports both shielded and unshielded twisted pair cable. UTP is default but STP can be enabled during configuration by a pull-up on MSA<7> or by setting bit D6 of configuration register C. In UTP mode TXO+ and TXOD+ are driven and TXO- and TXOD- are TRI-STAT-ED. In STP mode, TXO- and TXOD- are driven and TXO+ and TXOD+ are TRI-STAT-ED.

### Auto-Switch Function

When an auto-switch function is enabled at configuration by a pull-up on MSA<5> or by setting bit D4 of the configuration register C, it allows the transceiver to switch between TP and AUI outputs. If there is an absence of link pulses, the transceiver will switch to AUI mode. Similarly, when the transceiver starts detecting link pulses it will switch to TP mode. The switching from one mode to the next is only done after the current package has been transmitted or received. If the twisted pair output is jabbering and gets into link fail state, then the switch to AUI mode is only done after the jabbering is done, including the time it takes to unjab (unjab time). When auto-switching is enabled the THIN output is automatically generated if AUI is selected.

FIGURE 17. Typical DP83907 LED Connection

TL/F/12082-12

### Status Information

Status information is provided by the DP83907 on the ACT\_led, COL\_led and GDLNK\_led outputs as described in the pin description table. These outputs are suitable for driving status LED's as shown in Figure 17. All outputs are open drain.

Recommended Transformers for Internal Filter mode:

- 1) Valor PT4160
- 2) Pulse PE-68029
- 3) PCA EPE6087A
- 4) Delta THX16B02
- 5) Belfus A553-3899-06
- 6) Kappa TP3036

## 4.0 Functional Description (Continued)

FIGURE 18. Encoder/Decode Block Diagram

TL/F/12082-13

### 4.10 ENCODER/DECODER (ENDEC) MODULE

The ENDEC consists of four main logical blocks:

- The oscillator generates the 10 MHz transmit clock signal for system timing.
- The Manchester encoder accepts NRZ data from the controller, encodes the data to Manchester, and transmits the data differentially to the transceiver, through the differential transmit driver.
- The Manchester decoder receives Manchester data from the transceiver, converts it to NRZ data and clock pulses, and sends it to the controller.
- The collision translator indicates to the controller the presence of a valid 10 MHz collision signal to the PLL.

#### Oscillator

The oscillator is controlled by a 20 MHz parallel resonant crystal connected between X1 and X2 or by an external clock on X1. The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock for the controller. The oscillator also provides internal clock signals to the encoding and decoding circuits.

#### CRYSTAL OPERATION

If the crystal used with the internal oscillator circuit is not properly selected, the DP83907 oscillator may not reliably start oscillation under all conditions.

If this occurs, it could be deceiving to a designer, since his prototypes may work fine. However, when the designer does qualification testing or starts production, he may en-

counter a higher than expected board yield loss due to the oscillator not starting. The DP83907's oscillator circuit clocks the Encoder-Decoder logic. The DP83907's oscillator also clocks the twisted pair interface block. If the oscillator does not start, the DP83907 will not be able to transmit or receive.

FIGURE 19. Crystal Connection to DP83907 (see text for component values)

TL/F/12082-14

## 4.0 Functional Description (Continued)

If a crystal is connected to the DP83907, it is recommended that the circuit shown in *Figure 19* be used and that the components used meet the following:

- Crystal XT1: AT cut parallel resonant crystal
- Series Resistance:  $\leq 25\Omega$
- Specified Load Capacitance:  $\leq 20$  pF
- Accuracy: 0.005% (50 ppm)
- Typical Load:  $50 \mu W - 75 \mu W$

The recommended values for capacitors C1 and C2 should be 26 pF minus the board capacitance on that pin. Therefore if both X1 and X2 have 4 pF of board capacitance then a 22 pF capacitor should be used.

According to the IEEE 802.3 standard, the entire oscillator circuit (crystal and amplifier) must be accurate to 0.01%. When using a crystal, the X2 pin is not guaranteed to provide a TTL compatible logic output, and should not be used to drive external standard logic. If additional logic needs to be driven, then an external oscillator should be used, as described in the following section.

### Oscillator Module Operation

If the designer wishes to use a crystal clock oscillator, one that provides the following should be employed:

- 1) TTL or CMOS output with a 0.01% frequency tolerance
- 2) 40–60% duty cycle

The circuit is shown in *Figure 20*. When using a clock oscillator it is recommended that the designer connect the oscillator output to the X1 pin and leave the X2 pin floating.

TL/F/12082-15

**FIGURE 20. DP83907 Connection for Oscillator Module Manchester Encoder and Differential Driver**

The differential transmit pair, on the secondary of the employed transformer, drives up to 50 meters of twisted pair AUI cable.

The DP83907 allows full-step to be compatible with IEEE 802.3. Transmit+ and Transmit- are equal in the idle state, providing zero differential voltage to operate with transformer coupled loads.

TL/F/12082-16

**FIGURE 21. Connection from DP83907's AUI Port to a AUI Connector**

## 4.0 Functional Description (Continued)

### Manchester Decoder

The decoder consists of a differential receiver and a PLL to separate a Manchester encoded data stream into internal clock signals and data. The differential input must be externally terminated with two  $39\Omega$  resistors connected in series if the standard  $78\Omega$  transceiver drop cable is used. In thin Ethernet applications, these resistors are optional. To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with levels less than  $-175$  mV. Signals more negative than  $-300$  mV. Data becomes valid typically within 6-bit times. The DP83907 may tolerate bit jitter up to 20 ns in the received data. The decoder detects the end of a frame when no more mid-bit transitions are detected.

### Collision Translator

When in AUI Mode, the Ethernet transceiver (DP8392 CTI) detects a collision, it generates a 10 MHz signal to the differential collision inputs ( $CD\pm$ ) of the DP83907. When these inputs are detected active, the DP83907 uses this signal to back off its current transmission and reschedule another one.

In this mode the  $COL_{led}$  output will indicate when the  $CD+$  lines are active during activity on the network. This means it will correctly indicate any collision on the network, but will not be lit for heartbeat or if there is no cable connected.

The collision differential inputs are terminated the same way as the differential receive inputs. The squelch circuitry is also similar, rejecting pulses levels less than  $-175$  mV.

### AV<sub>CC</sub> Power Supply Consideration

The AV<sub>CC</sub> pin is the +5V power supply for the phase lock loop (PLL) of the ENDEC unit. Since this is an analog circuit, excessive noise on the AV<sub>CC</sub> pin can affect the performance of the PLL. This noise, if in the 10 KHz–400 KHz range, can reduce the jitter performance of the ENDEC, resulting in missing packets or CRC errors.

If the power supply noise is causing significant packet reception error, a low pass filter could be added to reduce the power supply noise and hence improve the jitter performance. Standard analog design techniques should be utilized when laying out the power supply traces on the board. If the digital power supply is used, it may be desirable to add a one pole RC filter (designed to have a cut-off frequency of 1 KHz) as shown in Figure 22 to improve the jitter performance. The AV<sub>CC</sub> draws 3 mA–4 mA so the voltage across the resistor is less than 90 mV, which will not affect the PLL's operation.

TL/F/12082-17

FIGURE 22. Filtering Power Supply Noise

## 5.0 Register Descriptions

### 5.1 CONFIGURATION REGISTERS

These registers are used to configure the operation of the DP83907 typically after power up. These registers control the configuration of bus interface, setting options like interrupt selection, I/O base address, and other specific modes.

#### MODE CONFIGURATION REGISTER A

To prevent any accidental writes of this register it is "hidden" behind a previously unused register. Register 0AH in the DP83907's Page 0 of registers was previously reserved on a read. Now Configuration Register A can be read at that address and can be written to by following a read to 0AH with a write to 0AH. If any other DP83907 register accesses take place between the read and the write then the write to 0AH will access the Remote Byte Count Register 0.

7	RES	<p><b>RESERVED:</b> This bit must be set low for normal operation.</p>																

## 5.0 Register Descriptions (Continued)

### MODE CONFIGURATION REGISTER B

To prevent any accidental writes of this register it is "hidden" behind a previously unused register. Register 0BH in the DP83907's Page 0 of registers was previously reserved on a read. Now Configuration Register B can be read at that address and can be written to by following a read to 0BH with a write to 0BH. If any other DP83907 register accesses take place between the read and the write then the write to 0BH will access the Remote Byte Count Register 1. **Care should be taken when writing to this register as GDLINK and BE are not simple read/write bits.** e.g., the user can not change the physical layer by reading B, or-ing the returned value with the bits to be set and writing this value to B. This could inadvertently disable link integrity generation and clear a bus error indication before it was noted.

7	6	5	4	3	2	1	0
EELOAD	BPWR	BE	RES	IO16CON	GDLINK	PHYS1	PHYS0

Bit	Symbol	Function
0-1	PHYS0- PHYS1	<p><b>PHYSICAL LAYER INTERFACE:</b> These 2 bits determine which type of physical interface the DP83907 is using. The 2 TPI interfaces use twisted pair outputs and inputs, while the other 2 interfaces use the AUI outputs and inputs. In 10BASE5 mode the THICK/THIN output pin is driven low, in 10BASE2 mode it is driven high. This can be used to enable the DC-DC converter required by the 10BASE2 specification to provide electrical isolation. The Non spec TPI mode is a twisted pair mode with reduced receive squelch levels. This allows the use of longer cable lengths than specified in the twisted pair specification, or the use of cable with higher losses.</p> <p>Bit 1 0</p> <p>0 0 TPI (10BASE-T Compatible Squelch Level)</p> <p>0 1 Thin Ethernet (10BASE2)</p> <p>1 0 Thick Ethernet (10BASE5) (AUI Port)</p> <p>1 1 TPI (Reduced Squelch Level)</p>
2	GDLINK	<p><b>GOOD LINK:</b> When a 1 is written to this bit the link test pulse generation and integrity checking is disabled. When this bit is read it will indicate the link status, reflecting the value shown on the LED output. It is 0 if the DP83907 is in AUI mode or if link testing is enabled and the link integrity is bad (i.e., the twisted pair link has been broken). It is 1 if the DP83907 is in TPI mode, link integrity checking is enabled and the link integrity is good (i.e., the twisted pair link has <b>not</b> been broken) or if the link testing is disabled.</p>
3	IO16CON	<p><b>IO16 CONTROL:</b> When this bit is set high the DP83907 generates <math>\overline{IO16}</math> after <math>\overline{IOR\overline{D}}</math> or <math>\overline{IOW\overline{R}}</math> go active. If low this output is generated only on address decode.</p>
4	RES	<p><b>RESERVED:</b> This bit must be set low for normal operation.</p>
5	BE	<p><b>BUS ERROR:</b> This bit shows that the DP83907 has detected a bus error condition. This will go high if the DP83907 attempts to insert wait states into a system access and the system terminates the cycle without inserting the wait states. Writing a one to this bit clears it to zero. Writing a zero has no effect.</p>
6	BPWR	<p><b>BOOT PROM WRITE:</b> When this bit is low no write cycles are generated to the boot PROM.</p>
7	EELOAD	<p><b>EEPROM LOAD:</b> Writing a 1 to this bit enables the EEPROM load algorithm as detailed in Section 4. <b>This bit should not be configured to be high, either from switches or an EEPROM.</b></p>

## 5.0 Register Descriptions (Continued)

### SIGNATURE REGISTER

This register is intended to allow the software programmer to determine which of the DP83907 family of devices and what board configuration is being used. This register is "hidden" behind a used register. Register 01H in the DP83907's Page 1 of registers is Physical Address Register 0, which is read/write. Now the Signature Register can be read at that address by following a read to 01H, on Page 1, with another read to 01H. If any other DP83907 register accesses take place between the two reads then the second read will access Physical Address Register 0. All writes are to Physical Address Register 0. The user can determine if the Signature Register exists by writing, while in Page 1, a known value to the Physical Address Register 0 then reading it back twice. The first read will be the known value. If the second read is not equal to the value written then the Signature Register exists. **This operation should only be attempted while the DP83907 is in STOP mode (STP bit in the Command Register set high).**

### 5.2 NIC CORE REGISTERS

All registers are 8-bit wide and mapped into two pages which are selected in the Command Register (PS0, PS1). Pins RA0-RA3 are used to address registers within each page. Page 0 registers are those registers which are commonly accessed during DP83907 operation while page 1 registers are used primarily for initialization. The registers are partitioned to avoid having to perform two write/read cycles to access commonly used registers.

## 5.0 Register Descriptions (Continued)

### COMMAND REGISTER (CR) 00H (READ/WRITE)

The Command Register is used to initiate transmissions, enable or disable Remote DMA operations and to select register pages. To issue a command the microprocessor sets the corresponding bit(s) (RD2, RD1, RD0, TXP). Further commands may be overlapped, but with the following rules: (1) If a transmit command overlaps with a remote DMA operation, bits RD0, RD1, and RD2 must be maintained for the remote DMA command when setting the TXP bit. Note, if a remote DMA command is re-issued when giving the transmit command, the DMA will complete immediately if the remote byte count register has not been re-initialized. (2) If a remote DMA operation overlaps a transmission, RD0, RD1, and RD2 may be written with the desired values and a "0" written to the TXP bit. Writing a "0" to this bit has no effect. (3) A remote write DMA may not overlap remote read operation or vice versa. Either of these operations must either complete or be aborted before the other operation may start. Bits PS1, PS0, RD2, and STP may be set any time.

7	6	5	4	3	2	1	0
PS1	PS0	RD2	RD1	RD0	TXP	STA	STP

Bit	Symbol	Description																								
D0	STP	<p><b>STOP:</b> Software reset command, takes the controller off-line, no packets will be received or transmitted. Any reception or transmission in progress will continue to completion before entering the reset state. To exit this state, the STP bit must be reset and the STA bit must be set high. To perform a software reset, this bit should be set high. The software reset has executed only when indicated by the RST bit in the ISR being set to 1. STP powers up high.</p> <p><b>Note:</b> If the DP83907 has previously been in start mode and the STP is set, both the STP and STA bits will remain set.</p>																								
D1	STA	<p><b>START:</b> This bit is used to activate the NIC Core after either power up, or when the NIC Core has been placed in a reset mode by software command or error. STA powers up low.</p>																								
D2	TXP	<p><b>TRANSMIT PACKET:</b> This bit must be set to initiate transmission of a packet. TXP is internally reset either after the transmission is completed or aborted. This bit should be set only after the Transmit Byte Count and Transmit Page Start registers have been programmed.</p>																								
D3-D5	RD0-RD2	<p><b>REMOTE DMA COMMAND:</b> These three encoded bits control operation of the Remote DMA channel. RD2 can be set to abort any Remote DMA command in progress. The Remote Byte Count Registers should be cleared when a Remote DMA has been aborted. The Remote Start Addresses are not restored to the starting address if the Remote DMA is aborted.</p> <table border="1"> <thead> <tr> <th>RD2</th> <th>RD1</th> <th>RD0</th> <th></th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>0</td> <td>Not Allowed</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>Remote Read</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>Remote Write (Note 2)</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>Send Packet</td> </tr> <tr> <td>1</td> <td>X</td> <td>X</td> <td>Abort/Complete Remote DMA (Note 1)</td> </tr> </tbody> </table> <p><b>Note 1:</b> If a remote DMA operation is aborted and the remote byte count has not decremented to zero, the data transfer port should be read, for a remote read or send packet, or written to, for a remote write. ## 5.0 Register Descriptions (Continued)

### INTERRUPT STATUS REGISTER (ISR) 07H (READ/WRITE)

This register is accessed by the host processor to determine the cause of an interrupt. Any interrupt can be masked in the Interrupt Mask Register (IMR). Individual interrupt bits are cleared by writing a "1" into the corresponding bit of the ISR. The valid interrupt output is active as long as any unmasked signal is set, and will not go low until all unmasked bits in this register have been cleared. The ISR must be cleared after power up by writing it with all 1's.

7	6	5	4	3	2	1	0
RST	RDC	CNT	OVW	TXE	RXE	PTX	PRX

Bit	Symbol	Description
D0	PRX	<b>PACKET RECEIVED:</b> Indicates packet received with no errors.
D1	PTX	<b>PACKET TRANSMITTED:</b> Indicates packet transmitted with no errors.
D2	RXE	<b>RECEIVE ERROR:</b> Indicates that a packet was received with one or more of the following errors: —CRC Error —Frame Alignment Error —FIFO Overrun —Missed Packet
D3	TXE	<b>TRANSMIT ERROR:</b> Set when packet transmitted with one or more of the following errors: —Excessive Collisions —FIFO Underrun
D4	OVW	<b>OVERWRITE WARNING:</b> Set when receive buffer ring storage resources have been exhausted. (Local DMA has reached Boundary Pointer.)
D5	CNT	<b>COUNTER OVERFLOW:</b> Set when MSB of one or more of the Network Tally Counters has been set.
D6	RDC	<b>REMOTE DMA COMPLETE:</b> Set when Remote DMA operation has been completed.
D7	RST	<b>RESET STATUS:</b> Set when DP83907 enters reset state and cleared when a Start Command is issued to the CR. This bit is also set when a Receive Buffer Ring overflow occurs and is cleared when one or more packets have been removed from the ring. Writing to this bit has no effect. <b>Note:</b> This bit does not generate an interrupt, it is merely a status indicator.

## 5.0 Register Descriptions (Continued)

### INTERRUPT MASK REGISTER (IMR) 0FH (WRITE)

The Interrupt Mask Register is used to mask interrupts. Each interrupt mask bit corresponds to a bit in the Interrupt Status Register (ISR). If an interrupt mask bit is set, an interrupt will be issued whenever the corresponding bit in the ISR is set. If any bit in the IMR is set low, an interrupt will not occur when the bit in the ISR is set. **The IMR powers up all zeros.**

D6	Reserved	Reserved																				
D7	Reserved	Reserved																				

## 5.0 Register Descriptions (Continued)

### TRANSMIT STATUS REGISTER (TSR) 04H (READ)

This register records events that occur on the media during transmission of a packet. It is cleared when the next transmission is initiated by the host. All bits remain low unless the event that corresponds to a particular bit occurs during transmission. Each transmission should be followed by a read of this register. The contents of this register are not specified until after the first transmission.

7	6	5	4	3	2	1	0
OWC	CDH	FU	CRS	ABT	COL	—	PTX

Bit	Symbol	Description
D0	PTX	<b>PACKET TRANSMITTED:</b> Indicates transmission without error. (No excessive collisions or FIFO underrun) (ABT = "0", FU = "0").
D1	Reserved	Reserved
D2	COL	<b>TRANSMIT COLLIDED:</b> Indicates that the transmission collided at least once with another station on the network. The number of collisions is recorded in the Number of Collisions Registers (NCR).
D3	ABT	<b>TRANSMIT ABORTED:</b> Indicates the DP83907 aborted transmission because of excessive collisions. (Total number of transmissions including original transmission attempt equals 16.)
D4	CRS	<b>CARRIER SENSE LOST:</b> This bit is set when carrier is lost during transmission of the packet. Transmission is not aborted on loss of carrier.
D5	FU	<b>FIFO UNDERRUN:</b> If the DP83907 cannot gain access of the bus before the FIFO empties, this bit is set. Transmission of the packet will be aborted.
D6	CDH	<b>CD HEARTBEAT:</b> Failure of the transceiver to transmit a collision signal after transmission of a packet will set this bit. The Collision Detect (CD) heartbeat signal must commence during the first 6.4 $\mu$ s of the Interframe Gap following a transmission. In certain collisions, the CD Heartbeat bit will be set even though the transceiver is not performing the CD heartbeat test.
D7	OWC	<b>OUT OF WINDOW COLLISION:</b> Indicates that a collision occurred after a slot time (51.2 $\mu$ s). Transmissions rescheduled as in normal collisions.

## 5.0 Register Descriptions (Continued)

### RECEIVE CONFIGURATION REGISTER (RCR) OCH (WRITE)

This register determines operation of the DP83907 during reception of a packet and is used to program what types of packets to accept.

7	6	5	4	3	2	1	0
—	—	MON	PRO	AM	AB	AR	SEP

Bits	Symbols	Description
D0	SEP	<b>SAVE ERRORED PACKETS</b> 0: Packets with receive errors are rejected. 1: Packets with receive errors are accepted. Receive errors are CRC and Frame Alignment errors.
D1	AR	<b>ACCEPT RUNT PACKETS:</b> This bit allows the receiver to accept packets that are smaller than 64 bytes. The packet must be at least 8 bytes long to be accepted as a runt. 0: Packets with fewer than 64 bytes rejected. 1: Packets with fewer than 64 bytes accepted.
D2	AB	<b>ACCEPT BROADCAST:</b> Enables the receiver to accept a packet with an all 1's destination address. 0: Packets with broadcast destination address rejected. 1: Packets with broadcast destination address accepted.
D3	AM	<b>ACCEPT MULTICAST:</b> Enables the receiver to accept a packet with a multicast address, all multicast addresses must pass the hashing array. 0: Packets with multicast destination address not checked. 1: Packets with multicast destination address checked.
D4	PRO	<b>PROMISCUOUS PHYSICAL:</b> Enables the receiver to accept all packets with a physical address. 0: Physical address of node must match the station address programmed in PAR0–PAR5. 1: All packets with physical addresses accepted.
D5	Reserved	Reserved (program to 0)
D6	Reserved	Reserved
D7	Reserved	Reserved

**Note:** D2 and D3 are "OR'd" together, i.e., if D2 and D3 are set the DP83907 will accept broadcast and multicast addresses as well as its own physical address. To establish full promiscuous mode, bits D2, D3, and D4 should be set. In addition the multicast hashing array must be set to all 1's in order to accept all multicast addresses.

## 5.0 Register Descriptions (Continued)

### RECEIVE STATUS REGISTER (RSR) OCH (READ)

This register records status of the received packet, including information on errors and the type of address match, either physical or multicast. The contents of this register are written to buffer memory by the DMA after reception of a good packet. If packets with errors are to be saved the receive status is written to memory at the head of the erroneous packet if an erroneous packet is received. If packets with errors are to be rejected the RSR will not be written to memory. The contents will be cleared when the next packet arrives. CRC errors, Frame Alignment errors and missed packets are counted internally by the DP83907 which relinquishes the Host from reading the RSR in real time to record errors for Network Management Functions. The contents of this register are not specified until after the first reception.

7	6	5	4	3	2	1	0
DFR	DIS	PHY	MPA	FO	FAE	CRC	PRX

Bit	Symbol	Description
D0	PRX	<b>PACKET RECEIVED INTACT:</b> Indicates packet received without error. (Bits CRC, FAE, FO, and MPA are zero for the received packet.)
D1	CRC	<b>CRC ERROR:</b> Indicates packet received with CRC error. Increments Tally Counter (CNTR1). This bit will also be set for Frame Alignment errors.
D2	FAE	<b>FRAME ALIGNMENT ERROR:</b> Indicates that the incoming packet did not end on a byte boundary and the CRC did not match at last byte boundary. Increments Tally Counter (CNTR0).
D3	FO	<b>FIFO OVERRUN:</b> This bit is set when the FIFO is not serviced causing overflow during reception. Reception of the packet will be aborted.
D4	MPA	<b>MISSED PACKET:</b> Set when packet intended for node cannot be accepted by SNIC because of a lack of receive buffers or if the controller is in monitor mode and did not buffer the packet to memory. Increments Tally Counter (CNTR2).
D5	PHY	<b>PHYSICAL/MULTICAST ADDRESS:</b> Indicates whether received packet had a physical or multicast address type. 0: Physical Address Match 1: Multicast/Broadcast Address Match
D6	DIS	<b>RECEIVER DISABLED:</b> Set when receiver disabled by entering Monitor mode. Reset when receiver is re-enabled when exiting Monitor mode.
D7	DFR	<b>DEFERRING:</b> Set when internal Carrier Sense or Collision signals are generated in the ENDEC module. If the transceiver has asserted the CD line as a result of the jabber, this bit will stay set indicating the jabber condition.

**Note:** Following coding applies to CRC and FAE bits:

FAE	CRC	Type of Error
0	0	No Error (Good CRC and <6 Dribble Bits)
0	1	CRC Error
1	0	Illegal, will not occur
1	1	Frame Alignment Error and CRC Error

## 5.0 Register Descriptions (Continued)

FIGURE 24. DMA Registers

TL/F/12082-19

### 5.3 DP8390 CORE DMA REGISTERS

The DMA Registers are partitioned into groups; Transmit, Receive and Remote DMA Registers. The Transmit registers are used to initialize the Local DMA Channel for transmission of packets while the Receive Registers are used to initialize the Local DMA Channel for packet Reception. The Page Stop, Page Start, Current and Boundary Registers are used by the Buffer Management Logic to supervise the Receive Buffer Ring. The Remote DMA Registers are used to initialize the Remote DMA

**Note:** In the figure above, registers are shown as 8 or 16 bits wide. Although some registers are 16-bit internal registers, all registers are accessed as 8-bit registers. Thus the 16-bit Transmit Byte Count Register is broken into two 8-bit registers. TBCR0 TBCR1. Also TPSR, PSTART, PSTOP, CURR and BRNY only check or control the upper 8 bits of address information on the bus. Thus they are shifted to positions 15-8 in the diagram above.

#### Transmit DMA Registers

##### TRANSMIT PAGE START REGISTER (TPSR)

This register points to the assembled packet to be transmitted. Only the eight higher order addresses are specified since all transmit packets are assembled on 256-byte page

boundaries. The bit assignment is shown below. The values placed in bits D7-D0 will be used to initialize the higher order address (A8-A15) of the Local DMA for transmission. The lower order bits (A7-A0) are initialized to zero.

#### Bit Assignment

	7	6	5	4	3	2	1	0
TPSR	A15	A14	A13	A12	A11	A10	A9	A8

(A7-A0 Initialized to 0)

##### TRANSMIT BYTE COUNT REGISTER 0,1 (TBCR0, TBCR1)

These two registers indicate the length of the packet to be transmitted in bytes. The count must include the number of bytes in the source, destination, length and data fields. The maximum number of transmit bytes allowed is 64K bytes. The DP83907 will not truncate transmissions longer than 1500 bytes. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
TBCR1	L15	L14	L13	L12	L11	L10	L9	L8
	7	6	5	4	3	2	1	0
TBCR0	L7	L6	L5	L4	L3	L2	L1	L0

## 5.0 Register Descriptions (Continued)

### Local DMA Receive Registers

#### PAGE START STOP REGISTERS (PSTART, PSTOP)

The Page Start and Page Stop Registers program the starting and stopping address of the Receive Buffer Ring. Since the DP83907 uses fixed 256-byte buffers aligned on page boundaries only the upper eight bits of the start and stop address are specified.

#### PSTART, PSTOP bit assignment

	7	6	5	4	3	2	1	0
PSTART	A15	A14	A13	A12	A11	A10	A9	A8
PSTOP								

#### BOUNDARY (BNRY) REGISTER

This register is used to prevent overflow of the Receive Buffer Ring. Buffer management compares the contents of this register to the next buffer address when linking buffers together. If the contents of this register match the next buffer address the Local DMA operation is aborted.

	7	6	5	4	3	2	1	0
BNRY	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT PAGE REGISTER (CURR)

This register is used internally by the Buffer Management Logic as a backup register for reception. CURR contains the address of the first buffer to be used for a packet reception and is used to restore DMA pointers in the event of receive errors. This register is initialized to the same value as PSTART and should not be written to again unless the controller is Reset.

	7	6	5	4	3	2	1	0
CURR	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT LOCAL DMA REGISTER 0,1 (CLDA0,1)

These two registers can be accessed to determine the current Local DMA Address.

	7	6	5	4	3	2	1	0
CLDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CLDA0	A7	A6	A5	A4	A3	A2	A1	A0

### Remote DMA Registers

#### REMOTE START ADDRESS REGISTERS (RSAR0,1)

Remote DMA operations are programmed via the Remote Start Address (RSAR0,1) and Remote Byte Count (RBCR0,1) registers. The Remote Start Address is used to point to the start of the block of data to be transferred and the Remote Byte Count is used to indicate the length of the block (in bytes).

	7	6	5	4	3	2	1	0
RSAR1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
RSAR0	A7	A6	A5	A4	A3	A2	A1	A0

#### REMOTE BYTE COUNT REGISTERS (RBC0,1)

	7	6	5	4	3	2	1	0
RBCR1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
RBCR0	A7	A6	A5	A4	A3	A2	A1	A0

#### Note:

RSAR0 programs the start address bits A0–A7.

RSAR1 programs the start address bits A8–A15.

Address incremented by two for word transfers, and by one for byte transfers. Byte count decremented by two for word transfers and by one for byte transfers.

RBCR0 programs LSB byte count.

RBCR1 programs MSB byte count.

#### CURRENT REMOTE DMA ADDRESS (CRDA0, CRDA1)

The Current Remote DMA Registers contain the current address of the Remote DMA. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
CRDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CRDA0	A7	A6	A5	A4	A3	A2	A1	A0

#### Physical Address Registers (PAR0–PAR5)

The physical address registers are used to compare the destination address of incoming packets for rejecting or accepting packets. Comparisons are performed on a byte-wide basis. The bit assignment shown below relates the sequence in PAR0–PAR5 to the bit sequence of the received packet.

	D7	D6	D5	D4	D3	D2	D1	D0
PAR0	DA7	DA6	DA5	DA4	DA3	DA2	DA1	DA0
PAR1	DA15	DA14	DA13	DA12	DA11	DA10	DA9	DA8
PAR2	DA23	DA22	DA21	DA20	DA19	DA18	DA17	DA16
PAR3	DA31	DA30	DA29	DA28	DA27	DA26	DA25	DA24
PAR4	DA39	DA38	DA37	DA36	DA35	DA34	DA33	DA32
PAR5	DA47	DA46	DA45	DA44	DA43	DA42	DA41	DA40

	Destination Address						Source			
	P/S	DA0	DA1	DA2	DA3	...	DA46	DA47	SA0	...

#### Note:

P/S = Preamble, Synchron

DA0 = Physical/Multicast Bit

#### Multicast Address Registers (MAR0–MAR7)

The multicast address registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 most significant bits of the CRC generator are latched. These 6 bits are then decoded by a 1 of 64 decode to index a unique filter bit (FB0–63) in the multicast address registers. If the filter bit selected is set, the multicast packet is accepted. The sys-

## 5.0 Register Descriptions (Continued)

tem designer would use a program to determine which filter bits to set in the multicast registers. All multicast filter bits that correspond to multicast address accepted by the node are then set to one. To accept all multicast packets all of the registers are set to all ones.

**Note:** Although the hashing algorithm does not guarantee perfect filtering of multicast address, it will perfectly filter up to 64 multicast addresses if these addresses are chosen to map into unique locations in the multicast filter.

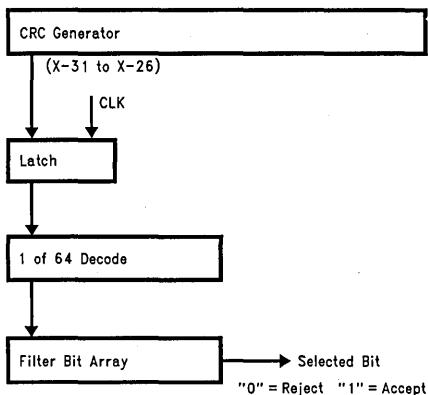

FIGURE 25. Multicast Addressing

TL/F/12082-20

## 6.0 Operation of DP83907

This section details the operation of the DP83907. The operations discussed are packet reception and transmission, bus operations, and loopback diagnostics.

### 6.1 TRANSMIT/RECEIVE PACKET ENCAPSULATION/DECAPSULATION;

A standard IEEE 802.3 packet consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data, and Frame Check Sequence (FCS). The typical format is shown in the figure following. The packets are Manchester encoded and decoded by the ENDEC module and transferred serially to the NIC module using NRZ data with a clock. All fields are of fixed length except for the data field. The DP83907 generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

FIGURE 26. Ethernet Packet

TL/F/12082-21

### Preamble and Start of Frame Delimiter (SFD)

The Manchester encoded alternating 1, 0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted each packet contains 62 bits of alternating 1, 0 preamble. Some of this preamble will be lost as the packet travels through the network. The preamble field is stripped by the NIC module. Byte alignment is performed with the Start of Frame Delimiter (SFD) pattern which consists of two consecutive 1's. The DP83907 does not treat the SFD pattern as a byte, it detects only the two bit pattern. This allows any preceding preamble within the SFD to be used for phase locking.

### Destination Address

The destination address indicates the destination of the packet on the network and is used to filter unwanted packets from reaching a node. There are three types of address formats supported by the DP83907: physical, multicast and broadcast. The physical address is a unique address that corresponds only to a single node. All physical addresses have an MSB of "0". These addresses are compared to the internally stored physical address registers. Each bit in the destination address must match in order for the DP83907 to accept the packet. Multicast addresses begin with an MSB of "1". The DP83907 filters multicast addresses using a standard hashing algorithm that maps all multicast addresses into a 6-bit value. This 6-bit value indexes a 64-bit array that filters the value. If the address consists of all 1's it is a broadcast address, indicating that the packet is intended for all nodes. A promiscuous mode allows reception of all packets: the destination address is not required to match any filters. Physical, broadcast, multicast, and promiscuous address modes can be selected.

### Source Address

The source address is the physical address of the node that sent the packet. Source addresses cannot be multicast or broadcast addresses. This field is simply passed to buffer memory.

### Length Field

The 2-byte length field indicates the number of bytes that are contained in the data field of the packet. This field is not interpreted by the DP83907.

### Data Field

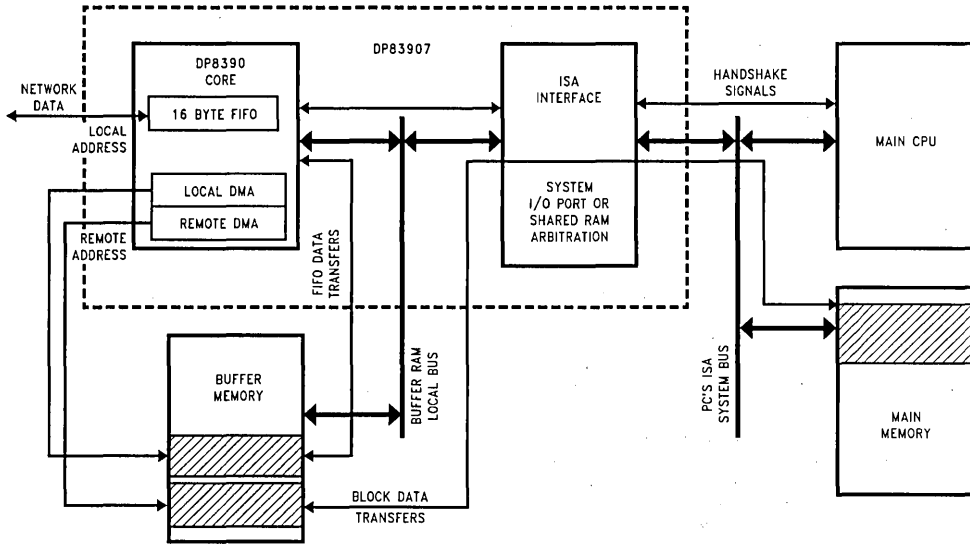

The data field consists of anywhere from 46 to 1500 bytes. Messages longer than 1500 bytes need to be broken into multiple packets. Messages shorter than 46 bytes will require appending a pad to bring the data field to the minimum length of 46 bytes. If the data field is padded, the number of valid data bytes is indicated in the length field. **The DP83907 does not strip or append pad bytes for short packets, or check for oversize packets.**

### FCS Field

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of errors when a packet is received. During reception, error free packets result in a specific pattern in the CRC generator. Packets with improper CRC will be rejected. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X^1 + 1$ ) polynomial is used for the CRC calculations.

### 6.0 Operation of DP83907 (Continued)

FIGURE 27. DP83907 Bus Architecture

#### 6.2 BUFFER MEMORY ACCESS CONTROL (DMA)

The buffer memory control capabilities of the DP83907 greatly simplify the use of the DP83907 in typical configurations. The local DMA channel transfers data between the FIFO and memory. On transmission, the packet is DMA'd from memory to the FIFO in bursts. Should a collision occur (up to 15 times), the packet is re-transmitted with no processor intervention. On reception, packets are moved via DMA from the FIFO to the receive buffer ring (as explained below).

A Remote DMA channel is also provided on the DP83907 to accomplish transfers between a buffer memory and an internal Data Port when using the DP83907 in I/O Mode. This

Remote DMA channel is not used when the DP83907 is used in a shared Memory mode. In this second mode the buffer memory is dual ported, and directly mapped into the system memory. In this mode the system CPU directly accesses the RAM under software control to transfer packet data.

The following sections describe the operation of the Local DMA channel for packet reception which is used in both modes. For Shared Memory mode the description of the Remote DMA does not apply.

For reference an example configuration using the DP83907 is shown in Figure 27.

TL/F/12082-23

FIGURE 28. DP83907 Receive Buffer Ring

## 6.0 Operation of DP83907 (Continued)

### 6.3 PACKET RECEPTION

The Local DMA receive channel uses a Buffer Ring Structure comprised of a series of contiguous fixed length 256 byte (128 word) buffers for storage of received packets. The location of the Receive Buffer Ring is programmed in two registers, a Page Start and a Page Stop Register. Ethernet packets consist of a distribution of shorter link control packets and longer data packets, the 256 byte buffer length provides a good compromise between short packets and longer packets to most efficiently use memory. In addition these buffers provide memory resources for storage of back-to-back packets in loaded networks. The assignment of buffers for storing packets is controlled by Buffer Management Logic in the DP83907. The Buffer Management Logic provides three basic functions: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of buffer pages that have been read by the host.

At initialization, a portion of the 64k byte (or 32k word) address space is reserved for the receive buffer ring. Two eight bit registers, the Page Start Address Register (PSTART) and the Page Stop Address Register (PSTOP) define the physical boundaries of where the buffers reside. The DP83907 treats the list of buffers as a logical ring; whenever the DMA address reaches the Page Stop Address, the DMA is reset to the Page Start Address.

FIGURE 29. Buffer Ring at Initialization

### Initialization of the Buffer Ring

Two static registers and two working registers control the operation of the Buffer Ring. These are the Page Start Register, Page Stop Register (both described previously), the Current Page Register and the Boundary Pointer Register. The Current Page Register points to the first buffer used to store a packet and is used to restore the DMA for writing status to the Buffer Ring or for restoring the DMA address in the event of a Runt packet, a CRC, or Frame Alignment error. The Boundary Register points to the first packet in the Ring not yet read by the host. If the local DMA address ever reaches the Boundary, reception is aborted. The Boundary Pointer is also used to initialize the Remote DMA for removing a packet and is advanced when a packet is removed. A simple analogy to remember the function of these registers is that the Current Page Register acts as a Write Pointer and the Boundary Pointer acts as a Read Pointer.

**Note 1:** At initialization, the Page Start Register value should be loaded into both the Current Page Register and the Boundary Pointer Register, if using the Send Packet Command. If using manual Remote Reads, the Current Page Register must always remain 1 + Boundary Register.

**Note 2:** The Page Start Register must not be initialized to 00H.

### Beginning of Reception

When the first packet begins arriving the DP83907 begins storing the packet at the location pointed to by the Current Page Register. An offset of 4 bytes is saved in this first buffer to allow room for storing receive status corresponding to this packet.

FIGURE 30. Received Packet Enters the Buffer Pages

## 6.0 Operation of DP83907 (Continued)

### Linking Receive Buffer Pages

If the length of the packet exhausts the first 256 byte buffer, the DMA performs a forward link to the next buffer to store the remainder of the packet. For a maximal length packet the buffer logic will link six buffers to store the entire packet. Buffers cannot be skipped when linking, a packet will always be stored in contiguous buffers. Before the next buffer can be linked, the Buffer Management Logic performs two comparisons. The first comparison tests for equality between the DMA address of the next buffer and the contents of the Page Stop Register. If the buffer address equals the Page Stop Register, the buffer management logic will restore the DMA to the first buffer in the Receive Buffer Ring value programmed in the Page Start Address Register. The second comparison tests for equality between the DMA address of the next buffer address and the contents of the Boundary Pointer Register. If the two values are equal the reception is aborted. The Boundary Pointer Register can be used to protect against overwriting any area in the receive buffer ring that has not yet been read. When linking buffers, buffer management will never cross this pointer, effectively avoiding any overwrites. If the buffer address does not match either the Boundary Pointer or Page Stop Address, the link to the next buffer is performed.

### Linking Buffers

Before the DMA can enter the next contiguous 256 byte buffer, the address is checked for equality to PSTOP and to the Boundary Pointer. If neither are reached, the DMA is allowed to use the next buffer.

- 1) Check for = to PSTOP
- 2) Check for = to Boundary

TL/F/12082-26

FIGURE 31. Linking Receive Buffer Pages

### Buffer Ring Overflow

If the Buffer Ring has been filled and the DMA reaches the Boundary Pointer Address, reception of the incoming packet will be aborted by the DP83907. Thus, the packets previously received and still contained in the Ring will not be destroyed.

In heavily loaded networks which cause overflows of the Receive Buffer Ring, the DP83907 may disable the local DMA and suspend further receptions even if the Boundary register is advanced beyond the Current register. In the event that the DP83907 should encounter a receive buffer overflow, it is necessary to implement the following routine. A receive buffer overflow is indicated by the DP83907's assertion of the overflow bit (OVW) in the Interrupt Status Register (ISR).

If this routine is not adhered to, the DP83907 may act in an unpredictable manner. It should also be noted that it is not permissible to service an overflow interrupt by continuing to empty packets from the receive buffer without implementing the prescribed overflow routine. A flow chart of the DP83907's overflow routine can be found in *Figure 32*.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

- 1) Read and store the value of the TXP bit in the DP83907's Command Register.
- 2) Issue the STOP command to the DP83907. This is accomplished by setting the STP bit in the DP83907's Command Register. Writing 21H to the Command Register will stop the DP83907.
- 3) Wait for at least 1.6 ms. Since the DP83907 will complete any transmission or reception that is in progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommended that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.

## 6.0 Operation of DP83907 (Continued)

4) Clear the DP83907's Remote Byte Count registers (RBCR0 and RBCR1).

5) Read the stored value of the TXP bit from step 1, above.

If this value is a 0, set the "Resend" variable to a 0 and jump to step 6.

If this value is a 1, read the DP83907's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 0 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the DP83907's ISR is read to determine whether or not the packet was recognized by the DP83907. If neither the PTX nor TXE bit was set, then the packet will essentially be lost and retransmitted only after a time-out takes place in the upper level software. By determining that the packet was lost at the driver level, a transmit command can be reissued to the DP83907 once the overflow routine is completed (as in step 11). Also, it is possible for the DP83907 to defer indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the DP83907 to operate correctly.

6) Place the DP83907 in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to "0,1" or "1,0", respectively.

7) Issue the START command to the DP83907. This can be accomplished by writing 22H to the Command Register. This is necessary to activate the DP83907's Remote DMA channel.

8) Remove one or more packets from the receive buffer ring.

9) Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.

10) Take the DP83907 out of loopback. This is done by writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)

11) If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by writing a value of 26H to the Command Register. If the "Resend" variable is 0, nothing needs to be done.

**Note 1:** If Remote DMA is not being used, the DP83907 does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7, eliminating or reducing the time spent polling in step 5.

**Note 2:** When the DP83907 is in STOP mode, the Missed Packet Tally counter is disabled.

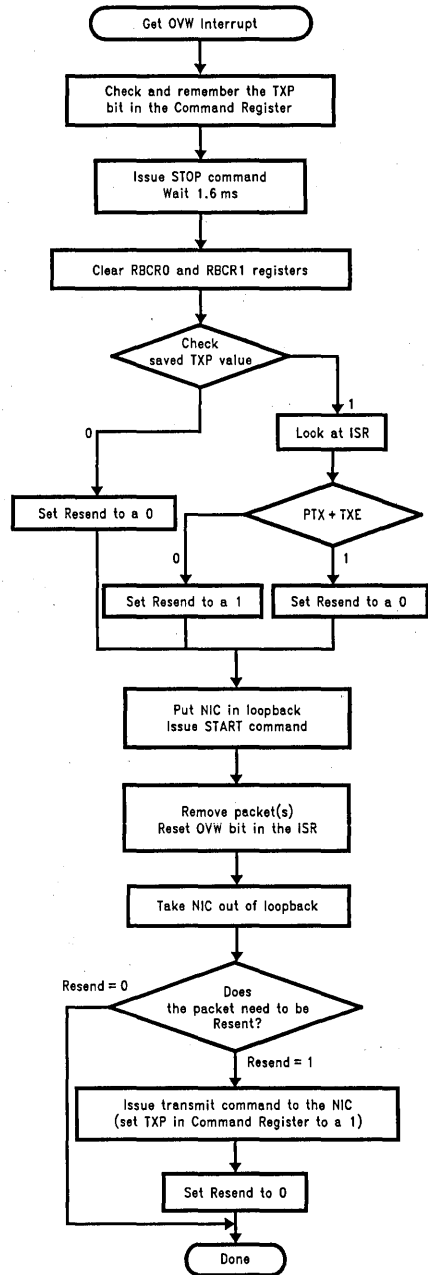

FIGURE 32. Overflow Routine

TL/F/12082-27

## 6.0 Operation of DP83907 (Continued)

**FIGURE 33. Received Packet Aborted If It Hits Boundary**

### Enabling the DP83907 on an Active Network

After the DP83907 has been initialized the procedure for disabling and then re-enabling the DP83907 on the network is similar to handling Receive Buffer Ring overflow as described previously.

- 1) Program Command Register for page 0 (Command Register = 21H)
- 2) Initialize Data Configuration Register (DCR)
- 3) Clear Remote Byte Count Registers (RBCR0, RBCR1) if using Remote DMA.
- 4) Initialize Receive Configuration Register (RCR)
- 5) Place the DP83907 in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
- 6) Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
- 7) Clear Interrupt Status Register (ISR) by writing OFFH to it.
- 8) Initialize Interrupt Mask Register (IMR)
- 9) Program Command Register for page 1 (Command Register = 61H)
  - i) Initialize Physical Address Registers (PAR0-PAR5)
  - ii) Initialize Multicast Address Registers (MAR0-MAR7)
  - iii) Initialize CURRENT pointer
- 10) Put DP83907 in START mode (Command Register = 22H). The local receive DMA is still not active since the DP83907 is in LOOPBACK.
- 11) Initialize the Transmit Configuration for the intended value. The DP83907 is now ready for transmission and reception.

### End of Packet Operations

At the end of the packet the DP83907 determines whether the received packet is to be accepted or rejected. It either branches to a routine to store the Buffer Header or to another routine that recovers the buffers used to store the packet.

**FIGURE 34. Termination of Received Packet-Packet Accepted**

### Successful Reception

If the packet is successfully received, the DMA is restored to the first buffer used to store the packet (pointed to by the Current Page Register). The DMA then stores the Receive Status, a Pointer to where the next packet will be stored (Buffer 4) and the number of received bytes. Note that the remaining bytes in the last buffer are discarded and reception of the next packet begins on the next empty 256-byte buffer boundary. The Current Page Register is then initialized to the next available buffer in the Buffer Ring. (The location of the next buffer had been previously calculated and temporarily stored in an internal scratchpad register.)

### Buffer Recovery for Rejected Packets

If the packet is a runt packet or contains CRC or Frame Alignment errors, it is rejected. The buffer management logic resets the DMA back to the first buffer page used to store the packet (pointed to by CURR), recovering all buffers that had been used to store the rejected packet. This operation will not be performed if the DP83907 is programmed to accept either runt packets or packets with CRC or Frame Alignment errors. The received CRC is always stored in buffer memory after the last byte of received data for the packet.

**FIGURE 35. Termination of Receive Packet-Packet Reject**

## 6.0 Operation of DP83907 (Continued)

### Error Recovery

If the packet is rejected as shown, the DMA is restored by the DP83907 by reprogramming the DMA starting address pointed to by the Current Page Register.

### Storage Format for Received Packets

The following diagrams describe the format for how received packets are placed into memory by the local DMA channel. These modes are selected in the Data Configuration Register.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 1		Receive Byte Count 0	
Byte 2		Byte 1	

BOS = 0, WTS = 1 in Data Configuration Register. This format is used with Series 32xxx, or 808xx processors.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 0		Receive Byte Count 1	
Byte 1		Byte 2	

BOS = 1, WTS = 1 in Data Configuration Register. This format is used with 680 x 0 type processors. (Note: the Receive Count ordering remains the same for BOS = 0 or 1.)

Receive Status
Next Packet Pointer
Receive Byte Count 0
Receive Byte Count 1
Byte 0
Byte 1

BOS = 0 WTS = 0 in Data Configuration Register. This format is used with general 8-bit processors.

### 6.4 PACKET TRANSMISSION

The Local DMA is also used during transmission of a packet. Three registers control the DMA transfer during transmission, a Transmit Page Start Address Register (TPSR) and the Transmit Byte Count Registers (TBCR0, 1). When the DP83907 receives a command to transmit the packet pointed to by these registers, buffer memory data will be moved into the FIFO as required during transmission. The DP83907 will generate and append the preamble, synch and CRC fields.

### General Transmit Packet Format

Transmit	Destination Address	6 Bytes
Byte	Source Address	6 Bytes
Count	Type/Length	2 Bytes
TBCR0, 1	Data Pad (if data < 46 Bytes)	≥ 46 Bytes

### Transmit Packet Assembly

The DP83907 requires a contiguous assembled packet with the format shown. The transmit byte count includes the Destination Address, Source Address, Length Field and Data. It does not include preamble and CRC. When transmitting data smaller than 46 bytes, the packet must be padded to a minimum size of 64 bytes. The programmer is responsible for adding and stripping pad bytes.

The packets are placed in the buffer RAM by the system. In I/O Mode the system programs the NIC Core's Remote DMA to mode the data from the data port to the RAM handshaking with system transfers loading the I/O data port. In Shared Memory Mode the packets are written directly to the RAM by system using standard memory transfer instructions (MOV).

For I/O mode the data transfer must be 16 bits (1 word) when in 16 bit mode, and 8 bits when the DP83907 is set in 8 bit mode. The data width is selected by setting the WTS bit in the Data Configuration Register and setting the DWID pin for the proper mode.

In Shared Memory mode data transfer can be accomplished by using either 8- or 16-bit data transfer instructions, because this mode responds to 8/16 bit data signaling on the ISA bus. In this mode Shared Memory Control Register 2 bit 6 sets the bus interface data width, and the NIC Core's data width is set by the WTS bit in the Data Configuration Register.

### Transmission

Prior to transmission, the TPSR (Transmit Page Start Register) and TBCR0, TBCR1 (Transmit Byte Count Registers) must be initialized. To initiate transmission of the packet the TXP bit in the Command Register is set. The Transmit Status Register (TSR) is cleared and the DP83907 begins to prefetch transmit data from memory (unless the DP83907 is currently receiving). If the interframe gap has timed out the DP83907 will begin transmission.

## 6.0 Operation of DP83907 (Continued)

### Conditions Required to Begin Transmission

In order to transmit a packet, the following three conditions must be met:

1. The Interframe Gap Timer has timed out the first 6.4  $\mu$ s of the Interframe Gap
2. At least one byte has entered the FIFO. (This indicates that the burst transfer has been started)
3. If a collision had been detected then before transmission the packet time must have timed out.

In typical systems the DP83907 prefetches the first burst of bytes before the 6.4  $\mu$ s timer expires. The time during which DP83907 transmits preamble can also be used to load the FIFO.

**Note:** If carrier sense is asserted before a byte has been loaded into the FIFO, the DP83907 will become a receiver.

### Collision Recovery

During transmission, the Buffer Management logic monitors the transmit circuitry to determine if a collision has occurred. If a collision is detected, the Buffer Management logic will reset the FIFO and restore the Transmit DMA pointers for retransmission of the packet. The COL bit will be set in the TSR and the NCR (Number of Collisions Register) will be incremented. If 15 retransmissions each result in a collision the transmission will be aborted and the ABT bit in the TSR will be set.

**Note:** NCR reads as zeroes if excessive collisions are encountered.

### Transmit Packet Assembly Format

The following diagrams describe the format for how packets must be assembled prior to transmission for different byte ordering schemes. The various formats are selected in the Data Configuration Register.

D15	D8	D7	D0
Destination Address 1	Destination Address 0		
Destination Address 3	Destination Address 2		
Destination Address 5	Destination Address 4		
Source Address 1	Source Address 0		
Source Address 3	Source Address 2		
Source Address 5	Source Address 4		
Type/Length 1	Type Length 0		
Data 1	Data 0		

BOS = 0, WTS = 1 in Data Configuration Register.

This format is used with Series 32xxx, or 808xx processors.

D15	D8	D7	D0
Destination Address 0		Destination Address 1	
Destination Address 2		Destination Address 3	
Destination Address 4		Destination Address 5	
Source Address 0		Source Address 1	
Source Address 2		Source Address 3	
Source Address 4		Source Address 5	
Type Length 0		Type/Length 1	
Data 0		Data 1	

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with 680x0 type processors.

D7	D0
Destination Address 0	
Destination Address 1	
Destination Address 2	
Destination Address 3	
Destination Address 4	
Destination Address 5	
Source Address 0	
Source Address 1	
Source Address 2	
Source Address 3	
Source Address 4	
Source Address 5	

BOS = 0, WTS = 0 in Data Configuration Register.

This format is used with general 8 bit processors.

**Note:** All examples above will result in a transmission of a packet in order of DA0, DA1, DA3... bits within each byte will be transmitted least significant bit first.

DA = Destination Address

## 6.0 Operation of DP83907 (Continued)

### 6.5 LOOPBACK DIAGNOSTICS

Three forms of local loopback are provided on the DP83907. The user has the ability to loopback through the deserializer on the controller, through the ENDEC module or transceiver. **Because of the half duplex architecture of the DP83907, loopback testing is a special mode of operation with the following restrictions:**

#### Restrictions During Loopback

The FIFO is split into two halves, one half is used for transmission the other for reception. Only 8-bit fields can be fetched from memory so two tests are required for 16-bit systems to verify integrity of the entire data path. During loopback the maximum latency to obtain access to the buffer memory is 2.0  $\mu$ s. Systems that wish to use the loopback test yet do not meet this latency can limit the loopback packet to 7 bytes without experiencing underflow. Only the last 8 bytes of the loopback packet are retained in the FIFO. The last 8 bytes can be read through the FIFO register which will advance through the FIFO to allow reading the receive packet sequentially.

Destination Address	= 6 bytes Station Physical Address
Source Address	= 6 bytes Station Physical Address
Length	2 bytes
Data	= 46 to 1500 bytes
CRC	Appended by DP8307 Controller if CRC = 0 in TCR

When in word-wide mode with Byte Order Select set, the loopback packet must be assembled in the even byte locations as shown below. (The loopback only operated with byte wide transfers.)

LS Byte (D6-D15)	MS Byte (D0-D7)
	Destination
	Source
	Length
	Data
	CRS

WTS = 1      BOS = 1      (DCR Bits)

When in word-wide mode with Byte Order Select low, the following format must be used for the loopback packet.

MS Byte (D8-D15)	LS Byte (D0-D7)
Destination	
Source	
Length	
Data	
CRS	

WTS = 1      BOS = 0      (DCR Bits)

**Note:** When using loopback in word mode 2n bytes must be programmed in the TBCR0, 1. When n = actual number of bytes assembled in even or odd location.

To initiate a loopback the user first assembles the loopback packet then selects the type of loopback using the Transmit Configuration register bits LB0, LB1. The transmit configuration register must also be set to enable or disable CRC generation during transmission. The user then issues a normal transmit command to send the packet. During loopback the receiver checks for an address match and if CRC bit in the TCR is set, the receiver will also check the CRC. The last 8 bytes of the loopback packet are buffered and can read out of the FIFO using FIFO read port.

#### Loopback Modes

**MODE 1:** Loopback Through the DP83907 Controller Module (LB1 = 0, LB0 = 1): If this loopback is used, The DP83907 Module's serializer is connected to the deserializer.

**MODE 2:** Loopback Through the ENDEC Module (LB1 = 1, LB0 = 0): If the loopback is to be performed through the SNI, the DP83907 provides a control (LPBK) that forces the ENDEC module to loopback all signals.

**MODE 3:** Loopback to the external coax interface or twisted pair interface module (LB1 = 1, LB0 = 1).

Packets can be transmitted to the cable in loopback mode to check all of the transmit and receive paths and the cable itself. If, in twisted pair mode, there is a link fail the transmitter will be disabled which could give misleading results in Mode 3. The link integrity should be checked, by reading Configuration Register B, before this test.

#### Reading the Loopback Packet

The last eight bytes of a received packet can be examined by 8 consecutive reads of the FIFO register. The FIFO pointer is increment after the rising edge of the CPU's read strobe by internally synchronizing and advancing the pointer. This may take up to four bus clock cycles, if the pointer has not been incremented by the time the CPU reads the FIFO register again, the DP83907 will insert wait states.

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the DP83907 to malfunction.

#### Alignment of the Received Packet in the FIFO

Reception of the packet in the FIFO begins at location zero, after the FIFO pointer reaches the last location in the FIFO, the pointer wraps to the top of the FIFO overwriting the previously received data. This process continued until the last byte is received. The DP83907 then appends the received byte count in the next two locations of the FIFO. The contents of the Upper Byte Count are also copied to the next FIFO location. The number of bytes used in the loopback packet determined the alignment of the packet in the FIFO. The alignment for a 64-byte packet is shown below.

FIFO Location	FIFO Contents	
0	Lower Byte Count	→ First Byte Read
1	Upper Byte Count	→ Second Byte Read
2	Upper Byte Count	•
3	Last Byte	•
4	CRC1	•
5	CRC2	•
6	CRC3	•
7	CRC4	→ Last Byte Read

## 6.0 Operation of DP83907 (Continued)

For the following alignment in the FIFO the packet length should be  $(N \times 8) + 5$  Bytes. Note that if the CRC bit in the TCR is set, CRC will not be appended by the transmitter. If the CRC is appended by the transmitter, the 1st four bytes, bytes N-3 to N, correspond to the CRC.

FIFO Location	FIFO Contents		
0	Byte N-4	→	First Byte Read
1	Byte N-3 (CRC1)	→	Second Byte Read
2	Byte N-2 (CRC2)		•
3	Byte N-1 (CRC3)		•
4	Byte N (CRC4)		•
5	Lower Byte Count		•
6	Upper Byte Count		•
7	Upper Byte Count	→	Last Byte Read

### Loopback Tests

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the DP83907 prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

- 1) Verify integrity of data path. Received data is checked against transmitted data.
- 2) Verify CRC logic's capability to generate good CRC on transmit, verify CRC on receive (good or bad CRC).
- 3) Verify that the Address Recognition Logic can
  - a) Recognize address match packets
  - b) Reject packets that fail to match an address

### Loopback Operation in the DP83907 Controller

Loopback is a modified form of transmission using only half of the FIFO. This places certain restrictions on the use of loopback testing. When loopback mode is selected in the TCR, the FIFO is split. A packet should be assembled in memory with programming of TPSR and TBCR0, TBCR1 registers. When the transmit command is issued the following operations occur:

### TRANSMITTER ACTIONS

- 1) Data is transferred from memory by the DMA until the FIFO is filled. For each transfer TBCR0 and TBCR1 are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
- 2) The DP83907 generates 56 bits of preamble followed by an 8-bit synch pattern.
- 3) Data transferred from FIFO to serializer.
- 4) If CRC = 1 in TCR, no CRC calculated by DP83907, the last byte transmitted is the last byte from the FIFO (Allows software CRC to be appended). If CRC = 0, DP83907 calculates and appends four bytes of CRC.
- 5) At end of Transmission PTX bit set in ISR.

### RECEIVER ACTIONS

- 1) Wait for synch, all preamble stripped.
- 2) Store packet in FIFO, increment receive byte count for each incoming byte.
- 3) If CRC = 0 in TRC, receiver checks incoming packet for CRC errors. If CRC = 1 in TCR, receiver does not check CRC errors, CRC error bit always set in RSR (for address matching packets).
- 4) At end of receive, receive byte count written into FIFO, receive status register is updated. The PRX bit is typically set in the RSR even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the RS to be set.

### EXAMPLES

The following examples show what results can be expected from a properly operating DP83907 during loopback. The restrictions and results of each type of loopback are listed for reference. The loopback tests are divided into two sets of tests. One to verify the data path, CRC generation and byte count through all three paths. The second set of tests uses internal loopback to verify the receiver's CRC checking and address recognition. For all of the tests the DCR was programmed to 40H.

Path	TCR	RCR	TSR	RSR	ISR
DP83907 Internal	02	00	53 (Note 1)	02 (Note 2)	02 (Note 3)

**Note 1:** Since carrier sense and collision detect are generated in the ENDEC module. They are blocked during internal loopback, carrier and CD heartbeat are not seen and the CRS and CDH bits are set.

**Note 2:** CRC errors are always indicated by receiver if CRC is appended by the transmitter.

**Note 3:** Only the PTX bit in the ISR is set, the PRX bit is only set if status is written to memory. In loopback this action does not occur and the PRX bit remains 0 for all loopback modes.

**Note 4:** All values are hex.

Path	TCR	RCR	TSR	RSR	ISR
DP83907 Internal	04	00	43 (Note 1)	02	02

**Note 1:** CDH is set, CRS is not set since it is generated by the external encoder/decoder.

Path	TCR	RCR	TSR	RSR	ISR
DP83907 Internal	06	00	03 (Note 1)	02	02 (Note 2)

**Note 1:** CDH and CRS should not be set. The TSR however, could also contain 01H, 03H, 07H and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** Will contain 08H if packet is not transmittable.

**Note 3:** During external loopback the DP83907 Controller is now exposed to network traffic, it is therefore possible for the contents of both the Receive portion of the FIFO and the RSR to be corrupted by any other packet on the network. Thus in a live network the contents of the FIFO and RSR should not be depended on. The DP83907 will still abide by the standard CSMA/CD protocol in external loopback mode. (i.e. The network will not be disturbed by the loopback packet).

**Note 4:** All values are hex.

## 6.0 Operation of DP83907 (Continued)

### CRC and Address Recognition

The next three tests exercise the address recognition logic and CRC. These tests should be performed using internal loopback only so that the DP83907 is isolated from interference from the network. These tests also require the capability to generate CRC in software.

The address recognition logic cannot be directly tested. The CRC and FAE bits in the RSR are only set if the address if the packet matches the address filters. If errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch. The following sequence of packets will test the address recognition logic. The DCR should be set to 40H, the TCR should be set to 03H with a software generated CRC.

Packet Contents		Results	
Test	Address	CRC	RSR
Test A	Matching	Good	01 (Note 1)
Test B	Matching	Bad	02 (Note 2)
Test C	Non-Matching	Bad	01

**Note 1:** Status will read 21H if multicast address used.

**Note 2:** Status will read 22H if multicast address used.

**Note 3:** In test A, the RSR is set up. In test B the address is found to match since the CRC is flagged as bad. Test C proves that the address recognition logic can distinguish a bad address and does not notify the RSR of the bad CRC. The receiving CRC is proven to work in test A and test B.

**Note 4:** All values are hex.

### Network Management Functions

Network management capabilities are required for maintenance and planning of a local area network. The DP83907 supports the minimum requirement for network management in hardware, the remaining requirements can be met with software. Software alone can not track during reception of packets: CRC errors, Frame Alignment errors, and missed packets, *Figure 36*.

Since errored packets can be rejected, the status associated with these packets is lost unless the CPU can access the Receive Status Register before the next packer arrives. In situations where another packet arrives very quickly, the CPU may have no opportunity to do this. The DP83907 Controller counts the number of packets with CRC errors and Frame Alignment errors. 8-bit counters have been selected to reduce overhead. The counters will generate interrupts whenever their MSBs are set so that a software routine can accumulate the network statistics and reset the counter before overflow occurs. The counters are sticky so that when they reach a count of 192 (C0H) counting is halted. An additional counter is provided to count the number of packets the DP83907 misses due to buffer overflow or being off-line. The structure of the counters is shown in *Figure 36*.

Additional information required for network management is available in the Receive and Transmit Status Registers. Transmit status is available after each transmission for information regarding events during transmission.

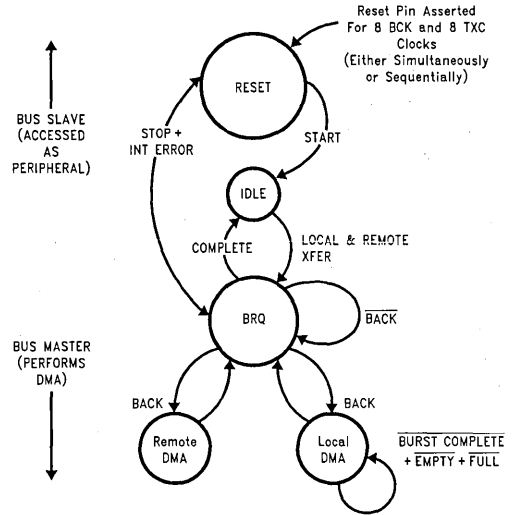

Typically, the following statistics might be gathered in software:

- Traffic:
  - Frames Sent OK
  - Frames Received OK
  - Multicast Frames Received
  - Packets Lost Due to Lack of Resources
  - Retries/Packet
- Errors:
  - CRC Errors
  - Alignment Errors
  - Excessive Collisions
  - Packet with Length Errors
  - Heartbeat Failure

### 6.6 MEMORY ARBITRATION AND BUS OPERATION

The DP83907 will always operate as a slave device on it's peripheral interface to the ISA bus. However on the memory bus, the DP83907 Controller operates in three possible modes:

1. Bus Master of Local Packet Buffer RAM
2. Bus Slave when accessed by the CPU via the Bus Interface
3. Idle, when no activity is occurring.

TL/F/12082-32

FIGURE 37. DP8390 Core Bus States

Upon power-up the DP83907 is in an indeterminate state. After receiving a hardware reset the DP83907 is a bus slave in the Reset State, the receiver and transmitter are both disabled in this state. The reset state can be re-entered under four conditions, soft reset (Stop Command), register reset (reset port), hard reset (RESET input) or an error that shuts down the receiver of transmitter (FIFO underflow or overflow, receive buffer ring overflow).

After initialization of registers, the DP83907 Controller is issued a Start command and the DP83907 enters Idle state. Until the DMA is required the DP83907 remains in idle state.

## 6.0 Operation of DP83907 (Continued)

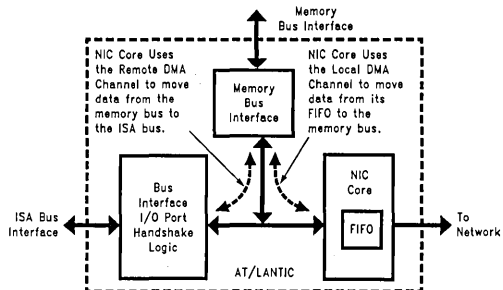

The idle state is exited and the DP83907 will drive the local memory bus when a request from the FIFO in the DP8390 (NIC) core causes the memory bus interface logic to issue a read or write operation, such as when the DP83907 is transmitting or receiving data.

The NIC Core's Remote DMA also requests access from the memory bus. When software programs an I/O data transfer between the CPU and the buffer RAM, the Remote DMA controls this request.

All Local DMA transfers are burst transfers, the DMA will transfer an exact burst of bytes programmed in the Data Configuration Register (DCR) then relinquish the memory bus. If there are remaining bytes in the FIFO the next burst will not be initiated until the FIFO threshold is exceeded.

### I/O Mode Operation

In I/O mode the DP83907 transfers data to and from the packet buffer RAM by utilizing the Remote DMA logic which is programmed by the main system CPU to transfer data through the DP83907's internal data

TL/F/12082-33

**FIGURE 38. I/O Operation: All Data Transfers and Arbitration is Controlled by the NIC Core**

### INTERLEAVED LOCAL/REMOTE OPERATION

When in I/O mode the remote DMA is used to transfer data to/from the main system. If a remote DMA transfer is initiated or in progress when a packet is being received or transmitted, the Remote DMA transfers will be interrupted for higher priority Local DMA transfers. When the Local DMA transfer is completed the Remote DMA will re-arbitrate for the bus and continue its transfers.

If the FIFO requires service while a remote DMA is in progress the Local DMA burst is appended to the Remote Transfer. When switching from a local transfer to a remote transfer there is a break to allow the CPU to fairly contend for the bus.

### REMOTE DMA BI-DIRECTIONAL PORT

The Remote DMA transfers data between the local buffer memory and the internal bi-directional port (memory to I/O transfer).

This transfer is arbitrated on a transfer by transfer basis versus the burst transfer mode used for Local DMA transfers. This bi-directional port is integrated onto the DP83907, and is read/written by the host. All transfers through this port are asynchronous. At any one time transfers are limited to one direction, either form the port to local buffer memory (Remote Write) or form local buffer memory to the port (Remote Read).

TL/F/12082-34

**FIGURE 39. 1st Received Packet Removed by Remote DMA**

### I/O MODE REMOVING PACKETS FROM RING

Network activity is isolated on a local bus, where the DP83907's local DMA channel performs burst transfers between the buffer memory and the DP83907's FIFO. The Remote DMA transfers data between the buffer memory and the host memory via the internal bi-directional I/O port. The Remote DMA provides local addressing capability and is used as a slave DMA by the host. The host system reads the I/O port to transfer data between the system and I/O port. The DP83907 allows Local and Remote DMA operations to be interleaved.

Packets are removed from the ring using the Remote DMA. When using the Remote DMA the Send Packet command can be used. This programs the Remote DMA to automatically remove the received packet pointed to by the Boundary Pointer. At the end of the transfer, the DP83907 moves the Boundary Pointer, freeing additional buffers for reception. The Boundary Pointer can also be moved manually by programming the Boundary Register. Care should be taken to keep the Boundary Pointer at least one buffer behind the Current Page Pointer.

Data transfer by the Remote DMA to the integrated I/O data port is dependent on whether the DP83907 is set into 8 bit mode or 16 bit mode. In 8 bit mode all transfers are 8 bits (1 byte) wide. When in 16 bit mode all transfers are 16 bits (1 word) wide. The data width is selected by setting the WTS bit in the data Configuration Register and setting the DWID pin for the proper mode.

The following is a suggested method for maintaining the Receive Buffer Ring pointers:

1. At initialization, set up a software variable (`next_pkt`) to indicate where the next packet will be read. At the beginning of each Remote Read DMA operation, the value of `next_pkt` will be loaded into RSAR0 and RSAR1.
2. When initializing the DP83907 Controller set:
  - BNDRY = PSTART
  - CURR = PSTART + 1
  - `next_pkt` = PSTART + 1
3. After a packet is DMAed from the Receive Buffer Ring, the Next Page Pointer (second byte in the DP83907 Controller buffer header) is used to update BNDRY and `next_pkt`.

6.0 Operation of DP83907 (Continued)

TL/F/12082-35

FIGURE 40. Remote DMA Auto Initialization from Buffer Ring

next\_pkt = Next Page Pointer

BNDRY = Next Page Pointer - 1

If BNDRY < PSTART then BNDRY = PSTOP - 1

Note the size of the Receive Buffer Ring is reduced by one 256-byte buffer, this will not, however impede the operation of the DP83907. The advantage of this scheme is that it easily differentiates between buffer full and buffer empty: it is full if BNDRY = CURR; empty when BNDRY = CURR-1. If, in I/O mode, send packet is used to empty the buffer ring this scheme cannot be used. BNDRY must be initialized equal to CURR, or the first executed send packet will not return data from the received packet, which will be written at CURR. The Overwrite Warning bit of the Interrupt Status Register must be used in this mode to differentiate between buffer full and buffer empty.

**I/O REMOTE DMA COMMANDS**

The Remote DMA channel is used in the I/O Mode to both assemble packets for transmission, and to remove received packets from the Receive Buffer Ring. It may also be used for moving blocks of data or commands between host memory and local buffer memory. (In Shared Memory Mode, the Remote DMA should be disabled, and not used. Packet transfer to/from the system is accomplished by normal CPU read/write operations.)

There are three modes of Remote DMA operation: Remote Write, Remote Read, or Send Packet.

Two register pairs are used to control the Remote DMA, a Remote Start Address (RSAR0, RSAR1) and a Remote Byte Count (RBCRO, RBCR1) register pair. The Start Address Register pair points to the beginning of the block to be moved while the Byte Count Register pair is used to indicate the number of bytes to be transferred. Full handshake logic is provided to move data between local buffer memory and a bi-directional I/O port.

**Remote Write:** A Remote Write transfer is used to move a block of data from the host into local buffer memory. The Remote DMA will read data from the I/O port and sequentially write it to local buffer memory beginning at the Remote Start Address. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches a count of zero.

**Remote Read:** A Remote Read transfer is used to move a block of data from local buffer memory to the host. The Remote DMA will sequentially read data from the local buffer memory, beginning at the Remote Start Address, and write data to the I/O port.

## 6.0 Operation of DP83907 (Continued)

The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

**Send Packet Command:** The Remote DMA channel can be automatically initialized to transfer a single packet from the Receive Buffer Ring. The CPU begins this transfer by issuing a "Send Packet" Command. The DMA will be initialized to the value of the Boundary Pointer Register and the Remote Byte Count Register pair (RBCR0, RBCR1) will be initialized to the value of the Receive Byte Count fields found in the Buffer Header of each packet. After the data is transferred, the Boundary Pointer is advanced to allow the buffers to be used for new receive packets. The Remote Read will terminate when the Byte Count equals zero. The Remote DMA is then prepared to read the next packet from the Receive Buffer Ring. If the DMA pointer crosses the Page Stop Register, it is reset to the Page Start Address. This allows the Remote DMA to remove packets that have wrapped around to the top of the Receive Buffer Ring.

**Note 1:** In order for the DP83907 Controller to correctly execute the Send Packet Command, the upper Remote Byte Count Register (RBCR1) must first be loaded with 0FH.

**Note 2:** The Send Packet command cannot be used with 680x0 type processors.

### I/O READ TIMING

- 1) The DMA reads word from local buffer memory and writes the word into the internal latch, increments the DMA address and decrements the byte count (RBCR0,1).
- 2) Internally a request line is asserted to enable the system to read the port. If the system reads this port before the data has been written, then the system is sent a wait signal to wait until the data has been written to the port. Once written the systems read is allowed to complete.
- 3) The system reads the port, the read strobe for the port is used as an acknowledgement to the Remote DMA and it goes back to step 1.

Steps 1–3 are repeated until the remote DMA is complete. (i.e., the byte count has gone to zero.)

Note that in order for the Remote DMA to transfer a word from memory to the latch, it must arbitrate access to the local buffer RAM. After each word is transferred to the internal latch, access to the RAM is relinquished. If a Local DMA is in progress, the Remote DMA is held off until the local DMA is complete.

### I/O WRITE TIMING

A Remote Write operation transfers data from the I/O port to the local buffer RAM. The system transfers a byte-word to the latch via IOWR. This write strobe is detected by the DP83907 and the byte/word is transferred to local buffer memory. The Remote DMA holds off further transfers into the latch until the current byte/word has been transferred from the latch.

- 1) DP83907 awaits data to be written by the system. System writes byte/word into latch.
- 2) Remote DMA reads contents of port and writes byte/word to local buffer memory, increments address and decrements byte count (RBCR0,1).
- 3) Go back to step 1.  
Steps 1–3 are repeated until the remote DMA is complete.

### 6.7 FUNCTIONAL BUS TIMING

This section describes the bus cycles that the DP83907 performs. These timings can be subdivided into 3 basic categories:

1. ISA I/O Access: There are register accesses in both modes, and I/O data accesses in I/O mode.
2. Shared RAM ISA Accesses: These are the timing for the ISA bus accesses through the DP83907 to the memory bus and buffer RAM.
3. Boot PROM ISA Accesses: These are the timing for the ISA bus accesses through the DP83907 to the memory bus and boot PROM.
4. Local and I/O RAM Accesses: This is the timing of the Local DMA, accesses from the NIC Core FIFO to the RAM, and the Remote DMA accesses to the RAM over the memory bus.

### ISA Bus I/O Accesses

The DP83907 is designed to directly interface to the ISA bus (PC AT backplane bus). The CPU can read or write any internal registers. All register accesses are byte wide. The functional timing for DP83907 accesses are shown in the following pages.

## 6.0 Operation of DP83907 (Continued)

### 8-Bit I/O Slave Read

TL/F/12082-36

This is the type of cycle used to read from a register or, in 8-bit mode, from a data transfer port. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IORD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will always appear on SD0-7.

### 8-Bit I/O Slave Write

TL/F/12032-37

This is the type of cycle used to write to a register or, in 8-bit mode, to a data transfer port. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IOWR}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will always be taken from SD0-7.

## 6.0 Operation of DP83907 (Continued)

TL/F/12082-38

This is the type of cycle used to read from a data transfer port in 16-bit mode. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IORD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{\text{IO16}}$  is generated, when an address within the DP83907's data transfer port is decoded, to indicate to the system that this is a 16-bit transfer. If the IO16CON bit in Configuration Register B is low then it will be a straight decode of the SA0-9 lines. If that bit is high the  $\overline{\text{IO16}}$  output will be generated after  $\overline{\text{IORD}}$  goes active, to indicate that this is a 16-bit transfer, and the address should be even, SA0 low. The data will appear on SD0-15.

TL/F/12082-39

This is the type of cycle used to write to a data transfer port in 16-bit mode. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IOWR}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{\text{IO16}}$  is generated, when an address within the DP83907's data transfer port is decoded, to indicate to the system that this is a 16-bit transfer. If the IO16CON bit in Configuration Register B is low then it will be a straight decode of the SA0-9 lines. If that bit is high the  $\overline{\text{IO16}}$  output will be generated after  $\overline{\text{IOWR}}$  goes active, to indicate that this is a 16-bit transfer, and the address should be even, SA0 low. The data will be taken from SD0-15.

## 6.0 Operation of DP83907 (Continued)

### 16-Bit I/O Cycle with IO16 Fix

Some Chips & Technologies and VLSI Technologies PC-AT chip sets have timing requirements in 16-bit I/O cycles that cannot be achieved by the default DP83907 cycle, described on the previous page. When that cycle is executed with these chip sets, the system does not recognize the CHRDY signal and does not insert wait states. The system executes a standard cycle and deasserts IORD or IOW even if CHRDY is still deasserted. The DP83907 recognizes if this situation has occurred, asserts CHRDY and sets a bus error bit in Configuration Register B to flag this error. Thus the user can test any new system to see if this error occurs and then take some remedial action. The DP83907 supports a fix which can be selected by software, by writing to Configuration Register B.

This fix is enabled by setting the IO16 bit of Configuration Register B. In normal operation any time a valid address exists on SA0-9 IO16 is generated. Delaying IO16 until after the IORD or IOW can cure the problem on non-compliant machines. The theory is that the system is fooled into thinking an 8-bit peripheral is responding, since IO16 is not generated for the valid address, and accepts 8-bit I/O cycle timings for CHRDY. It then rechecks IO16 after the IORD or IOW strobe and correctly determines it is a 16-bit peripheral. If a system did not recheck IO16 it would generate 2, 8-bit cycles instead of 1, 16-bit cycle. The DP83907 would interpret each 8-bit access as a 16-bit transfer and decrement it's DMA byte count by 2. Eventually the system would attempt to access the data transfer port when the DP83907 had finished transferring data and CHRDY would be deasserted indefinitely. To prevent misoperation this fix should only be implemented on systems that require it.

### ISA BUS BOOT PROM ACCESS TIMING

TL/F/12082-40

This is the type of cycle used to read the boot PROM. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-19 and a SMRD. If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will be driven from MSD0-7 onto SD0-7.

## 6.0 Operation of DP83907 (Continued)

TL/F/12082-41

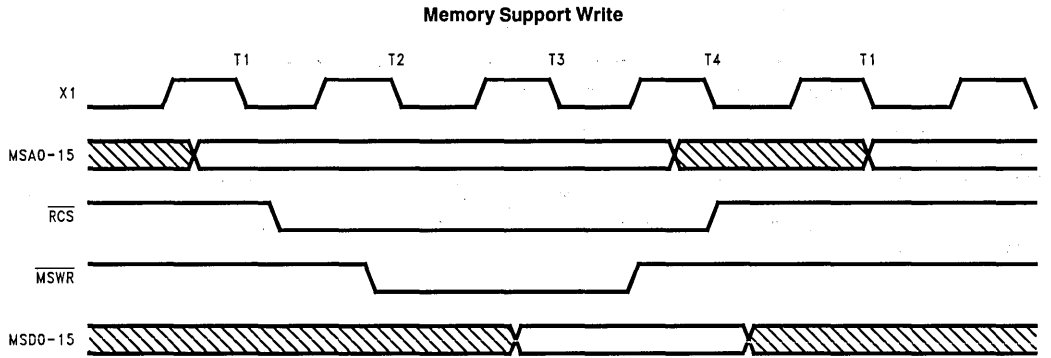

This is the type of cycle used to write to the boot PROM. These accesses are entirely asynchronous, with the DP83907 responding when it decodes the correct address on SA0-19 and a  $\overline{SMWR}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the DP83907 is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will normally be taken from SD0-7. However, if  $\overline{M16}$  is generated and the access is to an odd address the data will be taken from SD8-15. The data will always be driven onto MSD0-7. The BPWR bit of Configuration Register B must be high to allow write cycles to the boot PROM.

## 6.0 Operation of DP83907 (Continued)

### RAM ACCESS TIMING

This is a memory read cycle executed by the DP83907's internal DMA. This is used to either load the data transfer port, during a Remote Read in I/O mode, or to load the FIFO, for a transmission on the network, in both modes. This transfer is synchronized to X1.

This is a memory write cycle executed by the DP83907's internal DMA. This is used to either write from the data transfer port, during a Remote Write in I/O mode, or to empty the FIFO, during a reception from the network, in both modes. This transfer is synchronized to X1.

## 7.0 In-Circuit Test (ICT) Description

The test register is made available only when the test bit (D7 of cnfg. A) is set at the following I/O address:

I/O mode: Base + 1FHex.

The test register contains the following bits. Note that when the test bit is low the test register is held set except for D4 and D0 which is reset.

TABLE I. Test Modes (test pin = 1)

	Test Mode	D7	D6	D5	D4	D3	D2	D1	D0	SA<9>
1	V <sub>IH</sub> /V <sub>IL</sub>	1	1	1	1	1	1	1	0	X
2	V <sub>OH</sub> /V <sub>OL</sub>	1	1	1	0	1	0	1	0	1

V<sub>IL</sub>/V<sub>IH</sub> test mode when high will AND all inputs (except RESET pin) and present outcome on IRQ<3>. To enable this st-nc mode must NOT be entered.

V<sub>OH</sub>/V<sub>OL</sub> test mode is active in st-nc mode if SA<9> = 1. Then all o/p's switch with SA<4> as per Table 2.

V<sub>OH</sub>/V<sub>OL</sub> mode output states (SA<9> = 1)

TABLE II

Output	SA<4> = 0	SA<4> = 1
MSA<13:1>	1555 Hex	0AAA Hex
MSD<15:0>	AAAA Hex	5555 Hex
SD<15:0>	AAAA Hex	5555 Hex
IRQ<15, 12, 11, 10, 9, 5, 4, 3>	A2 Hex	5D Hex
MSWR	0	1

## DP83907 Preliminary Specification Design Guide

This document provides information on National Semiconductor's DP83907 target design parametric specifications. These specifications are provided as design targets for the DP83907. These parameters should be used to undergo systems design activities, and are not provided as guaranteed parametric specifications. At this time these specifications are **not** tested, and are subject to change based upon National's product characterization and yield analysis.

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to +7.0V
Storage Temperature ( $T_{STG}$ )	-65°C to +150°C
Package Power Dissipation ( $P_D$ )	900 mW
Lead Temperature ( $T_L$ ) (Soldering, 10 seconds)	260°C

### Operating Conditions

	Min	Max	Units
Supply Voltage ( $V_{CC}$ )	4.75	5.25	V
Operating Temperature ( $T_A$ )	0	+70	°C
ESD Tolerance:	2.0		kV
$C_{ZAP} = 100 \text{ pF}$ , $R_{ZAP} = 1.5 \text{ k}\Omega$			

### Preliminary DC Specifications

Symbol	Description	Conditions	Min	Max	Units
<b>SUPPLY CURRENT</b>					
$I_{CC}$	Average Active (Transmitting and Receiving) Supply Current	$X1 = 20 \text{ MHz Clock}$ $V_{IN} = \text{Switching}$		150	mA

## Preliminary DC Specifications (Continued)

Symbol	Description	Conditions	Min	Max	Units
<b>OSCILLATOR PINS (X1 AND X2)</b>					
$V_{IH}$	X1 Input High Voltage	X1 is Connected to an Oscillator	2.0		V
$V_{IL}$	X1 Input Low Voltage	X1 is Connected to an Oscillator		0.8	V
$I_{OSC}$	X1 Input Current	X1 is Connected to an Oscillator $V_{IN} = V_{CC}$ or GND		1	mA
<b>TPI</b>					
$R_{TOL}$	$TXO_d \pm$ , $TXO \pm$ Low Level Output Resistance	$I_{OL} = 25$ mA		15	$\Omega$
$R_{TOH}$	$TXO_d \pm$ , $TXO \pm$ High Level Output Resistance	$I_{OH} = -25$ mA		15	$\Omega$
$V_{SRON1}$	Receive Threshold Turn-On Voltage 10BASE-T Mode		$\pm 300$	$\pm 585$	mV
$V_{SRON2}$	Receive Threshold Turn-On Voltage Reduced Threshold		$\pm 175$	$\pm 300$	mV
$V_{SROFF}$	Receive Threshold Turn-Off Voltage	(Note 1)	$\pm 175$	$\pm 300$	mV
$V_{DIFF}$	Differential Mode Input Voltage Range	$V_{CC} = 5.0$ V (Note 1)	-3.1	+3.1	V
$V_{OD}$	Differential Output Voltage	On-Chip Filters Selected 100 $\Omega$ Load	Typical: 5.0 (Notes 1, 2)		V pk-pk
<b>AUI</b>					
$V_{OD}$	Differential Output Voltage ( $TX \pm$ )	78 $\Omega$ Termination (Note 1)	$\pm 550$	$\pm 1200$	mV
$V_{OB}$	Differential Idle Output Voltage Imbalance ( $TX \pm$ )	78 $\Omega$ Termination (Note 1)	Typical: 40 mV		
$V_U$	Undershoot Voltage ( $TX \pm$ )	78 $\Omega$ Termination (Note 1)	Typical: 80 mV		
$V_{DS}$	Differential Squelch Threshold ( $RX \pm$ , $CD \pm$ )		-175	-300	mV
$V_{CM}$	Differential Input Common Mode Voltage ( $RX \pm$ , $CD \pm$ )	(Note 1)	0	5.25	V

**Note 1:** Not Tested in Production Test.

**Note 2:** In on-chip filter mode, the value of TPI  $V_{OD}$  when measured driving a 100 $\Omega$  load may not meet the IEEE 802.3 specification over temperature and process without the use of a resistor on RTX. This does not adversely effect system performance. For more details please refer to Applications Note AN-974.

## Preliminary Switching Design Guidelines (Continued)

### ISA SLAVE ACCESSES (Continued)

Symbol	Description	8-Bit Transfers		16-Bit Transfers		Units
		Min	Max	Min	Max	
T27	SA0-19 Valid to BPCS Asserted (Note 11)		55	55		ns
T28a	MRD Asserted to MSR $\bar{D}$ Asserted		60	60		ns
T28b	MWR Asserted to MSWR $\bar{A}$ Asserted		120	120		ns
T30	SA0-19 Invalid to BPCS Negated (Note 11)	0				ns
T31	SMRD, Deasserted to MSR $\bar{D}$ Deasserted	0				ns
T33	MSWR Deasserted to MSD0-7 Invalid (Note 3)	0				ns
T35	BPCS Asserted to CHR $\bar{D}$ Y Asserted (Note 13)	175				ns
T36	MSRD Asserted to CHR $\bar{D}$ Y Asserted (Note 13)	150				ns
T38	MSD0-7 Asserted to CHR $\bar{D}$ Y Asserted (Note 13)	250				ns

**Note 1:** M $\bar{T}$ 6, I $\bar{O}$ T6 are only asserted for 16-bit transfers.

**Note 2:** CHR $\bar{D}$ Y is only deasserted if the NIC core can not service the access immediately. It is held deasserted until the NIC core is ready, causing the system to insert wait states.

**Note 3:** On 8-bit transfers only 8 bits of MSD0-15 and D0-7 are driven.

**Note 5:** This is the standard CHR $\bar{D}$ Y timing where CHR $\bar{D}$ Y is asserted after I $\bar{O}$ R $\bar{D}$  or I $\bar{O}$ W $\bar{R}$ .

**Note 6:** Read data valid is referenced to CHR $\bar{D}$ Y when wait states have been inserted.

**Note 7:** If no wait states are inserted read data valid can be measured from I $\bar{O}$ R $\bar{D}$ .

**Note 8:** This is a minimum timing with no additional wait states.

**Note 9:** This is the standard I $\bar{O}$ T6 timing where I $\bar{O}$ T6 is asserted after a valid address decode.

**Note 10:** This is the late I $\bar{O}$ T6 timing, required by some machines, where I $\bar{O}$ T6 is asserted after a valid address decode and I $\bar{O}$ R $\bar{D}$  or I $\bar{O}$ W $\bar{R}$  going active.

**Note 11:** This is a timing for a RAM access.

**Note 13:** This is a timing for a Boot PROM access.

**Note 14:** Guaranteed by design.

### SERIAL EEPROM TIMING

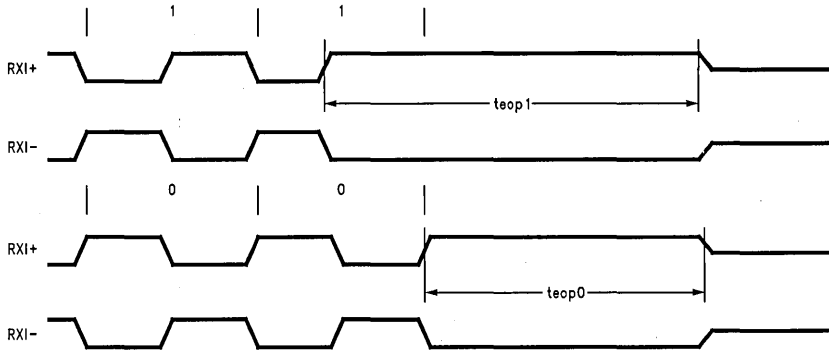

TL/F/12082-46

Symbol	Description	Min	Max	Units
T1	EECS Setup to MSD2	150		ns
T2	EECS Hold after MSD2	250		ns
T3	MSD2 Low Time	450		ns

## AUI TRANSMIT TIMING (End of Packet)

TL/F/12082-50

Symbol	Description	Min	Max	Units
$t_{TOh}$	Transmit Output High before Idle (Note 1)	200		ns
$t_{TOl}$	Transmit Output Idle Time (Note 1)	8000		ns

## AUI RECEIVE TIMING (End of Packet)

TL/F/12082-51

Symbol	Description	Min	Max	Units
$t_{eop1}$	Receive End of Packet Hold Time after Logic "1" (Note 1)	225		ns
$t_{eop0}$	Receive End of Packet Hold Time after Logic "0" (Note 1)	225		ns

**Note 1:** This parameter is guaranteed by design and is not tested.

# DP83905 AT/LANTIC™

## AT Local Area Network Twisted-Pair Interface Controller

### General Description

The AT/LANTIC AT Local Area Network Twisted-pair Interface Controller is a CMOS VLSI device designed for easy implementation of CSMA/CD local area networks.

Unique to the AT/LANTIC is the integration of the entire bus interface for PC-AT® ISA (Industry Standard Architecture) bus based systems. Hardware and software selectable options allow the AT/LANTIC's bus interface to be configured software compatible to either an NE2000 or Ethercard PLUS16™. All bus drivers and control logic are integrated to reduce board cost and area.

Supported network interfaces include 10BASE5 or 10BASE2 Ethernet via an external transceiver connected to its AUI port, and Twisted-pair Ethernet (10BASE-T) using the on-board transceiver. The AT/LANTIC provides the Ethernet Media Access Control (MAC), Encode-Decode (ENDEC) with an AUI interface, and 10BASE-T transceiver functions in accordance with the IEEE 802.3 standards.

The AT/LANTIC's integrated 10BASE-T transceiver fully complies with the IEEE standard. This functional block incorporates the receiver, transmitter, collision, heartbeat, loop-back, jabber, and link integrity blocks as defined in the standard. The transceiver when combined with equalization resistors, transmit/receive filters, and pulse transformers provides a complete physical interface from the AT/LANTIC Controller's ENDEC module and the twisted pair medium.

(Continued)

### Features

- Controller and integrated bus interface solution for IEEE 802.3, 10BASE5, 10BASE2, and 10BASE-T
- Software compatible with *Novell®'s NE2000/Plus* industry standard Ethernet Adapters
- Selectable buffer memory size
- No external bus logic or drivers
- Integrated controller, ENDEC, and transceiver
- Full IEEE 802.3 AUI interface
- Single 5V supply

#### 10BASE-T TRANSCEIVER MODULE:

- Integrates transceiver functionality:
  - Transmitter and receiver functions
  - Collision detect, heartbeat and jabber
  - Selectable link integrity test or link disable
  - Polarity Detection/Correction

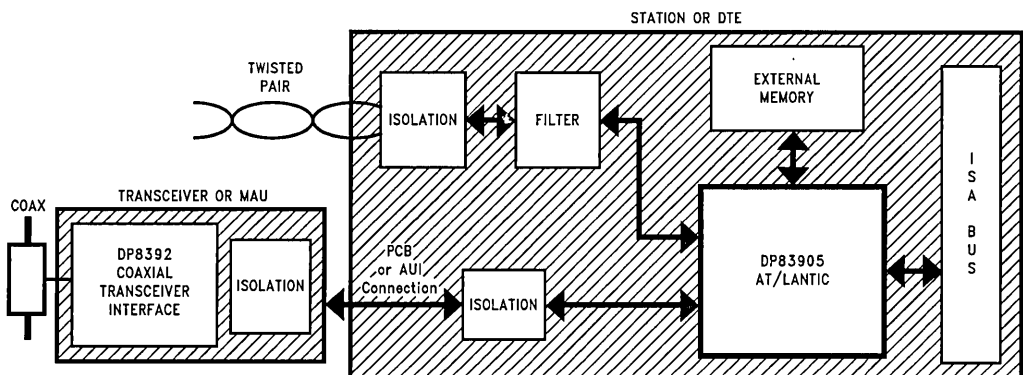

#### ENDEC MODULE:

- 10 Mbit/s Manchester encoding/decoding
- Squelch on receive and collision pairs

#### MAC/CONTROLLER MODULE:

- Software compatible with DP8390, DP83901, DP83902
- Efficient buffer management implementation

## 1.0 System Diagram

TL/F/11498-1

## General Description (Continued)

The integrated ENDEC module allows Manchester encoding and decoding via a differential transceiver and phase lock loop decoder at 10 Mbit/sec. Also included are a collision detect translator and diagnostic loopback capability. The ENDEC module interfaces directly to the transceiver module, and also provides a fully IEEE compliant AUI (Attachment Unit Interface) for connection to other media transceivers.

The Media Access Control function which is provided by the Network Interface Control module (NIC) provides simple and efficient packet transmission and reception control by means of off-board memory which can be accessed either through an I/O port or mapped into the system memory.

AT/LANTIC Controller provides a comprehensive solution for 10BASE-T IEEE 802.3 networks. Due to the inherent constraints of CMOS processing, isolation is required at the AUI differential signal interface for 10BASE5 and 10BASE2 applications.

## 2.0 Pin Description

Pin No.	Pin Name	Type*	Description
<b>ISA BUS INTERFACE PINS</b>			
94-97 99-106 108-115	SA0-SA19	I TTL	<b>LATCHED ADDRESS BUS:</b> Low-order 20 bits of the system's 24 bit address bus. These lines are enabled onto the bus, by the system, when BALE is high and are latched when BALE returns low. These bits are used to decode accesses to the AT/LANTIC Controller's I/O map and to the boot PROM. In addition they are used to decode accesses to the AT/LANTIC Controller's memory in shared memory mode.
76-82	LA17-LA23	I TTL	<b>UNLATCHED ADDRESS BUS:</b> High order 7 bits of the 24-bit system address bus. These lines are valid on the falling edge of BALE. These bits are used to decode accesses to the AT/LANTIC Controller's memory in shared memory mode.
127, 128, 130, 131, 133, 134, 136, 137, 73, 72, 70, 69, 67, 66, 64, 63.	SD0-SD15	I/O 3SH	<b>SYSTEM DATA BUS:</b> 16-bit system data bus. Used to transfer data between the system and the AT/LANTIC Controller.
88	BALE	I TTL	<b>BUS ADDRESS LATCH ENABLE:</b> This signal indicates when the system address lines are valid.
83	SBHE	I TTL	<b>SYSTEM BUS HIGH ENABLE:</b> This signal indicates that the system expects a transfer on the upper byte lane.
86	M16	O OCH	<b>16-BIT MEMORY TRANSFER:</b> In 16-bit shared memory mode this signal indicates that the AT/LANTIC Controller has decoded an address within the 128 kbyte space that it occupies part of.
84	IOT16	O OCH	<b>16-BIT I/O TRANSFER:</b> In I/O mode this signal indicates that the AT/LANTIC Controller is responding to a 16-bit I/O access by driving 16-bits of data on the bus.
74	MWR	I TTL	<b>MEMORY WRITE STROBE:</b> Strobe from system to write to AT/LANTIC Controller's memory map. <i>This pin should be connected to allow the CHRDY fix in 16-bit I/O mode to operate correctly. (See Section 6.0)</i>
75	MRD	I TTL	<b>MEMORY READ STROBE:</b> Strobe from system to read from AT/LANTIC Controller's memory map. <i>This pin should be connected to allow the CHRDY fix in 16-bit I/O mode to operate correctly. (See Section 6.0)</i>
119, 120	SMRD & SMWR	I TTL	<b>LOW MEMORY STROBES:</b> In Memory mode these signals strobe memory transfers in the same manner as MRD and MWR except that these signals only occur if the access is to the lowest 1 Megabyte. This partial address decode means that these signals can be used in an 8-bit slot to properly decode an access to this area. <i>The AT/LANTIC Controller will use MRD and MWR in 16-bit Memory mode and will use SMRD and SMWR in Memory mode when DWID is low (8-bit mode). SMRD and SMWR are also used to access the BOOT PROM.</i>
118	IOWR	I TTL	<b>I/O WRITE STROBE:</b> Strobe from system to write to the AT/LANTIC Controller's I/O map.
117	IORD	I TTL	<b>I/O READ STROBE:</b> Strobe from system to read from the AT/LANTIC Controller's I/O map.
126	RESET	I TTL	<b>RESET:</b> This signal is output by the system to reset all devices on the bus.

\*Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3SH = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type*	Description
<b>ISA BUS INTERFACE PINS (Continued)</b>			
123	CHRDY	O OCH	<b>CHANNEL READY:</b> This signal is used to insert wait states into system accesses.
122	AEN	I TTL	<b>DMA ACTIVE:</b> This signal indicates that the system's DMA controller has control of the bus.
89–92	INT0–3	O 3SH	<b>INTERRUPT REQUEST:</b> The operation of these 4 outputs is determined by the Configuration registers. They can either be used to directly drive the interrupt lines or used as a 3-bit code with a strobe to generate up to 8 interrupts.
61	DWID	I MOS	<b>DATA WIDTH:</b> This input specifies whether the AT/LANTIC Controller is interfacing to an 8- or 16-bit ISA bus. When high it is in 16-bit mode. It has an internal pull-down resistor.
93	ISACK	I TTL	<b>ISA CLOCK:</b> Clock from ISA bus. This signal is only required if CHRDY timing has to be altered, by changing the CHRDY bit of Configuration Register B.
<b>NETWORK INTERFACE PINS</b>			
156–153	TX0d+, TX0–, TXO+, TXOd–	O TPI	<b>TWISTED PAIR TRANSMIT OUTPUTS:</b> These high drive CMOS level outputs are resistively combined external to the chip to produce a differential output signal with equalization to compensate for Intersymbol Interference (ISI) on the twisted pair medium.
150, 151	RX1+, RX1–	I TPI	<b>TWISTED PAIR RECEIVE INPUTS:</b> These inputs feed a differential amplifier which passes valid data to the ENDEC module.
141, 142	TX– TX+	O AUI	<b>AUI TRANSMIT OUTPUT:</b> Differential driver which sends the encoded data to the transceiver. The outputs are source followers which require 270Ω pull-down resistors.
145, 146	RX– RX+	I AUI	<b>AUI RECEIVE INPUT:</b> Differential receive input pair from the transceiver.
147, 148	CD– CD+	I AUI	<b>AUI COLLISION INPUT:</b> Differential collision pair input from the transceiver.
5	$\overline{\text{TXLED}}$	O LED	<b>TRANSMIT:</b> An open-drain active low output. It is asserted for approximately 50 ms whenever the AT/LANTIC Controller transmits data in either AUI or TPI modes.
4	$\overline{\text{RXLED}}$	O LED	<b>RECEIVE:</b> An open-drain active low output. It is asserted for approximately 50 ms whenever receive data is detected in either AUI or TPI mode.
3	$\overline{\text{COLED}}$	O LED	<b>COLLISION:</b> An open-drain active low output. It is asserted for approximately 50 ms whenever the AT/LANTIC Controller detects a collision in either AUI or TPI modes.
1	$\overline{\text{GDLNK}}$	O LED	<b>GOOD LINK:</b> An open-drain active low output. This pin operates as an output to display link integrity status if this function has not been disabled by the GDLNK bit in Configuration Register B. This output is off if the AT/LANTIC Controller is in AUI mode or if link testing is enabled and the link integrity is bad (i.e. the twisted pair link has been broken). This output is on if the AT/LANTIC Controller is in Twisted Pair Interface (TPI) mode, link integrity checking is enabled and the link integrity is good (i.e. the twisted pair link has <b>not</b> been broken) or if the link testing is disabled.
2	$\overline{\text{POLED}}$	O LED	<b>POLARITY:</b> An open-drain active low output. This signal is normally inactive. When the TPI module detects seven consecutive link pulses or three consecutive received packets with reversed polarity $\overline{\text{POLED}}$ is asserted.

\*Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3SH = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type*	Description
<b>NETWORK INTERFACE PINS (Continued)</b>			
7	X1 (OSCIN)	I XTAL	<b>CRYSTAL OR EXTERNAL OSCILLATOR INPUT</b>
8	X2 (OSCOU)	O XTAL	<b>CRYSTAL FEEDBACK OUTPUT:</b> Used in crystal connections only. Should be left completely unconnected when using an oscillator module.
10	THIN	O DCDC	<b>THIN CABLE:</b> This output is high if AT/LANTIC Controller is configured for thin cable. It can be used to enable the DC-DC converter required by the thin ethernet configuration.
<b>EXTERNAL MEMORY SUPPORT</b>			
58-50	MSD0-7, CA0-7, DO, DI, SK	I/O, I, O MOS	<b>MEMORY SUPPORT DATA BUS—CONFIGURATION REGISTER A INPUT EEPROM SIGNALS:</b> MSD0-7: When RESET is inactive these pins can be used to access external memory and boot PROM. CA0-7: When RESET is active Configuration Register A is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0. DO, DI, SK: When RESET goes from an active to an inactive level AT/LANTIC Controller will read the contents of an EEPROM, using these signals, and load the contents into internal registers. These internal registers will then be mapped into the space taken up by the PROM in the NE2000 and Ethercard PLUS16. After the EEPROM read operation has completed these pins will revert to MSD0-2 (D0 = MSD0, DI = MSD1, SK = MSD2).
48-45 43-40	MSD8-15 or CB0-7	I/O, I MOS	<b>MEMORY SUPPORT DATA BUS—CONFIGURATION REGISTER B INPUT:</b> MSD8-15: When RESET is inactive these pins can be used to access external memory. CB0-7: When RESET is active Configuration Register B is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0.
31-25, 22	MSA1-8 or CC0-7	O, I MOS	<b>MEMORY SUPPORT ADDRESS BUS—CONFIGURATION REGISTER C INPUT:</b> MSA1-8: When RESET is inactive these pins drive the memory support address bus. CC0-7: When RESET is active Configuration Register C is loaded with the data value on these pins. If the user puts an external pull-up on any of these pins then the corresponding register bit is set to a 1. If the pin is left unconnected then the register bit is 0.
21-15	MSA9-15	O MOS	<b>MEMORY SUPPORT ADDRESS BUS:</b> MSA9-15: When RESET is inactive these pins drive the memory support address bus. When the memory is only 8 bits wide A0 will appear on A13, in compatible mode, and on A15, in non-compatible mode.
33	MSRD	O MOS	<b>MEMORY SUPPORT BUS READ:</b> Strokes data from the external RAM into the AT/LANTIC Controller via the memory support data bus.
32	MSWR	O MOS	<b>MEMORY SUPPORT BUS WRITE:</b> Strokes data from the AT/LANTIC Controller into the external RAM via the memory support data bus.
37	BPCS	O MOS	<b>BOOT PROM CHIP SELECT:</b> Selects the boot PROM on the memory support data bus.

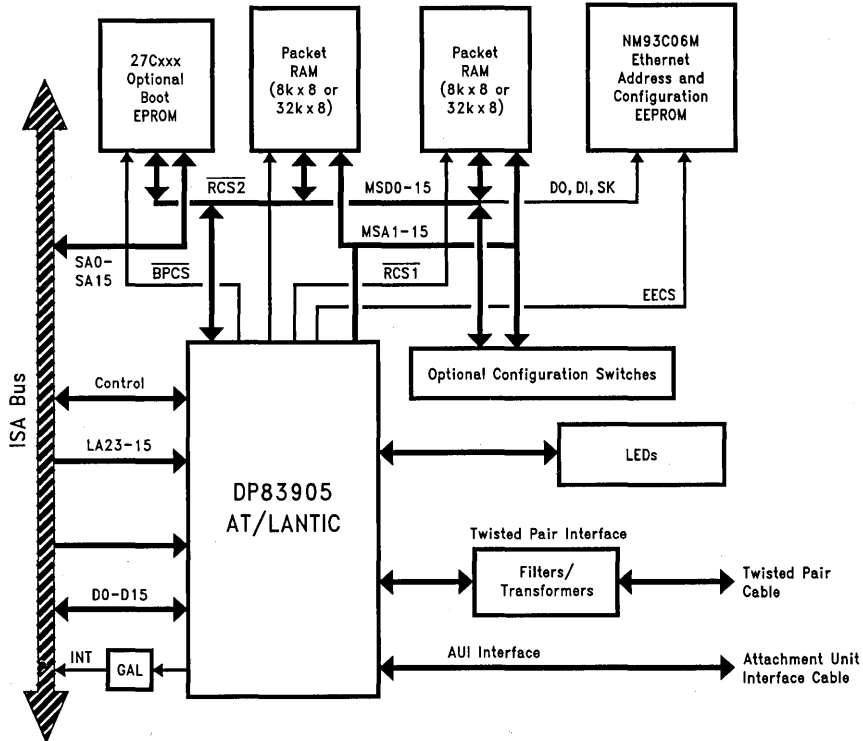

\*Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3SH = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

## 2.0 Pin Description (Continued)

Pin No.	Pin Name	Type*	Description
<b>EXTERNAL MEMORY SUPPORT (Continued)</b>			
33	$\overline{RCST}$	O MOS	<b>RAM CHIP SELECT 1:</b> Drives the chip select of the external RAM on the lower half of the memory support data bus.
34	$\overline{RCS2}$	O MOS	<b>RAM CHIP SELECT 2:</b> Drives the chip select of the external RAM on the upper half of the memory support data bus.
38	EECS	O MOS	<b>EEPROM CHIP SELECT:</b> Strobes data from the EEPROM onto the memory support data bus.
39	EECONFIG	I TTL	<b>CONFIGURE FROM EEPROM:</b> When this pin is tied high the AT/LANTIC Controller loads the configuration from an EEPROM.
12	BSCLK	I TTL	<b>INTERNAL BUS CLOCK:</b> This controls the speed of the NIC core if it is not running off of an internal clock (see Configuration Register C). This pin should be tied to ground if it is unused.
<b>LOW POWER SUPPORT</b>			
62	LOWPWR	I TTL	<b>LOW POWER:</b> Instructs AT/LANTIC Controller to enter its low power mode, as detailed in Section 4.5. Should be tied to ground for normal operation.
<b>TEST SUPPORT</b>			
11	TEST	I MOS	<b>TEST:</b> This input is only used for test mode. It should be left unconnected as it has an internal pull-down resistor which will enable correct operation.
<b>POWER SUPPLY PINS</b>			
160	PLL <sub>VCC</sub>		<b>PLL 5V SUPPLY PINS:</b> This pin supplies 5V to the AT/LANTIC's analog PLL inside the ENDEC block. To maximize data recovery it is recommended that analog layout and decoupling rules be applied between this pin and PLL <sub>GND</sub> .
159	PLL <sub>GND</sub>		<b>PLL NEGATIVE (GROUND) SUPPLY PINS</b>
157, 152, 144, 143, 139	PV <sub>CC</sub>		<b>PHYSICAL MEDIA 5V SUPPLY PINS:</b> These pins supply 5V to the AT/LANTIC's analog physical media interface circuitry.
158, 149, 140, 138	PG <sub>ND</sub>		<b>PHYSICAL LAYER NEGATIVE (GROUND) SUPPLY PINS:</b> These pins are the ground to the AT/LANTIC's analog physical media interface circuitry.
9	OV <sub>CC</sub>		<b>OSCILLATOR 5V SUPPLY PINS:</b> This pin supplies 5V to the AT/LANTIC's oscillator and LED circuitry.
6	OG <sub>ND</sub>		<b>OSCILLATOR NEGATIVE (GROUND) SUPPLY PINS:</b> This pin is the ground to the AT/LANTIC's oscillator and LED circuitry.
59, 49, 24, 13	V <sub>CC</sub>		<b>POSITIVE 5V SUPPLY PINS:</b> These pins supply power to the AT/LANTIC Controller's logic.
60, 54, 44, 35, 23, 14	G <sub>ND</sub>		<b>NEGATIVE (GROUND) SUPPLY PINS:</b> These are the supply pins for the AT/LANTIC Controller's logic. It is suggested that decoupling capacitors be connected between the V <sub>CC</sub> and G <sub>ND</sub> pins. It is essential to provide a path to ground for the G <sub>ND</sub> pins with the lowest possible impedance.
132, 121, 107, 87, 68	IFV <sub>CC</sub>		<b>INTERFACE POSITIVE 5V SUPPLY PINS:</b> These pins supply power to the AT/LANTIC Controller's ISA interface.
135, 129, 125, 124, 116, 98, 85, 71, 65	IFG <sub>ND</sub>		<b>INTERFACE NEGATIVE (GROUND) SUPPLY PINS:</b> These are the supply pins for the AT/LANTIC Controller's ISA interface. It is suggested that decoupling capacitors be connected between the IFV <sub>CC</sub> and IFG <sub>ND</sub> pins. It is essential to provide a path to ground for the IFG <sub>ND</sub> pins with the lowest possible impedance.

\*Driver Types are: I = Input, O = Output, I/O = Bi-directional Output, OCH = Open Collector, 3SH = TRI-STATE Output, TTL = TTL Compatible, AUI = Attachment Unit Interface, TPI = Twisted Pair Interface, LED = LED Drive, MOS = CMOS Level Compatible, XTAL = Crystal.

### 3.0 Simplified Application Diagram

TL/F/11498-3

### 4.0 Functional Description

The AT/LANTIC Controller is a highly integrated and configurable Ethernet controller making it suitable for most Ethernet applications. The AT/LANTIC Controller integrates the functions of the following blocks:

1. DP8390 Ethernet Controller Core and Media Access Control logic.
2. ISA Bus Interface containing all logic required to connect the DP8390 core to a packet buffer RAM and the ISA bus.
3. Media Interface which includes an Encoder/Decoder block with an AUI (Attachment Unit Interface) and a 10BASE-T Twisted Pair Interface.

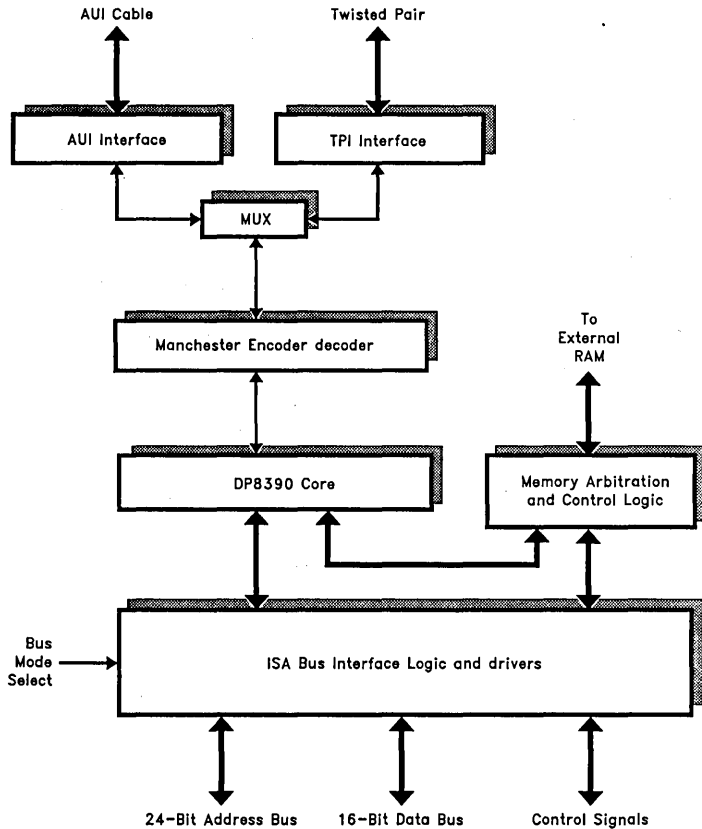

#### 4.1 BUS INTERFACE BLOCK

The AT/LANTIC Controller's Bus interface block provides the circuitry to interface the Ethernet controller logic, and the external packet buffer RAM to an ISA (Industry Standard Architecture) Bus. The bus interface provides several configuration modes which offer various different features depending on the designer's specific design requirements. The possible modes are:

1. 16-Bit or 8-Bit Shared Memory Compatible Mode
2. 16-Bit or 8-Bit Shared Memory Enhanced Mode
3. 16-Bit or 8-Bit I/O Port Compatible Mode
4. 16-Bit or 8-Bit I/O Port Enhanced Mode

This section describes the function of each of these modes.

### 4.0 Functional Description (Continued)

**FIGURE 1. Block Diagram of AT/LANTIC Controller**

TL/F/11498-4

#### DETERMINING 8- OR 16-BIT WIDE DATA

AT/LANTIC Controller can treat the system data bus and all internal data busses as 8 or 16 bits wide. 8- or 16-bit mode is determined by the DWID pin. For an adapter card this bit can be used to automatically detect if the card has been plugged into an 8- or 16-bit slot. If this pin is connected to a V<sub>DD</sub> on the upper connector it will be high when plugged into a 16-bit slot, enabling 16-bit mode, and floating when plugged into an 8-bit slot. When floating the internal pull-down resistor will enable 8-bit mode.

In this mode the AT/LANTIC Controller's internal memory map, using external RAM devices, is mapped into the host system's memory map. Both the AT/LANTIC Controller and the host system can directly access this memory. The AT/LANTIC Controller controls the arbitration for this memory area, giving priority to its internal accesses. It also has an internal FIFO to allow for any latency on internal transfers introduced by system accesses. If a system access occurs while an internal access is current the AT/LANTIC Controller will insert wait states into the system cycle until the internal transfer is complete.

#### SHARED MEMORY ARCHITECTURE

TL/F/11498-5

**FIGURE 2. Shared Memory**

In this mode the AT/LANTIC Controller's internal registers are accessed within the system's I/O map. The address within this I/O map is set by Configuration Register A. The user programs the address of the shared memory within the host systems memory map by writing to a register in AT/LANTIC Controller. The memory is not accessible by the user until after this register has been programmed.

There are two basic Shared Memory modes, compatible mode, and non-compatible mode, as described in the following text.

## 4.0 Functional Description (Continued)

### Shared Memory Compatible Mode I/O Address Mapping

The shared memory is at an address decided by the Address Decode Register and the base I/O address of AT/LANTIC Controller is configured in Configuration Register A. At that address the following structure appears.

Addr	D7-0	
00	Control 1	
01	AT detect	(Read only)
02	Unused	
03	Unused	
04	Unused	
05	Control 2	
06	Unused	
07	Unused

0D	Node addr 5	(Read only)
0E	05h	(Read only)
0F	Checksum	(Read only)
10 to 1F	NIC registers	

(a)

(b)

**FIGURE 3. Shared Memory Mode a) Register Mapping and b) NIC Core Memory Map**

The AT Detect Register indicates whether AT/LANTIC Controller is in an 8- or 16-bit slot. The least significant bit of this register is set high when AT/LANTIC Controller is in 16-bit mode and low in 8-bit mode. Addresses 08H to 10H are

specified as the PROM space for compatibility with the Ethercard PLUS16. This is actually an array of 8-bit registers which are loaded from an external EEPROM after AT/LANTIC Controller is initialized by a reset pulse. The user should program the EEPROM to contain these values. The 8k words of memory can be accessed directly by the host system in the same manner as any other memory. Typically the programmer would remove data from this buffer using a "MOV" or "MOVSW" instruction.

### 8-BIT SHARED MEMORY COMPATIBLE MODE

In this mode the I/O map remains the same. The NIC core can still operate in 16-bit mode, if bit 6 of Control Register 2 is set high and the full 16 kbytes of RAM are still available. However, only 8-bit system accesses are allowed. If bit 6 of Control register 2 is low the NIC core must operate in 8-bit mode and only 8k of memory is available. The NIC Core data width is set by the WTS bit in the Data Configuration Register.

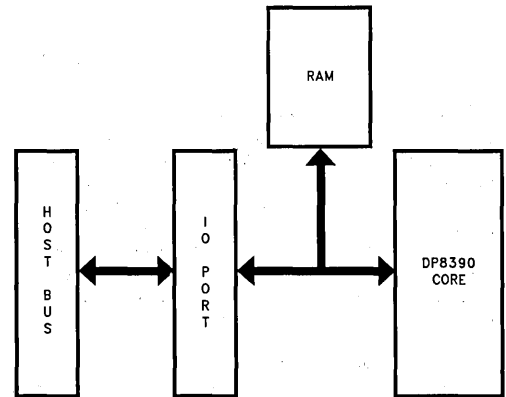

A low cost card, using only one 8 kbyte RAM, can be designed. If the DWID pin is left unconnected, or tied to GND, then the AT/LANTIC Controller will always operate in 8-bit mode, regardless of the slot the board is in.

If DWID is low the address bits of Control Register 2 should not be written to as they have no effect. In this mode the address comparator assumes that SA19 is to be compared to a logic high, with the other address comparisons programmed into Control Register 1.

### SHARED MEMORY NON-COMPATIBLE MODE

These modes are similar to the compatible mode. The difference is that they map a full 64 kbytes of RAM into the PC's memory address space. The I/O map remains the same.

### I/O PORT ARCHITECTURE

TL/F/11498-6

**FIGURE 4. I/O Port**

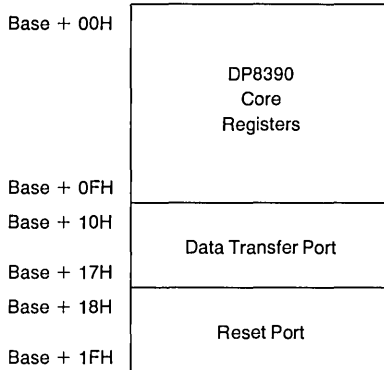

This is the architecture used by Novell's NE2000. In this mode the AT/LANTIC Controller's internal memory map is accessed byte or word at a time, via a port within the system's I/O space. AT/LANTIC Controller is programmed by the user to control the transfers between its internal memory and the I/O port.

In this mode the AT/LANTIC Controller's internal registers and the memory access port are accessed within the system's I/O map. The address within this I/O map is set by Configuration Register A.

## 4.0 Functional Description (Continued)

### 16-BIT I/O PORT COMPATIBLE MODE I/O ADDRESS MAPPING

This mode is compatible with Novell's NE2000. The base I/O address of the AT/LANTIC Controller is configured by Configuration Register A (either upon power up or by software writing to this register). At that address the following structure appears.

**FIGURE 5. I/O Port Mode Register I/O Map**

The registers within this area are 8 bits wide, but the data transfer port is 16 bits wide. The AT/LANTIC Controller's registers can be programmed to control the passing of data between its internal memory and the data transfer port. By accessing the data transfer port (using I/O instructions) the user can transfer data to or from the AT/LANTIC Controller's internal memory. The AT/LANTIC Controller's internal memory map is as shown in *Figure 6*.

AT/LANTIC Controller actually has a 64k address range but only does partial decoding on these devices. The PROM data is mirrored at all decodes up to 4000H and the entire map is repeated at 8000H. To access either the PROM or the RAM the user must initiate a Remote DMA transfer between the I/O port and memory.

On a remote read the AT/LANTIC Controller moves data from its internal memory map to the I/O port and the host system reads it by using an "INW" or "INSW" instruction from the I/O address of the data transfer port. If the system attempts to read the port before AT/LANTIC Controller has written the next word of data to it AT/LANTIC Controller will insert wait states into the system cycle, using the CHRDY

b) 16-Bit Prom Map**

## 4.0 Functional Description (Continued)

line. AT/LANTIC Controller will not begin the next memory read until the previous word of data has been read.

On a remote write the system writes data to the I/O port, using an "OUTW" or "OUTSW" instruction, and AT/LANTIC Controller moves it to its buffer memory. If the system attempts to write to the port before AT/LANTIC Controller has moved the data to memory AT/LANTIC Controller will insert wait states into the system cycle, using the CHRDY line. AT/LANTIC Controller will not begin the next memory write until a new word has been written to the I/O port.

Addresses 00H to 1FH are specified as the PROM space for compatibility with the NE2000. This is actually an array of 8-bit registers which are loaded from an external EEPROM after AT/LANTIC Controller is initialized by an ISA RESET. They should contain the same data as the PROM did in the NE2000 and in the same format. As can be seen the PROM registers are only 8-bits wide. To transfer the data out the user must initiate a 16-bit DMA read transfer and discard the most significant byte of data on each transfer.

At address 00H of the PROM is a six byte Ethernet address for this node. The upper two addresses of the PROM store contain bytes which identify whether the AT/LANTIC Controller is in 8- or 16-bit mode. For 16-bit mode these bytes both contain the value 57H, for 8-bit mode they both contain 42H.

### 8-BIT I/O PORT COMPATIBLE MODE

This mode is compatible with the 8-bit mode offered by Novell's NE2000. The NE2000 automatically detects whether it is in an 8- or 16-bit slot and configures itself appropriately. As explained in the previous paragraphs, the user can determine whether the board is in 8- or 16-bit mode by reading the PROM. In 8-bit mode only 8 kbytes of RAM are addressable, as in the 8-bit mode of the NE2000. The I/O map is the same as the 16-bit mode, the memory map is shown in Figure 7. Again the PROM has only a partial decode, so is mirrored at all addresses up to 4000H. The PROM still occupies 32 bytes of address space, although it only has 16 bytes of data, as the data at all odd address locations is merely a mirror of the data at the previous even address location. The RAM is mirrored at 6000H and the entire map mirrored at 8000H.

A low cost card, using only one 8 kbyte RAM, can be designed. If the DWID pin is left unconnected, or tied to GND, then the AT/LANTIC Controller will always operate in 8-bit mode, regardless of the slot the board is in.

### I/O PORT NON-COMPATIBLE MODE

This mode is similar to Novell's NE2000, but this mode allows the user to use the full 64 kbytes of address space except for an initial page for the PROM. The memory map for this board is shown in Figure 8. The memory map is the same for both 8- and 16-bit modes. Although the PROM store occupies 256 bytes, it is only 16 bytes long. The entire map is mirrored at 8000H.

A low cost card, using only one 8 kbyte RAM, can be designed. If the DWID pin is left unconnected, or tied to GND, then the AT/LANTIC Controller will always operate in 8-bit mode, regardless of the slot the board is in.

## 4.0 Functional Description (Continued)

### 4.2 POWER ON RESET OPERATION

The AT/LANTIC Controller configures itself after a Reset signal is applied. To be recognized as a valid Power-On-Reset the Reset signal must be active for at least 415  $\mu$ s. Figure 9 shows how the RESET circuitry operates.

**FIGURE 9. RESET Operation**

The ISA standard determines that within 500 ns of RESET going active all devices should enter the appropriate reset condition. The AT/LANTIC Controller will generate the internal signal IOinactive after RESET has been active for 415 ns, which will disable all outputs and cause RESET to be the only input monitored. The AT/LANTIC Controller will not respond to a RESET pulse of shorter duration than this. An internal timer continues to monitor the amount of time RESET is active. After 415  $\mu$ s it is considered a valid Power-On-Reset and an internal signal called RegLoad is generated.

When a Power-On-Reset occurs the AT/LANTIC Controller latches in the values on the configuration pins and uses these to configure the internal registers and options. Internally these pins contain pull-down resistors, which are enabled when IOinactive goes active. If any pins are unconnected they default to a logic zero. The internal pull-down resistor has a high resistance to allow the external pull-up resistors to be of a high value. This limits the current taken by the memory support bus. The suggested external resistor value is 10 k $\Omega$ . The configuration registers are loaded from the memory support bus when RESET goes inactive if RegLoad is active. The internal pull-down resistors are enabled onto the bus until RegLoad has gone inactive.

A Power-On-Reset also causes the AT/LANTIC Controller to load the internal PROM store from the EEPROM, which can take up to 320  $\mu$ s. This occurs after RegLoad has gone inactive. The AT/LANTIC Controller will be inaccessible during this time. If EECONFIG is held high the configuration data loaded on the falling edge of RESET will be overwritten with data read from the serial EEPROM. Regardless of the level on EECONFIG the PROM store will always be loaded with data from the serial EEPROM during the time specified as EELoad.

### 4.3 EEPROM OPERATION

The AT/LANTIC Controller uses an NM93C06, or EEPROM with compatible timings. The NM93C06 is a 256-bit device, arranged as 16 words each 16 bits wide. The programmed contents of the EEPROM is shown in Figure 10.

#### Mapping EEPROM Into PROM Space

Data is read from the EEPROM at boot time and stored in registers within the AT/LANTIC Controller. While this operation takes place the AT/LANTIC Controller can not be ac-

00H	E'net Address 1	E'net Address 0

**Note 1:** The contents of locations 03H and 04H differ between I/O Mode and Shared Memory Mode. The Shared Memory Mode values are shown in parentheses. For compatibility with both modes default to the shared memory mode values.

**Note 2:** Programming 73H into the upper address is not absolutely required but is strongly recommended for future compatibility of manufacturing process.

**FIGURE 10. EEPROM Programming Map**

cessed by the system. These registers are mapped into the space traditionally occupied by the PROM in the NE2000 or the EtherCard PLUS16. The size and format of this data read is determined by the mode of operation.

#### SHARED MEMORY MODE

In this mode, program the EEPROM to contain the node's Ethernet address in the first six bytes, a byte identifying the type of board AT/LANTIC Controller is emulating in byte 7 and a checksum byte in byte 8. The two's complement sum of these eight bytes should equal FFH.

In this Mode the AT/LANTIC Controller reads the first 4 words from the EEPROM and maps them into the I/O map at the appropriate address.

#### I/O PORT MODE

In this mode, program the EEPROM to contain the node's Ethernet address in the first six bytes. The user should then program 5757H and 4242H into the subsequent bytes. The AT/LANTIC Controller will decide which of these values should be loaded into the PROM store depending on the DWID pin. (The data width is programmed in this mode by setting the WTS bit in the Data Configuration Register and setting the DWID pin for the proper mode.) If some other numerical values are preferred to indicate the mode then they can be programmed at this location in the EEPROM and AT/LANTIC Controller will put them at the correct address.

In this mode the AT/LANTIC Controller reads the first 7 words from the EEPROM and maps them into the memory map at the appropriate address. If in 16-bit mode it also

## 4.0 Functional Description (Continued)

reads the next word in the EEPROM and appends this. If in 8-bit mode it skips a word, then reads and appends the next word.

### Storing and Loading Configuration from EEPROM

If the EECONFIG pin is high during boot up the AT/LANTIC Controller's configuration is read from the EEPROM, before the PROM data is read. The configuration data is stored within the upper two words of the EEPROM's address space. Configuration Registers A and B are located in the lower of these words, Register C in the lower byte of the upper word, as shown in *Figure 10*.

To write this configuration into the EEPROM the user must follow the routine specified in the pseudo code below. This operation will work regardless of the level on EECONFIG. The EELOAD bit of Configuration Register B being set starts the EEPROM write process. Care should be taken not to accidentally set the GDLINK bit and therefore disable link integrity checking. The next 3 writes to this register load the values that will be stored in the configuration register (note that the last 2 of these writes do not have to follow the normal practice of preceding a write to this register with a read to this address). The AT/LANTIC Controller will then commence the EEPROM write. The write has been completed when the EELOAD bit goes to zero. This loading procedure should be followed exactly and interrupts should be disabled until it has completed, to prevent any accidental accesses to the AT/LANTIC Controller.

EEPROM\_LOAD()

```
{
    DISABLE_INTERRUPTS();
    value = READ(CONFIG_B);
    value = value AND 1 GDLINK;
    value = value OR EELOAD;
    WRITE(CONFIG_B, value);
    READ(CONFIG_B);
    WRITE(CONFIG_B, config_for_A);
    WRITE(CONFIG_B, config_for_B);
    WRITE(CONFIG_B, config_for_C);
    while (value AND EELOAD)
    {
        value = READ(CONFIG_B);
        WAIT();
    }
    ENABLE_INTERRUPTS();
}
```

### 4.4 JUMPERED AND JUMPERLESS OPERATION SUPPORT

The AT/LANTIC Controller supports several options that enable the implementation of either a "jumpered" or "jumperless" power on configuration when installed into a standard PC compatible's ISA bus. A wide range of options are provided to ensure that the AT/LANTIC Controller can be configured by an end user to function in all possible PC-AT system configurations. Several types of configuration options can be implemented examples including:

1. Full jumper options: All programmable options are selected by utilizing jumpers on the board. Option selection requires no special software. An example of this is shown in the *Figure 11*.

2. I/O address jumpers only: All other options configurable via software. This option simplifies installation while maximizing compatibility.
3. Jumperless: Special scheme provides contention-free I/O address selection.

The AT/LANTIC Controller's Configuration Registers are the key to providing the ability to implement various configuration options. These registers are configured by the same method in shared memory and I/O port modes, 8- or 16-bit modes. The bit definitions of these registers are provided in Section 5. All three registers are configured by hardware selection during the Power-On-Reset of the system. Two of these registers can be configured via software (the Mode Configuration Registers A and B). The third register (Hardware Configuration Register C) is only configured during reset.

The following table indicates *most* of the AT/LANTIC Controller options that a designer may like to have user configurable. (This list does not represent the complete list. For the full list see the Configuration register descriptions in Section 5.)

**TABLE I. Some Configuration Options for AT/LANTIC Controller**

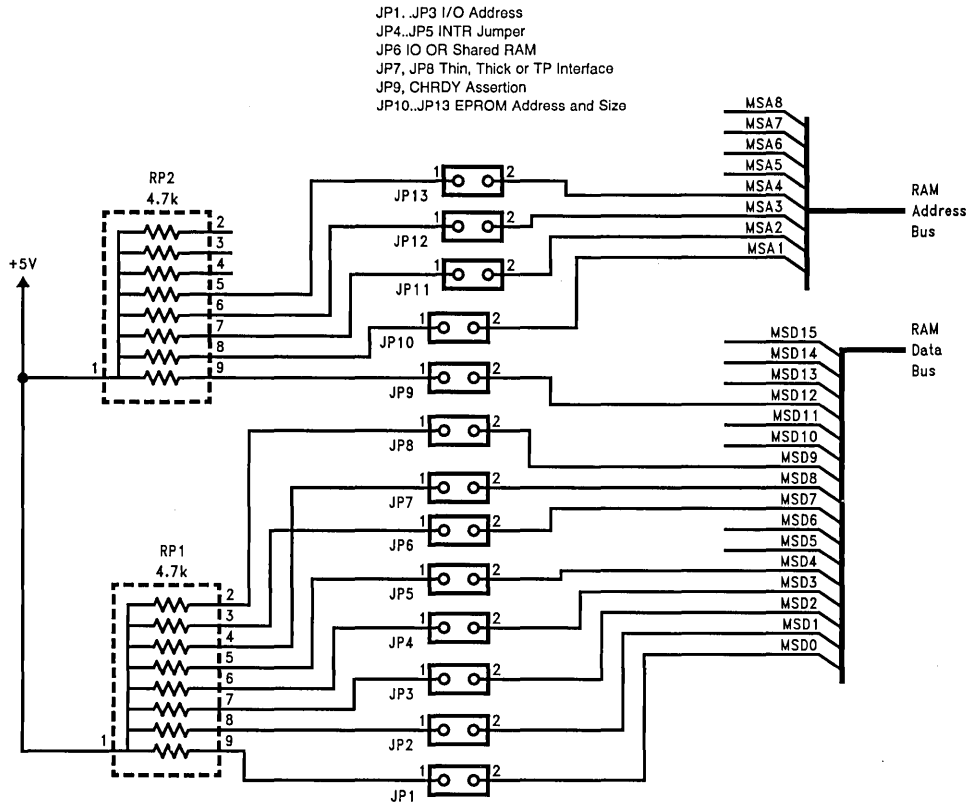

Option	Selections	
I/O Base Address	0300H Software 0240H 0280H	02C0H 0320H 0340H 0360H
Interrupt No.	4 Interrupts	8 Interrupts
Boot PROM Address	Disabled 0C000H 0C400H 0C800H	0CC00H 0D000H 0D400H 0D800H 0DC00H
Boot PROM Size	None 16k	32k 64k
Media Selection	Twisted Pair AUI Port	Thin Ethernet
Architecture	I/O Mode	Shared RAM Mode
Bus Timing Options	IOCHRDY Mode	MEM16 Mode

The three basic options are described below. Because of the variety of programmable options there are a number of variations possible, only a few typical examples will be discussed.

#### FULLY JUMPERED OPERATION

This option is shown in *Figure 11*. In this configuration most options are selected by jumpers on the AT/LANTIC Controller's memory bus. For this option all configuration options are set upon power-on by the AT/LANTIC Controller as described in Section 4.2. Accessing the configuration registers is unnecessary and the EEPROM need only contain the

## 4.0 Functional Description (Continued)

TL/F/11498-B

FIGURE 11. Example of Jumper Configuration

Ethernet ID address (Configuration Register B bit 7 should be set to disable EEPROM configuration mode, and Configuration Register C bit 7 could be set to disable software configuration completely).

### MINIMAL JUMPERS

The AT/LANTIC Controller's configuration registers provide the capability to enable software to configure various options (some may be hardwired). For the one option that is not easily configured on the ISA bus is the I/O address options. The reason for this is that the I/O locations must first be known by the software in order for the software (usually a device driver) to access the AT/LANTIC Controller. However, upon power up, in order to access a register to configure the I/O base address to avoid conflicts some default location must be given (typically set in hardware on the memory bus). It is possible that this default location conflicts with an already installed device. If this is the case then one possible solution, is to provide a jumper option for only the I/O Addresses. A similar situation exists for the boot PROM memory addresses.

In this application all options except the I/O address and the boot PROM are hardwired on the memory bus to a default setting. After power up software can change the con-

figuration to avoid conflicts on these settings. The advantage of this approach is that for most systems the default I/O address setting is the correct one and no installation will be required in this case. This approach minimizes any compatibility issues.

### NO JUMPERS

The conflicts possible in the I/O base selection can be overcome by a special mode for software configuration of the I/O base address. By using this mode, and by using the configuration storage capability of the EEPROM a fully software configurable design on the ISA bus can be realized without address conflict problems.

This mode is invoked by having the AT/LANTIC Controller default to jumperless software configuration option in the I/O base selection. This mode enables configuration register A to be mapped to address location 278H which is defined to be a printer port's data register. If software writes to this location four consecutive times on the fourth write the AT/LANTIC Controller will load the data written into the I/O address bits of Configuration Register A. This data should set the I/O base address to a known conflict-free value. The AT/LANTIC Controller can now be configured and operated

## 4.0 Functional Description (Continued)

at the desired base I/O address. If desired the configuration software could change the EEPROM content to the new values eliminating the need to reconfigure upon each power up. Alternately the software could leave the EEPROM alone and execute the configuration using the printer port's data register upon each power up. This configuration scheme will only work once after each power-up. Therefore the user cannot enable the AT/LANTIC Controller from reserved mode, change it back into reserved mode, and enable it again. A power-on reset must occur between the first time it is enabled from the reserved mode and the second.

A second consideration is the location of the boot PROM in the system memory map, which also has the same conflict and programming considerations as the I/O address selection. However the solution is different, primarily because the boot PROM must be configured before power up. This is because during normal usage of the boot PROM the PC's BIOS will look for the ROM immediately after reset, not allowing configuration software to first select the boot PROM addressing prior to usage.

To configure the boot PROM without jumpers the configuration software must first power up the AT/LANTIC Controller, configure the EEPROM to the desired location, then hardware reset the AT/LANTIC Controller. After the reset the AT/LANTIC Controller's EEPROM will load in the desired boot PROM configuration automatically during the reset. Now after reset when the PC scans for the boot PROM, the ROM will be correctly mapped in the memory space enabling the network boot operation to proceed.

### Ethernet Cable Configuration

AT/LANTIC Controller offers the choice of all the possible Ethernet cabling options, that is Ethernet (10BASE5), Thin Ethernet (10BASE2) and Twisted-pair Ethernet (10BASE-T). The type of cabling used is controlled by Configuration Register B. AT/LANTIC Controller also supplies a THIN output signal which can be used to disable/enable an external DC-DC converter which is required for 10BASE2.

### 4.5 LOW POWER OPERATION

The AT/LANTIC Controller has a low power support mode that can be used to disable the Ethernet port and conserve power. It should be noted that the device is not operational in this mode and requires to be initialized after exiting this mode.

The power and ground pins to the AT/LANTIC Controller are split up into two groups, interface and core. By switching the power off to the core logic while still powering the interface logic the AT/LANTIC Controller can be powered down without crashing the ISA bus. The LOWPWR pin should be driven high to indicate that the device is about to go into low power then the power to the  $V_{DD}$  pins should be switched off. The same signal that is used to drive the LOWPWR pin can be used to drive a p-channel load switch to disable power to the core. This switch must have a very low on resistance to minimize the voltage difference between the  $V_{CC}$  and the  $IFV_{CC}$ . All devices on the memory support bus should also be powered from the  $V_{CC}$  supply.

### 4.6 BOOT PROM OPERATION

The AT/LANTIC Controller supports an optional boot PROM, the address and size of which can be set in Configuration Register C. This boot PROM can be any 8 bits wide storage device implemented with a non-volatile technology. Write cycles to this device can be enabled and disabled by programming Configuration Register B. This can be used to prevent unwanted write cycles to certain devices, such as a Flash EEPROM. **It should be noted that the address pins for the boot PROM should be connected directly to the ISA bus.** The AT/LANTIC Controller supplies the chip select to the device and buffers the data onto and from the ISA bus, so the memory support data bus should be connected to the boot PROM's data pins.

### 4.7 DP8390 CORE (NETWORK INTERFACE CONTROLLER)

The DP8390 Core logic, *Figure 12*, contains the Serializer/Deserializer which is controlled by the Protocol PLA, DMA Control, FIFO, Address Comparator, Multicast Hashing Register. The DP8390 core implements all of the IEEE 802.3 Media access control functions for the AT/LANTIC Controller, and interfaces to the internal ENDEC (on the left of the block diagram) and also interfaces to the Bus Interface and memory support bus via a number of address, data and control signal (and the right side of the block diagram). The following sections describe the functions of the DP8390 core.

#### Receive Deserializer

The Receive Deserializer is activated when the input signal Carrier Sense is asserted to allow incoming bits to be shifted into the shift register by the receive clock. The serial receive data is also routed to the CRC generator/checker. The Receive Deserializer includes a synch detector which detects the SFD (Start of Frame Delimiter) to establish where byte boundaries within the serial bit stream are located. After every eight receive clocks, the byte wide data is transferred to the 16-byte FIFO and the Receive Byte Count is incremented. The first six bytes after the SFD are checked for valid comparison by the Address Recognition Logic. If the Address Recognition Logic does not recognize the packet, the FIFO is cleared.

#### CRC Generator/Checker

During transmission, the CRC logic generates a local CRC field for the transmitted bit sequence. The CRC encodes all fields after the synch byte. The CRC is shifted out MSB first following the last transmit byte. During reception the CRC logic generates a CRC field from the incoming packet. This local CRC is serially compared to the incoming CRC appended to the end of the packet by the transmitting node. If the local and received CRC match, a specific pattern will be generated and decoded to indicate no data errors. Transmission errors result in different patterns and are detected, resulting in rejection of a packet.

## 4.0 Functional Description (Continued)

FIGURE 12. DP8390 Controller Core Simplified Block Diagram

TL/F/11498-9

### Transmit Serializer

The Transmit Serializer reads parallel data from the FIFO and serializes it for transmission. The serializer is clocked by the transmit clock generated internally. The serial data is also shifted into the CRC generator/checker. At the beginning of each transmission, the Preamble and Synch Generator append 62 bits of 1,0 preamble and a 1,1 synch pattern. After the last data byte of the packet has been serialized the 32-bit FCS (Frame Check Sequence) field is shifted directly out of the CRC generator. In the event of a collision the Preamble and Synch generator is used to generate a 32-bit JAM pattern of all 1's.

### Comparator-address Recognition Logic

The address recognition logic compares the Destination Address Field (first 6 bytes of the received packet) to the Physical address registers stored in the Address Register Array. If any one of the six bytes does not match the pre-programmed physical address, the Protocol Control Logic rejects the packet. All multicast destination addresses are filtered using a hashing technique. (See register description.) If the multicast address indexes a bit that has been set in the filter bit array of the Multicast Address Register Array the packet is accepted, otherwise it is rejected by the Protocol Control Logic. Each destination address is also checked for all 1's which is the reserved broadcast address.

### FIFO and Packet Data Operations

#### OVERVIEW

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the packet buffer memory, the AT/LANTIC Controller contains a 16-byte FIFO for buffering data between the media and the buffer RAM located on the memory support bus. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO at different rates. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory (via the

memory bus). It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

FIFO underruns or overruns are caused when a local DMA request is issued while an ISA bus access is current and the ISA cycle takes longer to complete than the local DMA's tolerable latency. This tolerable latency depends on the FIFO threshold, whether it is in byte or word wide mode and the speed of the DMA clock (BSCLK frequency). Note that this refers to standard ISA cycles NOT those where the CHRDY is deasserted extending the cycle.

#### FIFO THRESHOLD DETECTION

To assure that there is no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the n+1 byte has entered the FIFO; thus, with an 8 byte threshold, the AT/LANTIC Controller issues a request to the buffer RAM when the 9th byte has entered the FIFO, making the effective threshold 9 bytes. For Word Mode, the request is not generated until the n+2 bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to 8 byte threshold), a request to the buffer RAM is issued when the 10th byte has entered the FIFO, making the effective threshold 10 bytes.

#### TOLERABLE LATENCY CALCULATION

To prevent a FIFO **overrun** a byte (or word) of data must be **removed** from the FIFO before the 13th byte is written. Therefore the worst case tolerable latency is the time from the effective threshold being reached to the time the 13th byte is written minus the time taken to load the first byte (or word) of data to the FIFO during a local DMA burst (8 BSCLKs).

$$\begin{aligned} \text{tolerable latency} = & ((\text{overrun} - \text{effective}) \text{ threshold} \\ & \times \text{time to transfer byte on network}) \\ & - \text{time to fill 1st FIFO location} \end{aligned}$$

1

## 4.0 Functional Description (Continued)

For the case of a 4 word threshold using a 20 MHz BSCLK:

$$\begin{aligned} \text{tolerable latency} &= ((13 - 10) \times 800) - (8 \times 50) \text{ ns} \\ &= 2 \mu\text{s} \end{aligned}$$

To prevent a FIFO **underrun** a byte (or word) of data must be **added** from the FIFO before the last byte is removed. Therefore the worst case tolerable latency is the time from the effective threshold being reached to the time the last byte is removed minus the time taken to load the first byte (or word) of data to the FIFO during a local DMA burst (8 BSCLKs).

$$\begin{aligned} \text{tolerable latency} &= (\text{threshold} \\ &\quad \times \text{time to transfer byte on network}) \\ &\quad - \text{time to fill 1st FIFO location} \end{aligned}$$

For the case of a 4 word threshold using a 20 MHz BSCLK:

$$\begin{aligned} \text{tolerable latency} &= (4 \times 800) - (8 \times 50) \text{ ns} \\ &= 2.8 \mu\text{s} \end{aligned}$$

The worst case latency, either overrun or underrun, ultimately limits the overall latency that the AT/LANTIC Controller can tolerate. If the standard ISA cycles are shorter than the worst case latency then no FIFO overruns or underruns will occur.

### BEGINNING OF RECEIVE

At the beginning or reception, the AT/LANTIC Controller stores entire Address field of each incoming packet in the FIFO to determine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes.

Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that a request to access the buffer RAM is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu\text{s}$ . This operation affects the bus latencies at 2 byte and 4 byte thresholds during the first receive request since the FIFO must be filled to 8 bytes (or 4 words) before issuing a request to the buffer RAM.

### END OF RECEIVE

When the end of a packet is detected by the ENDEC module, the AT/LANTIC Controller enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet. The AT/LANTIC Controller holds onto the memory bus for the entire sequence. The longest time that local DMA will hold the buffer RAM occurs when a packet ends just as the AT/LANTIC Controller performs its last FIFO burst. The AT/LANTIC Controller, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completed by writing the header information to the buffer memory. The following steps occur during this sequence.

1. AT/LANTIC Controller issues request to access the RAM because the FIFO threshold has been reached.
2. During the burst, packet ends, resulting in the request being extended.
3. AT/LANTIC Controller flushes remaining bytes from FIFO.
4. AT/LANTIC Controller performs internal processing to prepare for writing the header.
5. AT/LANTIC Controller writes 4-byte (2-word) header
6. AT/LANTIC Controller de-asserts access to the buffer RAM.

### BEGINNING OF TRANSMIT

Before transmitting, the AT/LANTIC Controller performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next request to the buffer RAM is not issued until after the AT/LANTIC Controller actually begins transmitting data, i.e., after SFD.

### READING THE FIFO

If the FIFO is read during normal operation the AT/LANTIC Controller will "hang" the ISA bus by deasserting CHRDY and never asserting it. The FIFO should only be read during loopback diagnostics, when it will operate normally.

### PROTOCOL PLA

The Protocol PLA is responsible for implementing the IEEE 802.3 protocol, including collision recovery with random backoff. The Protocol PLA also formats packets during transmission and strips preamble and synch during reception.

### DMA AND BUFFER CONTROL LOGIC

The DMA and Buffer Control Logic is used to control two 16-bit DMA channels. During reception, the Local DMA stores packets in a receive buffer ring, located in buffer memory. During transmission the Local DMA uses programmed pointer and length registers to transfer a packet from local buffer memory to the FIFO.

A second DMA channel is used when the AT/LANTIC Controller is used in I/O Port mode. This DMA is used as a slave DMA to transfer data between the local buffer memory and the host system. The Local DMA and Remote DMA are internally arbitrated, with the Local DMA channel having highest priority. Both DMA channels use a common external bus clock to generate all required bus timing. External arbitration is performed with a standard bus request, bus acknowledge handshake protocol.

In the shared memory mode the Remote DMA is not used, because in this mode the system has direct read/write access to the buffer RAM.

## 4.0 Functional Description (Continued)

### 4.8 TWISTED PAIR INTERFACE MODULE

The TPI consists of five main logical functions:

- The Receiver/Smart Squelch, responsible for determining when valid data is present on the differential receive inputs (RXI±) and receiving the data.
- The Collision function checks for simultaneous transmission and reception of data on the TXO± and RXI± pins.
- The Link Detector/Generator checks the integrity of the cable connecting the two twisted pair MAUs.
- The Jabber disables the transmitter if it attempts to transmit a longer than legal packet.
- The TX Driver and Pre-emphasis transmits Manchester encoded data to the twisted pair network via the summing resistors and transformer/filter.

### Receiver and Smart Squelch

The AT/LANTIC Controller implements an intelligent receive squelch on the RXI± differential inputs to ensure that impulse noise on the receive inputs will not be mistaken for a valid signal.

The squelch circuitry employs a combination of amplitude and timing measurements to determine the validity of data on the twisted pair inputs. There are two voltage level options for the smart squelch. One mode, 10BASE-T mode, uses levels that meet the 10BASE-T specification. The second mode, reduced squelch mode, uses a lower squelch threshold level, and can be used in longer cable applications where smaller signal levels may be applied. The squelch level mode can be selected in the AT/LANTIC Controller configuration registers.

Figure 14 shows the operation of the smart squelch in 10BASE-T mode.

FIGURE 13. Twisted Pair Interface Module Block Diagram

TL/F/11498-10

## 4.0 Functional Description (Continued)

FIGURE 14. Twisted Pair Squelch Waveform

TL/F/11498-11

The signal at the start of packet is checked by the smart squelch and any pulses not exceeding the squelch level (either positive or negative, depending upon polarity) will be rejected. Once this first squelch level is overcome correctly the opposite squelch level must then be exceeded within 150 ns later. Finally the signal must exceed the original squelch level within a further 150 ns to ensure that the input waveform will not be rejected. The checking procedure results in the loss of typically three bits at the beginning of each packet.

Only after all these conditions have been satisfied will a control signal be generated to indicate to the remainder of the circuitry that valid data is present. At this time the smart squelch circuitry is reset.

In the reduced squelch mode the operation is identical except that the lower squelch levels shown in *Figure 14* are used.

Valid data is considered to be present until either squelch level has not been generated for a time longer than 150 ns, indicating End of Packet. Once good data has been detected the squelch levels are reduced to minimize the effect of noise causing premature End of Packet detection.

### Collision

A collision is detected by the TPI module when the receive and transmit channels are active simultaneously. If the TPI is receiving when a collision is detected it is reported to the controller immediately. If, however, the TPI is transmitting when a collision is detected the collision is not reported until seven bits have been received while in the collision state. This prevents a collision being reported incorrectly due to noise on the network. The signal to the controller remains for the duration of the collision.

Approximately 1  $\mu\text{s}$  after the transmission of each packet a signal called the Signal Quality Error (SQE) consisting of typically 10 cycles of 10 MHz is generated. This 10 MHz signal, also called the Heartbeat, ensures the continued functioning of the collision circuitry.

### Link Detector/Generator

The link generator is a timer circuit that generates a link pulse as defined by the 10 Base-T specification that will be generated by the transmitter section. The pulse which is 100 ns wide is transmitted on the TXO+ output, every 16 ms, in the absence of transmit data.

The pulse is used to check the integrity of the connection to the remote MAU. The link detection circuit checks for valid pulses from the remote MAU and if valid link pulses are not received the link detector will disable the transmit, receive and collision detection functions.

The  $\overline{\text{GDLNK}}$  output can directly drive a LED to show that there is a good twisted pair link. For normal conditions the LED will be on. The link integrity function can be disabled by setting the GDLNK bit of Configuration Register B.

### Jabber

The jabber timer monitors the transmitter and disables the transmission if the transmitter is active for greater than 26 ms. The transmitter is then disabled for the whole time that the Endec module's internal transmit enable is asserted. This signal has to be deasserted for approximately 750 ms (the unjab time) before the Jabber re-enables the transmit outputs.

### Transmitter

The transmitter consists of four signals, the true and complement Manchester encoded data (TXO $\pm$ ) and these signals delayed by 50 ns (TXOd $\pm$ )

These four signals are resistively combined TXO+ with TXOd- and TXO- with TXOd+. This is known as digital pre-emphasis and is required to compensate for the twisted pair cable which acts like a low pass filter causing greater attenuation to the 10 MHz (50 ns) pulses of the Manchester encoded waveform than the 5 MHz (100 ns) pulses.

An example of how these signals are combined is shown in the following diagram.

### 4.0 Functional Description (Continued)

FIGURE 15. Typical Summed Transmit Waveform

TL/F/11498-12

The signal with pre-emphasis shown above is generated by resistively combining TX0+ and TX0d-. This signal along with its complement is passed to the transmit filter.

TL/F/11498-13

### 4.0 Functional Description (Continued)

FIGURE 17. Typical AT/LANTIC Controller LED Connection

FIGURE 18. Encoder/Decode Block Diagram

## 4.0 Functional Description (Continued)

### Status Information

Status information is provided by the AT/LANTIC Controller on the  $\overline{RXLED}$ ,  $\overline{TXLED}$ ,  $\overline{COLED}$  and  $\overline{POL}$  outputs as described in the pin description table. These outputs are suitable for driving status LED's as shown in *Figure 17*. All outputs are open drain.

Recommended integrated Filter-Transformer-choke modules:

1. Pulse Engineering PE65424
2. Valor FL1012 or FL1030.

### 4.9 ENCODER/DECODER (ENDEC) MODULE

The ENDEC consists of four main logical blocks:

- a. The oscillator generates the 10 MHz transmit clock signal for system timing.
- b. The Manchester encoder accepts NRZ data from the controller, encodes the data to Manchester, and transmits the data differentially to the transceiver, through the differential transmit driver.
- c. The Manchester decoder receives Manchester data from the transceiver, converts it to NRZ data and clock pulses, and sends it to the controller.
- d. The collision translator indicates to the controller the presence of a valid 10 MHz collision signal to the PLL.

### Oscillator

The oscillator is controlled by a 20 MHz parallel resonant crystal connected between X1 and X2 or by an external clock on X1. The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock for the controller. The oscillator also provides internal clock signals to the encoding and decoding circuits.

### CRYSTAL OPERATION

If the crystal used with the internal oscillator circuit is not properly selected, the AT/LANTIC Controller oscillator may not reliably start oscillation under all conditions.

If this occurs, it could be deceiving to a designer, since his prototypes may work fine. However, when the designer does qualification testing or starts production, he may encounter a higher than expected board yield loss due to the oscillator not starting. The AT/LANTIC Controller's oscillator circuit clocks the Encoder-Decoder logic. The AT/LANTIC Controller's oscillator also clocks the twisted pair interface block. If the oscillator does not start, the AT/LANTIC Controller will not be able to transmit or receive.

If a crystal is connected to the AT/LANTIC Controller, it is recommended that the circuit shown in *Figure 19* be used and that the components used meet the following:

- Crystal XT1: AT cut parallel resonant crystal  
 Series Resistance:  $\leq 25\Omega$   
 Specified Load Capacitance:  $\leq 20$  pF  
 Accuracy: 0.005% (50 ppm)  
 Typical Load: 50  $\mu$ W–75  $\mu$ W

The recommended values for capacitors C1 and C2 are 26 pF minus the board capacitance on that pin. Therefore if both X1 and X2 have 4 pF of board capacitance, then a 22 pF capacitor should be used.

According to the IEEE 802.3 standard, the entire oscillator circuit (crystal and amplifier) must be accurate to 0.01%. When using a crystal, the X2 pin is not guaranteed to provide a TTL compatible logic output, and should not be used

TL/F/11498-16

**FIGURE 19. Crystal Connection to AT/LANTIC Controller (see text for component values)**

to drive external standard logic. If additional logic needs to be driven, then an external oscillator should be used, as described in the following section.

### OSCILLATOR MODULE OPERATION

If the designer wishes to use a crystal clock oscillator, one that provides the following should be employed:

1. TTL or CMOS output with a 0.01% frequency tolerance
2. 40%–60% duty cycle

The circuit is shown in *Figure 20*. When using a clock oscillator it is recommended that the designer connect the oscillator output to the X1 pin and leave the X2 pin floating.

TL/F/11498-17

**FIGURE 20. AT/LANTIC Controller Connection for Oscillator Module**

### Manchester Encoder and Differential Driver

The differential transmit pair, on the secondary of the employed transformer, drives up to 50 meters of twisted pair AUI cable. These outputs are source followers which require two 270 $\Omega$  pull-down resistors to ground (see *Figure 21*).

The AT/LANTIC Controller allows full-step to be compatible with IEEE 802.3. Transmit+ and Transmit- are equal in the idle state, providing zero differential voltage to operate with transformer coupled loads.

### Manchester Decoder

The decoder consists of a differential receiver and a PLL to separate a Manchester encoded data stream into internal

## 4.0 Functional Description (Continued)

FIGURE 21. Connection from AT/LANTIC Controller's AUI Port to the AUI Connector

TL/F/11498-19

clock signals and data. The differential input must be externally terminated with two 39Ω resistors connected in series if the standard 78Ω transceiver drop cable is used, in thin Ethernet applications, these resistors are optional. To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with levels less than -175 mV. Data becomes valid typically within 6 bit times. The AT/LANTIC Controller may tolerate bit jitter up to 20 ns in the received data. The decoder detects the end of a frame when no more mid-bit transitions are detected.

### Collision Translator

When in AUI Mode, the Ethernet transceiver (DP8392 CT) detects a collision, it generates a 10 MHz signal to the differential collision inputs (CD±) of the AT/LANTIC Controller. When these inputs are detected active, the AT/LANTIC Controller uses this signal to back off its current transmission and reschedule another one.

In this mode the  $\overline{\text{COLED}}$  output will indicate when the CD± lines are active during activity on the network. This means it will correctly indicate any collision on the network, but will not be lit for heartbeat or if there is no cable connected.

The collision differential inputs are terminated the same way as the differential receive inputs. The squelch circuitry is also similar, rejecting pulse levels less than -175 mV.

### PLL V<sub>CC</sub> Power Supply Consideration

The PLL V<sub>CC</sub> pin is the +5V power supply for the phase lock loop (PLL) of the ST-NIC ENDEC unit. Since this is an

analog circuit, excessive noise on the PLL V<sub>CC</sub> pin can affect the performance of the PLL. This noise, if in the 10 kHz-400 kHz range, can reduce the jitter performance of the ENDEC, resulting in missing packets or CRC errors.

If the power supply noise is causing significant packet reception error, a low pass filter could be added to reduce the power supply noise and hence improve the jitter performance. Standard analog design techniques should be utilized when laying out the power supply traces on the board. If the digital power supply is used, it may be desirable to add a one pole RC filter (designed to have a cut-off frequency of 1 kHz) as shown in Figure 4 to improve the jitter performance. The PLL V<sub>CC</sub> only draws 3 mA-4 mA so the voltage across the resistor is less than 90 mV, which will not affect the PLL's operation.

FIGURE 22. Filtering Power Supply Noise

TL/F/11498-18

## 5.0 Register Descriptions

### 5.1 CONFIGURATION REGISTERS

These registers are used to configure the operation of the AT/LANTIC Controller typically after power up. These registers control the configuration of bus interface, setting options like interrupt selection, I/O base address, and other specific modes.

#### MODE CONFIGURATION REGISTER A

To prevent any accidental writes of this register it is "hidden" behind a previously unused register. Register 0AH in the AT/LANTIC Controller's Page 0 of registers was previously reserved on a read. Now Configuration Register A can be read at that address and can be written to by following a read to 0AH with a write to 0AH. If any other AT/LANTIC Controller register accesses take place between the read and the write then the write to 0AH will access the Remote Byte Count Register 0.

## 5.0 Register Descriptions (Continued)

### Mode Configuration Register B

To prevent any accidental writes of this register it is "hidden" behind a previously unused register. Register 0BH in the AT/LANTIC Controller's Page 0 of registers was previously reserved on a read. Now Configuration Register B can be read at that address and can be written to by following a read to 0BH with a write to 0BH. If any other AT/LANTIC Controller register accesses take place between the read and the write then the write to 0BH will access the Remote Byte Count Register 1. **Care should be taken when writing to this register as GDLINK and BE are not simple read/write bits, e.g., the user cannot change the physical layer by reading B, or-ing the returned value with the bits to be set, and writing this value to B. This could inadvertently disable link integrity generation and clear a bus error indication before it was noted.**

7	6	5	4	3	2	1	0
EELoad	BPWR	BE	CHRDY	IO16CON	GDLINK	PHYS1	PHYS0

Bits	Symbols	Function
0-1	PHYS0- PHYS1	<b>PHYSICAL LAYER INTERFACE:</b> These 2 bits determine which type of physical interface the AT/LANTIC Controller is using. The 2 TPI interfaces use twisted pair outputs and inputs, while the other 2 interfaces use the AUI outputs and inputs. In 10BASE5 mode the THIN output pin is driven low, in 10BASE2 mode it is driven high. This can be used to enable the DC-DC converter required by the 10BASE2 specification to provide electrical isolation. The Non spec TPI mode is a twisted pair mode with reduced receive squelch levels. This allows the use of longer cable lengths than specified in the twisted pair specification, or use of cable with higher losses. <ul style="list-style-type: none"> <li>0 0 TPI (10BASE-T Compatible Squelch Level)</li> <li>0 1 Thin Ethernet (10BASE2)</li> <li>1 0 Thick Ethernet (10BASE5) (AUI Port)</li> <li>1 1 TPI (Reduced Squelch Level)</li> </ul>
2	GDLNK	<b>GOOD LINK:</b> When a 1 is written to this bit the link test pulse generation and integrity checking is disabled. When this bit is read it will indicate link status, reflecting the value shown on the LED output. It is 0 if the AT/LANTIC Controller is in AUI mode or if link testing is enabled and the link integrity is bad (i.e., the twisted pair link has been broken). It is 1 if the AT/LANTIC Controller is in TPI mode, link integrity checking is enabled and the link integrity is good (i.e., the twisted pair link has <b>not</b> been broken) or if the link testing is disabled.
3	IO16CON	<b>IO16 CONTROL:</b> When this bit is set high the AT/LANTIC Controller generates $\overline{IO16}$ after $\overline{IORD}$ or $\overline{IOWR}$ go active. If low this output is generated only on address decode.
4	CHRDY	<b>CHRDY FROM IORD OR IOWR OR FROM BALE:</b> When this bit is low the AT/LANTIC Controller will generate CHRDY after the command strobe. When high it will generate it after BALE goes high.
5	BE	<b>BUS ERROR:</b> This bit shows that the AT/LANTIC Controller has detected a bus error condition. This will go high if the AT/LANTIC Controller attempts to insert wait states into a system access and the system terminates the cycle without inserting the wait states. Writing a one to this bit clears it to zero. Writing a zero has no effect.
6	BPWR	<b>BOOT PROM WRITE:</b> When this bit is low no write cycles are generated to the boot PROM.
7	EELoad	<b>EEPROM LOAD:</b> Writing a 1 to this bit enables the EEPROM load algorithm as detailed in Section 4. <b>This bit should not be configured to be high, either from switches or an EEPROM.</b>

## 5.0 Register Descriptions (Continued)

### Hardware Configuration Register C

This register is configured during a RESET and can not be accessed by software.

7	6	5	4	3	2	1	0
SOFEN	CLKSEL	INTMOD	COMP	BPS3	BPS2	BPS1	BPS0

Bits	Symbols	Function																																																																																																
0-3	BPS0-3	<p><b>BOOT PROM SELECT:</b> Selects address at which boot PROM begins and the size. When the system reads within the selected memory area AT/LANTIC Controller reads the data in through MSD0-7 and drives it onto the system data bus. The following are valid addresses and sizes:</p> <table border="1" style="width: 100%; border-collapse: collapse; margin-top: 5px;"> <thead> <tr> <th style="width: 5%;">Bit 3</th> <th style="width: 5%;">Bit 2</th> <th style="width: 5%;">Bit 1</th> <th style="width: 5%;">Bit 0</th> <th style="width: 20%;">Address</th> <th style="width: 40%;">Size (I/O / Shared Mem.)</th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>0</td> <td>X</td> <td>X</td> <td>No boot PROM</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>0</td> <td>0C000H</td> <td>8k/16k</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>1</td> <td>0C400H</td> <td>8k/16k</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>0</td> <td>0C800H</td> <td>8k/16k</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>1</td> <td>0CC00H</td> <td>8k/16k</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>0</td> <td>0D000H</td> <td>8k/16k</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>1</td> <td>0D400H</td> <td>8k/16k</td> </tr> <tr> <td>1</td> <td>0</td> <td>0</td> <td>0</td> <td>0D800H</td> <td>8k/16k</td> </tr> <tr> <td>1</td> <td>0</td> <td>0</td> <td>1</td> <td>0DC00H</td> <td>8k/16k</td> </tr> <tr> <td>1</td> <td>0</td> <td>1</td> <td>0</td> <td>0C000H</td> <td>32k/32k</td> </tr> <tr> <td>1</td> <td>0</td> <td>1</td> <td>1</td> <td>0C800H</td> <td>32k/32k</td> </tr> <tr> <td>1</td> <td>1</td> <td>0</td> <td>0</td> <td>0D000H</td> <td>32k/32k</td> </tr> <tr> <td>1</td> <td>1</td> <td>0</td> <td>1</td> <td>0D800H</td> <td>32k/32k</td> </tr> <tr> <td>1</td> <td>1</td> <td>1</td> <td>0</td> <td>0C000H</td> <td>64k/64k</td> </tr> <tr> <td>1</td> <td>1</td> <td>1</td> <td>1</td> <td>0D000H</td> <td>64k/64k</td> </tr> </tbody> </table>	Bit 3	Bit 2	Bit 1	Bit 0	Address	Size (I/O / Shared Mem.)	0	0	0	X	X	No boot PROM	0	0	1	0	0C000H	8k/16k	0	0	1	1	0C400H	8k/16k	0	1	0	0	0C800H	8k/16k	0	1	0	1	0CC00H	8k/16k	0	1	1	0	0D000H	8k/16k	0	1	1	1	0D400H	8k/16k	1	0	0	0	0D800H	8k/16k	1	0	0	1	0DC00H	8k/16k	1	0	1	0	0C000H	32k/32k	1	0	1	1	0C800H	32k/32k	1	1	0	0	0D000H	32k/32k	1	1	0	1	0D800H	32k/32k	1	1	1	0	0C000H	64k/64k	1	1	1	1	0D000H	64k/64k

4	COMP	<p><b>COMPATIBLE:</b> This bit determines if the AT/LANTIC Controller's memory and I/O maps are compatible with the EtherCard PLUS and Novell boards or if they use the full 64k address space available to the NIC. A low level indicates compatible mode.</p>																																																																																																
5	INTMOD	<p><b>INTERRUPT MODE:</b> When this bit is low the AT/LANTIC Controller is in Direct Drive interrupt mode. When it is high Coded Output interrupt mode is used.</p>																																																																																																
6	CLKSEL	<p><b>CLOCK SELECT:</b> If this bit is low the NIC core is clocked by the 20 MHz. If this bit is high the NIC core is clocked by the signal on the BSCLK pin.</p>																																																																																																
7	SOFEN	<p><b>SOFTWARE ENABLE:</b> If this bit is set low then the user can program configuration registers A and B in software. If this bit is set high then the configuration registers are not accessible. If EECONFIG is high, the configuration from the switches will be overwritten by the configuration from the EEPROM even if this bit is pulled high.</p>																																																																																																

## 5.0 Register Descriptions (Continued)

### 5.2 SHARED MEMORY MODE CONTROL REGISTERS

The following tables describe the functionality of the two control registers and the 8/16 detection registers.

#### Shared Memory AT Detect Register (Read only)

7	6	5	4	3	2	1	0
x	x	x	x	x	x	x	ATDET

Bits	Symbols	Function
D0	ATDET	<b>ATDET:</b> This bit shows the value on the DWID pin and can be read by software to determine whether the AT/LANTIC Controller is operating in an 8- or 16-bit slot. When this bit is read as a 1 the AT/LANTIC Controller is in a 16-bit slot (PC-AT system bus) and when read as a 0 it is in an 8-bit slot.

#### Shared Memory Control Register 1

7	6	5	4	3	2	1	0
RESET	MEME	A18	A17	A16	A15	A14	A13

Bits	Symbols	Function
D0-D5	A13-A18	<b>A13-18:</b> Lower part of the address register used to determine the position of the AT/LANTIC Controller's memory within the system memory map.
D6	MEME	<b>MEMORY ENABLE:</b> Enables external memory accesses when held high. This bit will power up low, so the user must program the base memory address and set this bit high to enable the memory into the system's memory map.
D7	RESET	<b>RESET:</b> Resets NIC core of AT/LANTIC Controller.

#### Shared Memory Control Register 2

7	6	5	4	3	2	1	0
8/16	MEMW	Unused	LA23	LA22	LA21	LA20	LA19

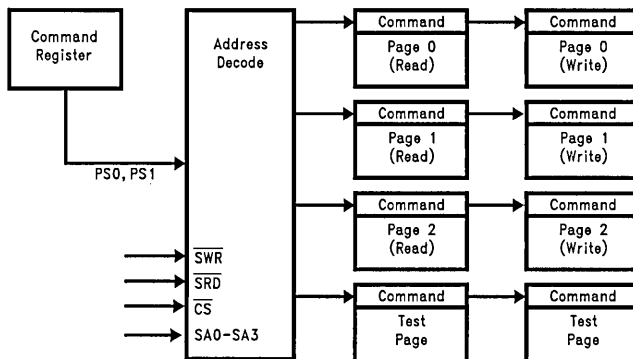

Bits	Symbols	Function
D0-D4	LA19-LA23	<b>LA19-23:</b> Upper part of the address register used to determine the position of the AT/LANTIC Controller's memory within the system memory map.
D5		<b>UNUSED</b>
D6	MEMW	<b>MEMORY WIDTH:</b> Sets width of external memory. When set low external memory is accessed as byte wide, so only 8 kbytes of memory are available. When set high external memory is accessed as word wide, so 16 kbytes are available. In non-compatible mode up to 64 kbytes of external memory is allowed when this bit is set high, or 32 kbytes when low. When bit 7 is set high this bit must also be set high.
D7	8/16	<b>8/16-BIT:</b> Allows 16-bit system accesses to external memory when set high. When low only 8-bit accesses are allowed. When high the generation of the M16 output is allowed.

## 5.0 Register Descriptions (Continued)

### 5.3 NIC CORE REGISTERS

All registers are 8-bit wide and mapped into two pages which are selected in the Command Register (PS0, PS1). Pins SA0–SA3 are used to address registers within each page. Page 0 registers are those registers which are commonly accessed during AT/LANTIC Controller operation while page 1 registers are used primarily for initialization. The registers are partitioned to avoid having to perform two write/read cycles to access commonly used registers.

Page 3 should never be modified.

## 5.0 Register Descriptions (Continued)

### COMMAND REGISTER (CR) 00H (READ/WRITE)

The Command Register is used to initiate transmissions, enable or disable Remote DMA operations and to select register pages. To issue a command the microprocessor sets the corresponding bit(s) (RD2, RD1, RD0, TXP). Further commands may be overlapped, but with the following rules: (1) If a transmit command overlaps with a remote DMA operation, bits RD0, RD1, and RD2 must be maintained for the remote DMA command when setting the TXP bit. Note, if a remote DMA command is re-issued when giving the transmit command, the DMA will complete immediately if the remote byte count register has not been re-initialized. (2) If a remote DMA operation overlaps a transmission, RD0, RD1, and RD2 may be written with the desired values and a "0" written to the TXP bit. Writing a "0" to this bit has no effect. (3) A remote write DMA may not overlap remote read operation or visa versa. Either of these operations must either complete or be aborted before the other operation may start. Bits PS1, PS0, RD2, and STP may be set any time.

7	6	5	4	3	2	1	0
PS1	PS0	RD2	RD1	RD0	TXP	STA	STP

Bits	Symbols	Description																								
D0	STP	<b>STOP:</b> Software reset command, takes the controller offline, no packets will be received or transmitted. Any reception or transmission in progress will continue to completion before entering the reset state. To exit this state, the STP bit must be reset and the STA bit must be set high. To perform a software reset, this bit should be set high. The software reset has executed only when indicated by the RST bit in the ISR being set to at 1. STP powers up high. <b>Note:</b> If the AT/LANTIC Controller has previously been in start mode and the STP is set, both the STP and STA bits will remain set.																								
D1	STA	<b>START:</b> This bit is used to activate the NIC Core after either power up, or when the NIC Core has been placed in a reset mode by software command or error. STA powers up low.																								
D2	TXP	<b>TRANSMIT PACKET:</b> This bit must be set to initiate transmission of a packet. TXP is internally reset either after the transmission is completed or aborted. This bit should be set only after the Transmit Byte Count and Transmit Page Start registers have been programmed.																								
D3–D5	RD0–RD2	<b>REMOTE DMA COMMAND:</b> These three encoded bits control operation of the Remote DMA channel. RD2 can be set to abort any Remote DMA command in progress. The Remote Byte Count Registers should be cleared when a Remote DMA has been aborted. The Remote Start Addresses are not restored to the starting address if the Remote DMA is aborted. <table border="1"> <thead> <tr> <th>RD2</th> <th>RD1</th> <th>RD0</th> <th></th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>0</td> <td>Not Allowed</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>Remote Read</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>Remote Write</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>Send Packet</td> </tr> <tr> <td>1</td> <td>X</td> <td>X</td> <td>Abort/Complete Remote DMA (Note 1)</td> </tr> </tbody> </table>	RD2	RD1	RD0		0	0	0	Not Allowed	0	0	1	Remote Read	0	1	0	Remote Write	0	1	1	Send Packet	1	X	X	Abort/Complete Remote DMA (Note 1)
RD2	RD1	RD0																								
0	0	0	Not Allowed																							
0	0	1	Remote Read																							
0	1	0	Remote Write																							
0	1	1	Send Packet																							
1	X	X	Abort/Complete Remote DMA (Note 1)																							
D6, D7	PS0, PS1	<b>PAGE SELECT:</b> These two encoded bits select which register page is to be accessed with addresses RA0–3. <table border="1"> <thead> <tr> <th>PS1</th> <th>PS0</th> <th></th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>Register Page 0</td> </tr> <tr> <td>0</td> <td>1</td> <td>Register Page 1</td> </tr> <tr> <td>1</td> <td>0</td> <td>Register Page 2</td> </tr> <tr> <td>1</td> <td>1</td> <td>Reserved</td> </tr> </tbody> </table>	PS1	PS0		0	0	Register Page 0	0	1	Register Page 1	1	0	Register Page 2	1	1	Reserved									
PS1	PS0																									
0	0	Register Page 0																								
0	1	Register Page 1																								
1	0	Register Page 2																								
1	1	Reserved																								

**Note 1:** If a remote DMA operation is aborted and the remote byte count has not decremented to zero, the data transfer port should be read, for a remote read or send packet, or written to, for a remote write. This is required to ensure future correct operation.

## 5.0 Register Descriptions (Continued)

### INTERRUPT STATUS REGISTER (ISR) 07H (READ/WRITE)

This register is accessed by the host processor to determine the cause of an interrupt. Any interrupt can be masked in the Interrupt Mask Register (IMR). Individual interrupt bits are cleared by writing a "1" into the corresponding bit of the ISR. The valid interrupt output is active as long as any unmasked signal is set, and will not go low until all unmasked bits in this register have been cleared. The ISR must be cleared after power up by writing it with all 1's.

7	6	5	4	3	2	1	0
RST	RDC	CNT	OVW	TXE	RXE	PTX	PRX

Bits	Symbols	Description
D0	PRX	<b>PACKET RECEIVED:</b> Indicates packet received with no errors.
D1	PTX	<b>PACKET TRANSMITTED:</b> Indicates packet transmitted with no errors.
D2	RXE	<b>RECEIVE ERROR:</b> Indicates that a packet was received with one or more of the following errors: —CRC Error —Frame Alignment Error —FIFO Overrun —Missed Packet
D3	TXE	<b>TRANSMIT ERROR:</b> Set when packet transmitted with one or more of the following errors: —Excessive Collisions —FIFO Underrun
D4	OVW	<b>OVERWRITE WARNING:</b> Set when receive buffer ring storage resources have been exhausted. (Local DMA has reached Boundary Pointer)
D5	CNT	<b>COUNTER OVERFLOW:</b> Set when MSB of one or more of the Network Tally Counters has been set.
D6	RDC	<b>REMOTE DMA COMPLETE:</b> Set when Remote DMA operation has been completed.
D7	RST	<b>RESET STATUS:</b> Set when AT/LANTIC Controller enters reset state and cleared when a Start Command is issued to the CR. This bit is also set when a Receive Buffer Ring overflow occurs and is cleared when one or more packets have been removed from the ring. Writing to this bit has no effect. <b>Note:</b> This bit does not generate an interrupt, it is merely a status indicator.

## 5.0 Register Descriptions (Continued)

### INTERRUPT MASK REGISTER (IMR) 0FH (WRITE)

The Interrupt Mask Register is used to mask interrupts. Each interrupt mask bit corresponds to a bit in the Interrupt Status Register (ISR). If an interrupt mask bit is set, an interrupt will be issued whenever the corresponding bit in the ISR is set. If any bit in the IMR is set low, an interrupt will not occur when the bit in the ISR is set. **The IMR powers up all zeros.**

7	6	5	4	3	2	1	0
—	RDCE	CNTE	OVWE	TXEE	RXEE	PTXE	PRXE

Bits	Symbols	Description
D0	PRXE	<b>PACKET RECEIVED INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received
D1	PTXE	<b>PACKET TRANSMITTED INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet is transmitted
D2	RXEE	<b>RECEIVE ERROR INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received with error
D3	TXEE	<b>TRANSMIT ERROR INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet transmission results in error
D4	OVWE	<b>OVERWRITE WARNING INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when Buffer Management Logic lacks sufficient buffers to store incoming packet
D5	CNTE	<b>COUNTER OVERFLOW INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when MSB of one or more of the Network Statistics counters has been set
D6	RDCE	<b>DMA COMPLETE INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when Remote DMA transfer has been completed
D7	reserved	reserved

## 5.0 Register Descriptions (Continued)

### DATA CONFIGURATION REGISTER (DCR) 0EH (WRITE)

This Register is used to program the AT/LANTIC Controller for 8- or 16-bit memory interface, select byte ordering in 16-bit applications and establish FIFO thresholds. **The DCR must be initialized prior to loading the Remote Byte Count Registers. LAS is set on power up.**

7	6	5	4	3	2	1	0
—	FT1	FT0	ARM	LS	LAS	BOS	WTS

Bits	Symbols	Description																								
D0	WTS	<p><b>WORD TRANSFER SELECT</b>                      0: Selects byte-wide DMA transfers                      1: Selects word-wide DMA transfers                      ;WTS establishes byte or word transfers for both Remote and Local DMA transfers  <b>Note:</b> When word-wide mode is selected, up to 32k words are addressable; A0 remains low.</p>																								
D1	BOS	<p><b>BYTE ORDER SELECT</b>                      0: MS byte placed on AD15–AD8 and LS byte on AD7–AD0. (32xxx, 80x86)                      1: MS byte placed on AD7–AD0 and LS byte on AD15–AD8. (680x0)                      ;Ignored when WTS is low</p>																								
D2	LAS	<p><b>LONG ADDRESS SELECT</b>                      0: Dual 16-bit DMA mode                      1: Single 32-bit DMA mode                        ;When LAS is high, the contents of the Remote DMA registers RSAR0, 1 are issued as A16–A31 Power up high</p>																								
D3	LS	<p><b>LOOPBACK SELECT</b>                      0: Loopback mode selected. Bits D1 and D2 of the TCR must also be programmed for Loopback operation                      1: Normal Operation</p>																								
D4	ARM	<p><b>AUTO-INITIALIZE REMOTE</b>                      0: Send Command not executed, all packets removed from Buffer Ring under program control                      1: Send Command executed, Remote DMA auto-initialized to remove packets from Buffer Ring  <b>Note:</b> Send Command cannot be used with 680x0 byte processors.</p>																								
D5 and D6	FT0 and FT1	<p><b>FIFO THRESHOLD SELECT:</b> Encoded FIFO threshold. Establishes point at which the memory bus is requested when filling or emptying the FIFO. During reception, the FIFO threshold indicates the number of bytes (or words) the FIFO has filled serially from the network before the FIFO is emptied onto the memory bus.  <b>Note:</b> FIFO threshold setting determines the DMA burst length.</p> <table border="1" style="margin-left: 20px;"> <thead> <tr> <th colspan="4">Receive Thresholds</th> </tr> <tr> <th>FT1</th> <th>FT0</th> <th>Word Wide</th> <th>Byte Wide</th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>1 Word</td> <td>2 Bytes</td> </tr> <tr> <td>0</td> <td>1</td> <td>2 Words</td> <td>4 Bytes</td> </tr> <tr> <td>1</td> <td>0</td> <td>4 Words</td> <td>8 Bytes</td> </tr> <tr> <td>1</td> <td>1</td> <td>6 Words</td> <td>12 Bytes</td> </tr> </tbody> </table> <p>During transmission, the FIFO threshold indicates the number of bytes (or words) the FIFO has filled from the Local DMA before being transferred to the memory. Thus, the transmission threshold is 13 bytes less the received threshold.</p>	Receive Thresholds				FT1	FT0	Word Wide	Byte Wide	0	0	1 Word	2 Bytes	0	1	2 Words	4 Bytes	1	0	4 Words	8 Bytes	1	1	6 Words	12 Bytes

Mode 2	1	0	Internal ENDEC Module Loopback (LPBK = 1)																			
Mode 3	1	1	External Loopback (LPBK = 0)																			
D3	ATD	<b>AUTO TRANSMIT DISABLE:</b> This bit allows another station to disable the AT/LANTIC Controller's transmitter by transmission of a particular multicast packet. The transmitter can be re-enabled by resetting this bit or by reception of a second particular multicast packet. 0: Normal Operation 1: Reception of multicast address hashing to bit 62 disables transmitter, reception of multicast address hashing to bit 63 enables transmitter.																				
D4	OFST	<b>COLLISION OFFSET ENABLE:</b> This bit modifies the backoff algorithm to allow prioritization of nodes. 0: Backoff Logic implements normal algorithm. 1: Forces Backoff algorithm modification to 0 to $2^{\min(3 + n, 10)}$ slot times for first three collisions, then follows standard backoff. (For the first three collisions, the station has higher average backoff delay making a low priority mode.)																				
D5	reserved	reserved																				
D6	reserved	reserved																				
D7	reserved	reserved																				

## 5.0 Register Descriptions (Continued)

### TRANSMIT STATUS REGISTER (TSR) 04H (READ)

This register records events that occur on the media during transmission of a packet. It is cleared when the next transmission is initiated by the host. All bits remain low unless the event that corresponds to a particular bit occurs during transmission. Each transmission should be followed by a read of this register. The contents of this register are not specified until after the first transmission.

7	6	5	4	3	2	1	0
OWC	CDH	FU	CRS	ABT	COL	—	PTX

Bits	Symbols	Description
D0	PTX	<b>PACKET TRANSMITTED:</b> Indicates transmission without error. (No excessive collisions or FIFO underrun)(ABT = "0", FU = "0")
D1	reserved	reserved
D2	COL	<b>TRANSMIT COLLIDED:</b> Indicates that the transmission collided at least once with another station on the network. The number of collisions is recorded in the Number of Collisions Registers (NCR).
D3	ABT	<b>TRANSMIT ABORTED:</b> Indicates the AT/LANTIC Controller aborted transmission because of excessive collisions. (Total number of transmissions including original transmission attempt equals 16.)
D4	CRS	<b>CARRIER SENSE LOST:</b> This bit is set when carrier is lost during transmission of the packet. Transmission is not aborted on loss of carrier.
D5	FU	<b>FIFO UNDERRUN:</b> If the AT/LANTIC Controller cannot gain access of the bus before the FIFO empties, this bit is set. Transmission of the packet will be aborted.
D6	CDH	<b>CD HEARTBEAT:</b> Failure of the transceiver to transmit a collision signal after transmission of a packet will set this bit. The Collision Detect (CD) heartbeat signal must commence during the first 6.4 $\mu$ s of the Interframe Gap following a transmission. In certain collisions, the CD Heartbeat bit will be set even though the transceiver is not performing the CD heartbeat test.
D7	OWC	<b>OUT OF WINDOW COLLISION:</b> Indicates that a collision occurred after a slot time (51.2 $\mu$ s). Transmissions rescheduled as in normal collisions.

## 5.0 Register Descriptions (Continued)

### RECEIVE CONFIGURATION REGISTER (RCR) 0CH (WRITE)

This register determines operation of the AT/LANTIC Controller during reception of a packet and is used to program what types of packets to accept.

7	6	5	4	3	2	1	0
—	—	MON	PRO	AM	AB	AR	SEP

Bits	Symbols	Description
D0	SEP	<b>SAVE ERRORED PACKETS</b> 0: Packets with receive errors are rejected. 1: Packets with receive errors are accepted. Receive errors are CRC and Frame Alignment errors.
D1	AR	<b>ACCEPT RUNT PACKETS:</b> This bit allows the receiver to accept packets that are smaller than 64 bytes. The packet must be at least 8 bytes long to be accepted as a runt. 0: Packets with fewer than 64 bytes rejected. 1: Packets with fewer than 64 bytes accepted.
D2	AB	<b>ACCEPT BROADCAST:</b> Enables the receiver to accept a packet with an all 1's destination address. 0: Packets with broadcast destination address rejected. 1: Packets with broadcast destination address accepted.
D3	AM	<b>ACCEPT MULTICAST:</b> Enables the receiver to accept a packet with a multicast address, all multicast addresses must pass the hashing array. 0: Packets with multicast destination address not checked. 1: Packets with multicast destination address checked.
D4	PRO	<b>PROMISCUOUS PHYSICAL:</b> Enables the receiver to accept all packets with a physical address. 0: Physical address of node must match the station address programmed in PAR0–PAR5. 1: All packets with physical addresses accepted.
D5	reserved	reserved (program to 0)
D6	reserved	reserved
D7	reserved	reserved

**Note:** D2 and D3 are "OR'd" together, i.e., if D2 and D3 are set the AT/LANTIC Controller will accept broadcast and multicast addresses as well as its own physical address. To establish full promiscuous mode, bits D2, D3, and D4 should be set. In addition the multicast hashing array must be set to all 1's in order to accept all multicast addresses.

## 5.0 Register Descriptions (Continued)

### RECEIVE STATUS REGISTER (RSR) OCH (READ)

This register records status of the received packet, including information on errors and the type of address match, either physical or multicast. The contents of this register are written to buffer memory by the DMA after reception of a good packet. If packets with errors are to be saved the receive status is written to memory at the head of the erroneous packet if an erroneous packet is received. If packets with errors are to be rejected the RSR will not be written to memory. The contents will be cleared when the next packet arrives. CRC errors, Frame Alignment errors and missed packets are counted internally by the AT/LAN-TIC Controller which relinquishes the Host from reading the RSR in real time to record errors for Network Management Functions. The contents of this register are not specified until after the first reception.

7	6	5	4	3	2	1	0
DFR	DIS	PHY	MPA	FO	FAE	CRC	PRX

Bits	Symbols	Description
D0	PRX	<b>PACKET RECEIVED INTACT:</b> Indicates packet received without error. (Bits CRC, FAE, FO, and MPA are zero for the received packet.)
D1	CRC	<b>CRC ERROR:</b> Indicates packet received with CRC error. Increments Tally Counter (CNTR1). This bit will also be set for Frame Alignment errors.
D2	FAE	<b>FRAME ALIGNMENT ERROR:</b> Indicates that the incoming packet did not end on a byte boundary and the CRC did not match at last byte boundary. Increments Tally Counter (CNTR0).
D3	FO	<b>FIFO OVERRUN:</b> This bit is set when the FIFO is not serviced causing overflow during reception. Reception of the packet will be aborted.
D4	MPA	<b>MISSED PACKET:</b> Set when packet intended for node cannot be accepted by SNIC because of a lack of receive buffers or if the controller is in monitor mode and did not buffer the packet to memory. Increments Tally Counter (CNTR2).
D5	PHY	<b>PHYSICAL/MULTICAST ADDRESS:</b> Indicates whether received packet had a physical or multicast address type. 0: Physical Address Match 1: Multicast/Broadcast Address Match
D6	DIS	<b>RECEIVER DISABLED:</b> Set when receiver disabled by entering Monitor mode. Reset when receiver is re-enabled when exiting Monitor mode.
D7	DFR	<b>DEFERRING:</b> Set when internal Carrier Sense or Collision signals are generated in the ENDEC module. If the transceiver has asserted the CD line as a result of the jabber, this bit will stay set indicating the jabber condition.

**Note:** Following coding applies to CRC and FAE bits

FAE	CRC	Type of Error
0	0	No Error (Good CRC and <6 Dribble Bits)
0	1	CRC Error
1	0	Illegal, will not occur
1	1	Frame Alignment Error and CRC Error

## 5.0 Register Descriptions (Continued)

FIGURE 24. DMA Register

TL/F11498-21

**Note:** In the figure above, registers are shown as 8- or 16-bits wide. Although some registers are 16-bit internal registers, all registers are accessed as 8-bit registers. Thus the 16-bit Transmit Byte Count Register is broken into two 8-bit registers, TBCR0 and TBCR1. Also TPSR, PSTART, PSTOP, CURR and BRNY only check or control the upper 8 bits of address information on the bus. Thus they are shifted to positions 15-8 in the diagram above.

### 5.4 DP8390 Core DMA Registers

The DMA Registers are partitioned into groups; Transmit, Receive and Remote DMA Registers. The Transmit registers are used to initialize the Local DMA Channel for transmission of packets while the Receive Registers are used to initialize the Local DMA Channel for packet Reception. The Page Stop, Page Start, Current and Boundary Registers are used by the Buffer Management Logic to supervise the Receive Buffer Ring. The Remote DMA Registers are used to initialize the Remote DMA.

#### Transmit DMA Registers

##### TRANSMIT PAGE START REGISTER (TPSR)

This register points to the assembled packet to be transmitted. Only the eight higher order addresses are specified since all transmit packets are assembled on 256-byte page boundaries. The bit assignment is shown below. The values placed in bits D7-D0 will be used to initialize the higher order address (A8-A15) of the Local DMA for transmission. The lower order bits (A7-A0) are initialized to zero.

#### Bit Assignment

	7	6	5	4	3	2	1	0
TPSR	A15	A14	A13	A12	A11	A10	A9	A8

(A7-A0 Initialized to 0)

##### TRANSMIT BYTE COUNT REGISTER 0,1 (TBCR0, TBCR1)

These two registers indicate the length of the packet to be transmitted in bytes. The count must include the number of bytes in the source, destination, length and data fields. The maximum number of transmit bytes allowed is 64 kbytes. The AT/LANTIC Controller will not truncate transmissions longer than 1500 bytes. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
TBCR1	L15	L14	L13	L12	L11	L10	L9	L8

	7	6	5	4	3	2	1	0
TBCR0	L7	L6	L5	L4	L3	L2	L1	L0

#### Local DMA Receive Registers

##### PAGE START STOP REGISTERS (PSTART, PSTOP)

The Page Start and Page Stop Registers program the starting and stopping address of the Receive Buffer Ring. Since

## 5.0 Register Descriptions (Continued)

the AT/LANTIC Controller uses fixed 256-byte buffers aligned on page boundaries only the upper eight bits of the start and stop address are specified.

PSTART, PSTOP bit assignment

	7	6	5	4	3	2	1	0
PSTART	A15	A14	A13	A12	A11	A10	A9	A8
PSTOP	A15	A14	A13	A12	A11	A10	A9	A8

### BOUNDARY (BNRY) REGISTER

This register is used to prevent overflow of the Receive Buffer Ring. Buffer management compares the contents of this register to the next buffer address when linking buffers together. If the contents of this register match the next buffer address the Local DMA operation is aborted.

	7	6	5	4	3	2	1	0
BNRY	A15	A14	A13	A12	A11	A10	A9	A8

### CURRENT PAGE REGISTER (CURR)

This register is used internally by the Buffer Management Logic as a backup register for reception. CURR contains the address of the first buffer to be used for a packet reception and is used to restore DMA pointers in the event of receive errors. This register is initialized to the same value as PSTART and should not be written to again unless the controller is Reset.

	7	6	5	4	3	2	1	0
CURR	A15	A14	A13	A12	A11	A10	A9	A8

### CURRENT LOCAL DMA REGISTER 0,1 (CLDA0,1)

These two registers can be accessed to determine the current Local DMA Address.

	7	6	5	4	3	2	1	0
CLDA1	A15	A14	A13	A12	A11	A10	A9	A8
	7	6	5	4	3	2	1	0
CLDA0	A7	A6	A5	A4	A3	A2	A1	A0

### Remote DMA Registers

#### REMOTE START ADDRESS REGISTERS (RSAR0,1)

Remote DMA operations are programmed via the Remote Start Address (RSAR0,1) and Remote Byte Count (RBCR0,1) registers. The Remote Start Address is used to point to the start of the block of data to be transferred and the Remote Byte Count is used to indicate the length of the block (in bytes).

	7	6	5	4	3	2	1	0
RSAR1	A15	A14	A13	A12	A11	A10	A9	A8
	7	6	5	4	3	2	1	0
RSAR0	A7	A6	A5	A4	A3	A2	A1	A0

#### REMOTE BYTE COUNT REGISTERS (RBCR0,1)

	7	6	5	4	3	2	1	0
RBCR1	A15	A14	A13	A12	A11	A10	A9	A8
	7	6	5	4	3	2	1	0
RBCR0	A7	A6	A5	A4	A3	A2	A1	A0

#### Notes:

RSAR0 programs the start address bits A0–A7.

RSAR1 programs the start address bits A8–A15.

Address incremented by two for word transfers, and by one for byte transfers. Byte count decremented by two for word transfers and by one for byte transfers.

RBCR0 programs LSB byte count.

RBCR1 programs MSB byte count.

#### CURRENT REMOTE DMA ADDRESS (CRDA0, CRDA1)

The Current Remote DMA Registers contain the current address of the Remote DMA. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
CRDA1	A15	A14	A13	A12	A11	A10	A9	A8
	7	6	5	4	3	2	1	0
CRDA0	A7	A6	A5	A4	A3	A2	A1	A0

#### Physical Address Registers (PAR0–PAR5)

The physical address registers are used to compare the destination address of incoming packets for rejecting or accepting packets. Comparisons are performed on a byte-wide basis. The bit assignment shown below relates the sequence in PAR0–PAR5 to the bit sequence of the received packet.

	D7	D6	D5	D4	D3	D2	D1	D0
PAR0	DA7	DA6	DA5	DA4	DA3	DA2	DA1	DA0
PAR1	DA15	DA14	DA13	DA12	DA11	DA10	DA9	DA8
PAR2	DA23	DA22	DA21	DA20	DA19	DA18	DA17	DA16
PAR3	DA31	DA30	DA29	DA28	DA27	DA26	DA25	DA24
PAR4	DA39	DA38	DA37	DA36	DA35	DA34	DA33	DA32
PAR5	DA47	DA46	DA45	DA44	DA43	DA42	DA41	DA40

	Destination Address					Source			
P/S	DA0	DA1	DA2	DA3	...	DA46	DA47	SA0	...

Note: P/S = Preamble, Sync  
DA0 = Physical/Multicast Bit

#### Multicast Address Registers (MAR0–MAR7)

The multicast address registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 most significant bits of the CRC generator are latched. These 6 bits are then decoded by a 1 of 64 decode to index a unique filter bit (FB0–63) in the multicast address registers. If the filter bit selected is set, the multicast packet is accepted. The system designer would use a program to determine which filter

## 5.0 Register Descriptions (Continued)

bits to set in the multicast registers. All multicast filter bits that correspond to multicast address accepted by the node are then set to one. To accept all multicast packets all of the registers are set to all ones.

**Note:** Although the hashing algorithm does not guarantee perfect filtering of multicast address, it will perfectly filter up to 64 multicast addresses if these addresses are chosen to map into unique locations in the multicast filter.

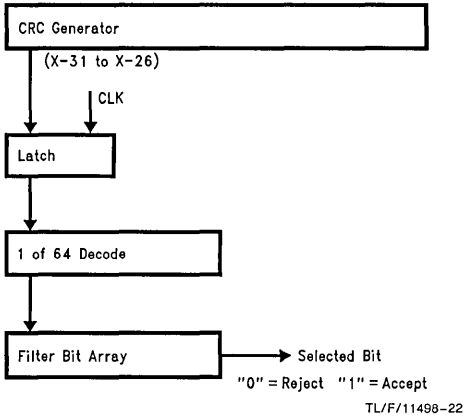

FIGURE 25. Multicast Addressing

## 6.0 Operation of AT/LANTIC Controller

This section details the operation of the AT/LANTIC Controller. The operations discussed are packet reception and transmission, bus operations, and loopback diagnostics.

### 6.1 TRANSMIT/RECEIVE PACKET ENCAPSULATION/DECAPSULATION

A standard IEEE 802.3 packet consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data, and Frame Check Sequence (FCS). The typical format is shown in the figure following. The packets are Manchester encoded and decoded by the ENDEC module and transferred serially to the NIC module using NRZ data with a clock. All fields are of fixed length except for the data field. The AT/LANTIC Controller generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

FIGURE 26. Ethernet Packet

### PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted each packet contains 62 bits of alternating 1,0 preamble. Some of this preamble will be lost as the packet travels through the network. The preamble field is stripped by the NIC module. Byte alignment is performed with the Start of Frame Delimiter (SFD) pattern which consists of two consecutive 1's. The AT/LANTIC Controller does not treat the SFD pattern as a byte, it detects only the two-bit pattern. This allows any preceding preamble within the SFD to be used for phase locking.

### Destination Address

The destination address indicates the destination of the packet on the network and is used to filter unwanted packets from reaching a node. There are three types of address formats supported by the AT/LANTIC: physical, multicast and broadcast. The physical address is a unique address that corresponds only to a single node. All physical addresses have an MSB of "0". These addresses are compared to the internally stored physical address registers. Each bit in the destination address must match in order for the AT/LANTIC Controller to accept the packet. Multicast addresses begin with an MSB of "1". The AT/LANTIC Controller filters multicast addresses using a standard hashing algorithm that maps all multicast addresses into a 6-bit value. This 6-bit value indexes a 64-bit array that filters the value. If the address consists of all 1's it is a broadcast address, indicating that the packet is intended for all nodes. A promiscuous mode allows reception of all packets: the destination address is not required to match any filters. Physical, broadcast, multicast, and promiscuous address modes can be selected.

### Source Address

The source address is the physical address of the node that sent the packet. Source addresses cannot be multicast or broadcast addresses. This field is simply passed to buffer memory.

### Length Field

The 2-byte length field indicates the number of bytes that are contained in the data field of the packet. This field is not interpreted by the AT/LANTIC Controller.

### Data Field

The data field consists of anywhere from 46 to 1500 bytes. Messages longer than 1500 bytes need to be broken into multiple packets. Messages shorter than 46 bytes will require appending a pad to bring the data field to the minimum length of 46 bytes. If the data field is padded, the number of valid data bytes is indicated in the length field. **The AT/LANTIC Controller does not strip or append pad bytes for short packets, or check for oversize packets.**

### FCS Field

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of errors when a packet is received. During reception, error free packets result in a specific pattern in

## 6.0 Operation of AT/LANTIC Controller (Continued)

the CRC generator. Packets with improper CRC will be rejected. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X + 1$ ) polynomial is used for the CRC calculations.

### 6.2 BUFFER MEMORY ACCESS CONTROL (DMA)

The buffer memory control capabilities of the AT/LANTIC Controller greatly simplify the use of the AT/LANTIC Controller in typical configurations. The local DMA channel transfers data between the FIFO and memory. On transmission, the packet is DMA'd from memory to the FIFO in bursts. Should a collision occur (up to 15 times), the packet is re-transmitted with no processor intervention. On reception, packets are moved via DMA from the FIFO to the receive buffer ring (as explained below).

A Remote DMA channel is also provided on the AT/LANTIC Controller to accomplish transfers between a buffer memory and an internal Data Port when using the AT/LANTIC Controller in I/O Mode. This Remote DMA channel is not used when the AT/LANTIC Controller is used in a shared Memory mode. In this second mode the buffer memory is dual ported, and directly mapped into the system memory. In this mode the system CPU directly accesses the RAM under software control to transfer packet data.

The following sections describe the operation of the Local DMA channel for packet reception which is used in both modes. For Shared Memory mode the description of the Remote DMA does not apply.

For reference an example configuration using the AT/LANTIC Controller is shown in *Figure 27*.

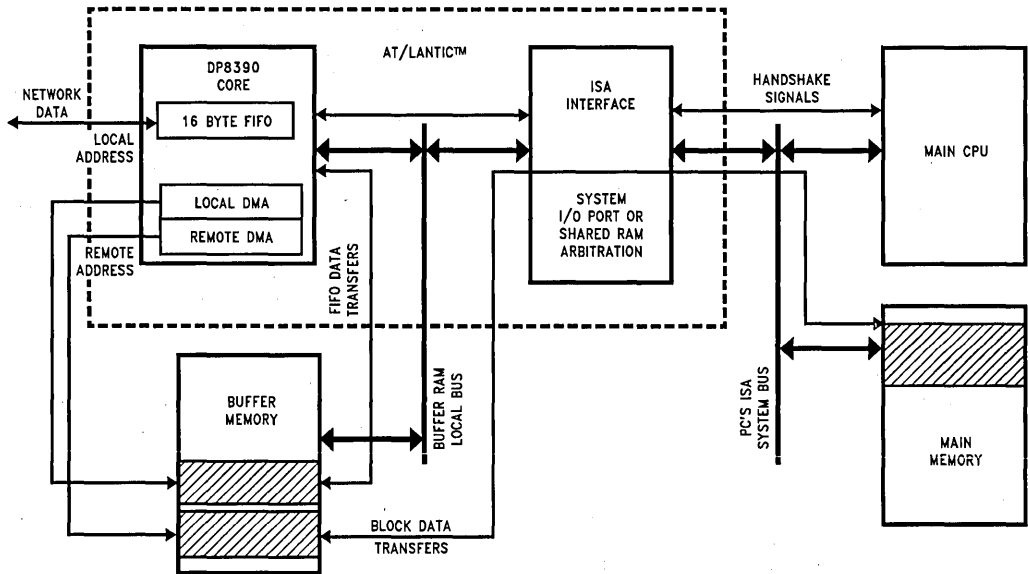

FIGURE 27. AT/LANTIC Controller Bus Architecture

TL/F/11498-24

## 6.0 Operation of AT/LANTIC Controller (Continued)

FIGURE 28. AT/LANTIC Controller Receiver Buffer Ring

### 6.3 PACKET RECEPTION

The Local DMA receive channel uses a Buffer Ring Structure comprised of a series of contiguous fixed length 256 byte (128 word) buffers for storage of received packets. The location of the Receive Buffer Ring is programmed in two registers, a Page Start and a Page Stop Register. Ethernet packets consist of a distribution of shorter link control packets and longer data packets, the 256 byte buffer length provides a good compromise between short packets and longer packets to most efficiently use memory. In addition these buffers provide memory resources for storage of back-to-back packets in loaded networks. The assignment of buffers for storing packets is controlled by Buffer Management Logic in the AT/LANTIC Controller. The Buffer Management Logic provides three basic functions: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of buffer pages that have been read by the host.

At initialization, a portion of the 64 kbyte (or 32 kword) address space is reserved for the receive buffer ring. Two eight bit registers, the Page Start Address Register (PSTART) and the Page Stop Address Register (PSTOP) define the physical boundaries of where the buffers reside. The AT/LANTIC Controller treats the list of buffers as a logical ring; whenever the DMA address reaches the Page Stop Address, the DMA is reset to the Page Start Address.

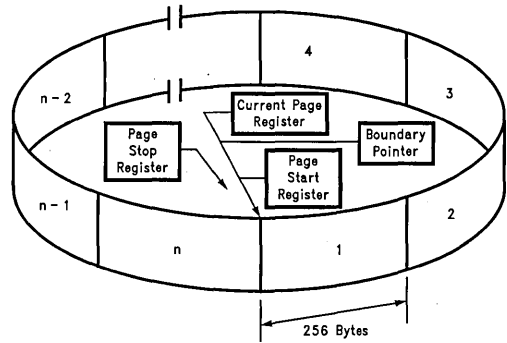

FIGURE 29. Buffer Ring at Initialization

#### Initialization of the Buffer Ring

Two static registers and two working registers control the operation of the Buffer Ring. These are the Page Start Register, Page Stop Register (both described previously), the Current Page Register and the Boundary Pointer Register. The Current Page Register points to the first buffer used to store a packet and is used to restore the DMA for writing status to the Buffer Ring or for restoring the DMA address in the event of a Runt packet, a CRC, or Frame Alignment error. The Boundary Register points to the first packet in the

1

## 6.0 Operation of AT/LANTIC Controller (Continued)

Ring not yet read by the host. If the local DMA address ever reaches the Boundary, reception is aborted. The Boundary Pointer is also used to initialize the Remote DMA for removing a packet and is advanced when a packet is removed. A simple analogy to remember the function of these registers is that the Current Page Register acts as a Write Pointer and the Boundary Pointer acts as a Read Pointer.

**Note 1:** At initialization, the Page Start Register value should be loaded into both the Current Page Register and the Boundary Pointer Register.

**Note 2:** The Page Start Register must not be initialized to 00H.

### Beginning of Reception

When the first packet begins arriving the AT/LANTIC Controller begins storing the packet at the location pointed to by the Current Page Register. An offset of 4 bytes is saved in this first buffer to allow room for storing receive status corresponding to this packet.

TL/F/11498-27

**FIGURE 30. Received Packet Enters the Buffer Pages**

### Linking Receive Buffer Pages

If the length of the packet exhausts the first 256 byte buffer, the DMA performs a forward link to the next buffer to store the remainder of the packet. For a maximal length packet the buffer logic will link six buffers to store the entire packet. Buffers cannot be skipped when linking, a packet will always be stored in contiguous buffers. Before the next buffer can be linked, the Buffer Management Logic performs two comparisons. The first comparison tests for equality between the DMA address of the next buffer and the contents of the Page Stop Register. If the buffer address equals the Page Stop Register, the buffer management logic will restore the DMA to the first buffer in the Receive Buffer Ring value programmed in the Page Start Address Register. The second comparison tests for equality between the DMA address of the next buffer address and the contents of the Boundary Pointer Register. If the two values are equal the reception is aborted. The Boundary Pointer Register can be used to protect against overwriting any area in the receive buffer ring that has not yet been read. When linking buffers, buffer management will never cross this pointer, effectively avoiding any overwrites. If the buffer address does not match either the Boundary Pointer or Page Stop Address, the link to the next buffer is performed.

### Linking Buffers

Before the DMA can enter the next contiguous 256 byte buffer, the address is checked for equality to PSTOP and to the Boundary Pointer. If neither are reached, the DMA is allowed to use the next buffer.

- 1) Check for = PSTOP
- 2) Check for = Boundary

TL/F/11498-28

**FIGURE 31. Linking Receive Buffer Pages**

### Buffer Ring Overflow

If the Buffer Ring has been filled and the DMA reaches the Boundary Pointer Address, reception of the incoming packet will be aborted by the AT/LANTIC Controller. Thus, the packets previously received and still contained in the Ring will not be destroyed.

In heavily loaded networks which cause overflows of the Receive Buffer Ring, the AT/LANTIC Controller may disable the local DMA and suspend further receptions even if the Boundary register is advanced beyond the Current register. In the event that the AT/LANTIC Controller should encounter a receive buffer overflow, it is necessary to implement the following routine. A receive buffer overflow is indicated by the AT/LANTIC Controller's assertion of the overflow bit (OVW) in the Interrupt Status Register (ISR).

If this routine is not adhered to, the AT/LANTIC Controller may act in an unpredictable manner. It should also be noted that it is not permissible to service an overflow interrupt by continuing to empty packets from the receive buffer without implementing the prescribed overflow routine. A flow chart of the AT/LANTIC™ Controller's overflow routine can be found in *Figure 32*.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

1. Read and store the value of the TXP bit in the AT/LANTIC Controller's Command Register.
2. Issue the STOP command to the AT/LANTIC Controller. This is accomplished by setting the STP bit in the AT/LANTIC Controller's Command Register. Writing 21 H to the Command Register will stop the AT/LANTIC Controller.
3. Wait for at least 1.6 ms. Since the AT/LANTIC Controller will complete any transmission or reception that is in progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommended that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.

## 6.0 Operation of AT/LANTIC Controller (Continued)

4. Clear the AT/LANTIC Controller's Remote Byte Count registers (RBCR0 and RBCR1).

5. Read the stored value of the TXP bit from step 1, above.

If this value is a 0, set the "Resend" variable to a 0 and jump to step 6.

If this value is a 1, read the AT/LANTIC Controller's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 0 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the AT/LANTIC Controller's ISR is read to determine whether or not the packet was recognized by the AT/LANTIC Controller. If neither the PTX nor TXE bit was set, then the packet will essentially be lost and re-transmitted only after a time-out takes place in the upper level software. By determining that the packet was lost at the driver level, a transmit command can be reissued to the AT/LANTIC Controller once the overflow routine is completed (as in step 11). Also, it is possible for the AT/LANTIC Controller to defer indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the AT/LANTIC Controller to operate correctly.

6. Place the AT/LANTIC Controller in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to 0,1 or 1,0 respectively.

7. Issue the START command to the AT/LANTIC Controller. This can be accomplished by Writing 22H to the Command Register. This is necessary to activate the AT/LANTIC Controller's Remote DMA channel.

8. Remove one or more packets from the receive buffer ring.

9. Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.

10. Take the AT/LANTIC Controller out of loopback. This is done by Writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)

11. If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by writing a value of 26H to the Command Register. If the "Resend" variable is 0, nothing needs to be done.

**Note 1:** If Remote DMA is not being used, the AT/LANTIC Controller does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7, eliminating or reducing the time spent polling in step 5.

**Note 2:** When the AT/LANTIC Controller is in STOP mode, the Missed Packet Tally counter is disabled.

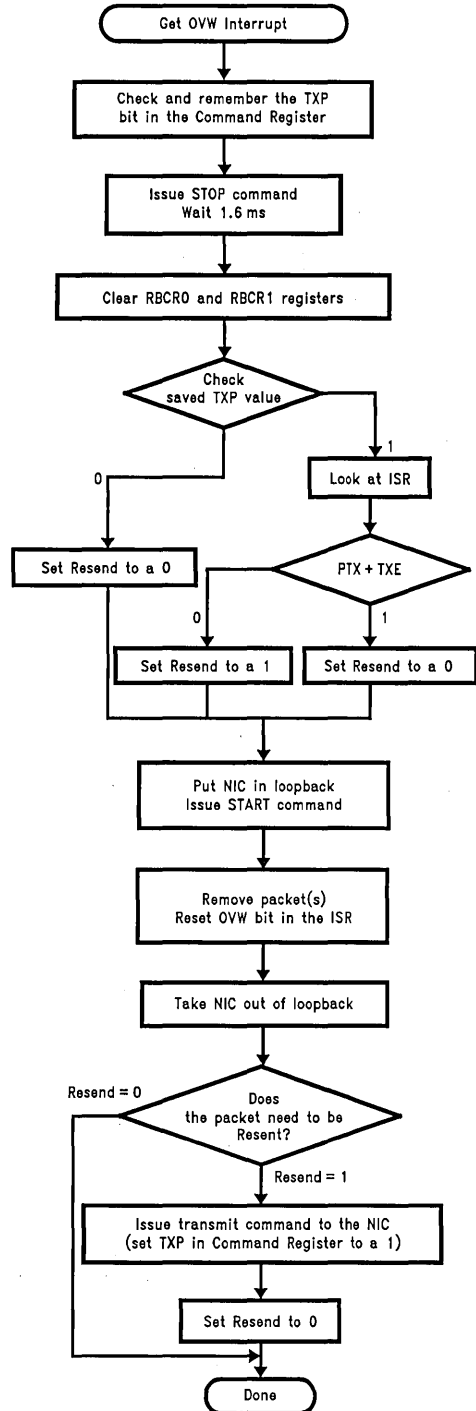

FIGURE 32. Overflow Routine

TL/F/11498-29

## 6.0 Operation of AT/LANTIC Controller (Continued)

FIGURE 33. Received Packet Aborted if it Hits Boundary

### Enabling the AT/LANTIC Controller on an Active Network

After the AT/LANTIC Controller has been initialized the procedure for disabling and then re-enabling the AT/LANTIC Controller on the network is similar to handling Receive Buffer Ring overflow as described previously.

1. Program Command Register for page 0 (Command Register = 21H)
2. Initialize Data Configuration Register (DCR)
3. Clear Remote Byte Count Registers (RBCR0, RBCR1) if using Remote DMA
4. Initialize Receive Configuration Register (RCR)
5. Place the AT/LANTIC Controller in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
6. Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
7. Clear Interrupt Status Register (ISR) by writing 0FFH to it
8. Initialize Interrupt Mask Register (IMR)
9. Program Command Register for page 1 (Command Register = 61H)
  - i) Initialize Physical Address Registers (PAR0-PAR5)
  - ii) Initialize Multicast Address Registers (MAR0-MAR7)
  - iii) Initialize CURRENT pointer
10. Put AT/LANTIC Controller in START mode (Command Register = 22H). The local receive DMA is still not active since the AT/LANTIC Controller is in LOOPBACK.
11. Initialize the Transmit Configuration for the intended value. The AT/LANTIC Controller is now ready for transmission and reception.

### End of Packet Operations

At the end of the packet the AT/LANTIC Controller determines whether the received packet is to be accepted or rejected. It either branches to a routine to store the Buffer Header or to another routine that recovers the buffers used to store the packet.

FIGURE 34. Termination of Received Packet—Packet Accepted

### Successful Reception

If the packet is successfully received, the DMA is restored to the first buffer used to store the packet (pointed to by the Current Page Register). The DMA then stores the Receive Status, a Pointer to where the next packet will be stored (Buffer 4) and the number of received bytes. Note that the remaining bytes in the last buffer are discarded and reception of the next packet begins on the next empty 256-byte buffer boundary. The Current Page Register is then initialized to the next available buffer in the Buffer Ring. (The location of the next buffer had been previously calculated and temporarily stored in an internal scratchpad register.)

### Buffer Recovery for Rejected Packets

If the packet is a runt packet or contains CRC or Frame Alignment errors, it is rejected. The buffer management logic resets the DMA back to the first buffer page used to store the packet (pointed to by CURR), recovering all buffers that had been used to store the rejected packet. This operation will not be performed if the AT/LANTIC Controller is programmed to accept either runt packets or packets with CRC or Frame Alignment errors. The received CRC is always stored in buffer memory after the last byte of received data for the packet.

FIGURE 35. Termination of Receive Packet—Packet Reject

## 6.0 Operation of AT/LANTIC Controller (Continued)

### Error Recovery

If the packet is rejected as shown, the DMA is restored by the AT/LANTIC Controller by reprogramming the DMA starting address pointed to by the Current Page Register.

### Storage Format for Received Packets

The following diagrams describe the format for how received packets are placed into memory by the local DMA channel. These modes are selected in the Data Configuration Register.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 1		Receive Byte Count 0	
Byte 2		Byte 1	

BOS = 0, WTS = 1 in Data Configuration Register. This format is used with Series 32xxx, or 808xx processors.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 0		Receive Byte Count 1	
Byte 1		Byte 2	

BOS = 1, WTS = 1 in Data Configuration Register. This format is used with 680x0 type processors. (Note: The Receiver Count ordering remains the same for BOS = 0 or 1.)

Receive Status
Next Packet Pointer
Receive Byte Count 0
Receive Byte Count 1
Byte 0
Byte 1

BOS = 0, WTS = 0 in Data Configuration Register. This format is used with general 8-bit processors.

### 6.4 PACKET TRANSMISSION

The Local DMA is also used during transmission of a packet. Three registers control the DMA transfer during transmission, a Transmit Page Start Address Register (TPSR) and the Transmit Byte Count Registers (TBCR0,1). When the AT/LANTIC Controller receives a command to transmit the packet pointed to by these registers, buffer memory data will be moved into the FIFO as required during transmission. The AT/LANTIC Controller will generate and append the preamble, synch and CRC fields.

#### General Transmit Packet Format

Transmit	Destination Address	6 Bytes
Byte	Source Address	6 Bytes
Count	Type/Length	2 Bytes
TBCR0, 1	Data	≥ 46 Bytes
	Pad (If data < 46 Bytes)	

### Transmit Packet Assembly

The AT/LANTIC Controller requires a contiguous assembled packet with the format shown. The transmit byte count includes the Destination Address, Source Address, Length Field and Data. It does not include preamble and CRC.

When transmitting data smaller than 46 bytes, the packet must be padded to a minimum size of 64 bytes. The programmer is responsible for adding and stripping pad bytes. The packets are placed in the buffer RAM by the system. In I/O Mode the system programs the NIC Core's Remote DMA to mode the data from the data port to the RAM handshaking with system transfers loading the I/O data port. In Shared Memory Mode the packets are written directly to the RAM by system using standard memory transfer instructions (MOV).

For I/O mode the data transfer must be 16 bits (1 word) when in 16-bit mode, and 8 bits when the AT/LANTIC Controller is set in 8-bit mode. The data width is selected by setting the WTS bit in the Data Configuration Register and setting the DWID pin for the proper mode.

In Shared Memory mode data transfer can be accomplished by using either 8- or 16-bit data transfer instructions, because this mode responds to 8/16-bit data signalling on the ISA bus. In this mode Shared Memory Control Register 2-bit 6 sets the bus interface data width, and the NIC Core's data width is set by the WTS bit in the Data Configuration Register.

### Transmission

Prior to transmission, the TPSR (Transmit Page Start Register) and TBCR0, TBCR1 (Transmit Byte Count Registers) must be initialized. To initiate transmission of the packet the TXP bit in the Command Register is set. The Transmit Status Register (TSR) is cleared and the AT/LANTIC Controller begins to prefetch transmit data from memory (unless the AT/LANTIC Controller is currently receiving). If the inter-frame gap has timed out the AT/LANTIC Controller will begin transmission.

### Conditions Required to Begin Transmission

In order to transmit a packet, the following three conditions must be met:

1. The Interframe Gap Timer has timed out the first 6.4 μs of the Interframe Gap
2. At least one byte has entered the FIFO. (This indicates that the burst transfer has been started)
3. If a collision had been detected then before transmission the packet time must have timed out.

In typical systems the AT/LANTIC Controller prefetches the first burst of bytes before the 6.4 μs timer expires. The time during which AT/LANTIC Controller transmits preamble can also be used to load the FIFO.

Note: If carrier sense is asserted before a byte has been loaded into the FIFO, the AT/LANTIC Controller will become a receiver.

### Collision Recovery

During transmission, the Buffer Management logic monitors the transmit circuitry to determine if a collision has occurred. If a collision is detected, the Buffer Management logic will reset the FIFO and restore the Transmit DMA pointers for retransmission of the packet. The COL bit will be set in the TSR and the NCR (Number of Collisions Register) will be incremented. If 15 retransmissions each result in a collision the transmission will be aborted and the ABT bit in the TSR will be set.

Note: NCR reads as zeroes if excessive collisions are encountered.

## 6.0 Operation of AT/LANTIC Controller (Continued)

### Transmit Packet Assembly Format

The following diagrams describe the format for how packets must be assembled prior to transmission for different byte ordering schemes. The various formats are selected in the Data Configuration Register.

D15	D8	D7	D0
Destination Address 1		Destination Address 0	
Destination Address 3		Destination Address 2	
Destination Address 5		Destination Address 4	
Source Address 1		Source Address 0	
Source Address 3		Source Address 2	
Source Address 5		Source Address 4	
Type/Length 1		Type Length 0	
Data 1		Data 0	

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with Series 32xxx, or 808xx processors.

D15	D8	D7	D0
Destination Address 0		Destination Address 1	
Destination Address 2		Destination Address 3	
Destination Address 4		Destination Address 5	
Source Address 0		Source Address 1	
Source Address 2		Source Address 3	
Source Address 4		Source Address 5	
Type/Length 0		Type Length 1	
Data 0		Data 1	

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with 680x0 type processors.

D7	D0
Destination Address 0	
Destination Address 1	
Destination Address 2	
Destination Address 3	
Destination Address 4	
Destination Address 5	
Source Address 0	
Source Address 1	
Source Address 2	
Source Address 3	
Source Address 4	
Source Address 5	

BOS = 0, WTS = 0 in a Data Configuration Register.

This format is used with 8-bit processors.

**Note:** All examples above will result in a transmission of a packet in order of DA0, DA1, DA3 . . . bits within each byte will be transmitted least significant bit first.

DA = Destination Address

### 6.5 LOOPBACK DIAGNOSTICS

Three forms of local loopback are provided on the AT/LANTIC Controller. The user has the ability to loopback through the deserializer on the controller, through the ENDEC module or transceiver. **Because of the half duplex architecture of the AT/LANTIC Controller, loopback testing is a special mode of operation with the following restrictions:**

#### Restrictions during Loopback

The FIFO is split into two halves, one half is used for transmission the other for reception. Only 8-bit fields can be fetched from memory so two tests are required for 16-bit systems to verify integrity of the entire data path. During loopback the maximum latency to obtain access to the buffer memory is 2.0  $\mu$ s. Systems that wish to use the loopback test yet do not meet this latency can limit the loopback packet to 7 bytes without experiencing underflow. Only the last 8 bytes of the loopback packet are retained in the FIFO. The last 8 bytes can be read through the FIFO register which will advance through the FIFO to allow reading the receive packet sequentially.

Destination Address	= 6 bytes Station Physical Address
Source Address	= 6 bytes Station Physical Address
Length	2 bytes
Data	= 46 to 1500 bytes
CRC	Appended by AT/LANTIC Controller if CRC = 0 in TCR

When in word-wide mode with Byte Order Select set, the loopback packet must be assembled in the even byte locations as shown below. (The loopback only operated with byte wide transfers.)

TL/F/11498-64

## 6.0 Operation of AT/LANTIC Controller (Continued)

When in word-wide mode with Byte Order Select low, the following format must be used for the loopback packet.

TL/F/11498-65

**Note:** When using loopback in word mode 2n bytes must be programmed in the TBCRO, 1. When n = actual number of bytes assembled in even or odd location.

To initiate a loopback the user first assembles the loopback packet then selects the type of loopback using the Transmit Configuration register bits LB0, LB1. The transmit configuration register must also be set to enable or disable CRC generation during transmission. The user then issues a normal transmit command to send the packet. During loopback the receiver checks for an address match and if CRC bit in the TCR is set, the receiver will also check the CRC. The last 8 bytes of the loopback packet are buffered and can read out of the FIFO using FIFO read port.

### Loopback Modes

**MODE1:** Loopback through the AT/LANTIC Controller Module (LB1 = 0, LB0 = 1): If this loopback is used, the AT/LANTIC Controller Module's serializer is connected to the deserializer.

**MODE 2:** Loopback through the ENDEC Module (LB1 = 1, LB0 = 0): If the loopback is to be performed through the SNI, the AT/LANTIC Controller provides a control (LPBK) that forces the ENDEC module to loopback all signals.

**MODE 3:** Loopback to the external coax interface or twisted pair interface module (LB1 = 1, LB0 = 1). Packets can be transmitted to the cable in loopback mode to check all of the transmit and receive paths and the cable itself. If, in twisted pair mode, there is a link fail the transmitter will be disabled which could give misleading results in Mode 3. The link integrity should be checked, by reading Configuration Register B, before this test.

**Note:** Collision and Carrier Sense can be generated by the ENDEC module and are masked by the NIC module. It is not possible to go directly between the loopback modes, it is necessary to return to normal operation (OOH) when changing modes.

### Reading the Loopback Packet

The last eight bytes of a received packet can be examined by 8 consecutive reads of the FIFO register. The FIFO pointer is increment after the rising edge of the CPU's read strobe by internally synchronizing and advancing the pointer. This may take up to four bus clock cycles, if the pointer has not been incremented by the time the CPU reads the FIFO register again, the AT/LANTIC Controller will insert wait states.

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the AT/LANTIC Controller to malfunction.

### Alignment of the Received Packet in the FIFO

Reception of the packet in the FIFO begins at location zero, after the FIFO pointer reaches the last location in the FIFO, the pointer wraps to the top of the FIFO overwriting the previously received data.

This process is continued until the last byte is received. The AT/LANTIC Controller then appends the received byte count in the next two locations of the FIFO. The contents of the Upper Byte Count are also copied to the next FIFO location. The number of bytes used in the loopback packet determined the alignment of the packet in the FIFO. The alignment for a 64-byte packet is shown below.

FIFO Location	FIFO Contents	
0	Lower Byte Count	→ First Byte Read
1	Upper Byte count	→ Second Byte Read
2	Upper Byte Count	•
3	Last Byte	•
4	CRC1	•
5	CRC2	•
6	CRC3	•
7	CRC4	→ Last Byte Read

For the following alignment in the FIFO the packet length should be  $(N \times 8) + 5$  Bytes. Note that if the CRC bit in the TCR is set, CRC will not be appended by the transmitter. If the CRC is appended by the transmitter, the 1st four bytes, bytes N-3 to N, correspond to the CRC.

FIFO Location	FIFO Contents	
0	Byte N-4	→ First Byte Read
1	Byte N-3 (CRC1)	→ Second Byte Read
2	Byte N-2 (CRC2)	•
3	Byte N-1 (CRC3)	•
4	Byte N (CRC4)	•
5	Lower Byte Count	•
6	Upper Byte Count	•
7	Upper Byte Count	→ Last Byte Read

### Loopback Tests

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the AT/LANTIC Controller prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

1. Verify integrity of data path. Received data is checked against transmitted data.
2. Verify CRC logic's capability to generate good CRC on transmit, verify CRC on receive (good or bad CRC).
3. Verify that the Address Recognition Logic can
  - a. Recognize address match packets
  - b. Reject packets that fail to match an address

### Loopback Operation in the AT/LANTIC Controller

Loopback is a modified form of transmission using only half of the FIFO. This places certain restrictions on the use of

## 6.0 Operation of AT/LANTIC Controller (Continued)

loopback testing. When loopback mode is selected in the TCR, the FIFO is split. A packet should be assembled in memory with programming of TPSR and TBCR0, TBCR1 registers. When the transmit command is issued the following operations occur:

### TRANSMITTER ACTIONS

1. Data is transferred from memory by the DMA until the FIFO is filled. For each transfer TBCR0 and TBCR1 are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
2. The AT/LANTIC Controller generates 56 bits of preamble followed by an 8-bit synch pattern.
3. Data transferred from FIFO to serializer.
4. If CRC = 1 in TCR, no CRC calculated by AT/LANTIC Controller, the last byte transmitted is the last byte from the FIFO (allows software CRC to be appended). If CRC = 0, AT/LANTIC Controller calculates and appends four bytes of CRC.
5. At end of Transmission PTX bit set in ISR.

### RECEIVER ACTIONS

1. Wait for synch, all preamble stripped.
2. Store packet in FIFO, increment receive byte count for each incoming byte.
3. If CRC = 0 in TRC, receiver checks incoming packet for CRC errors. If CRC = 1 in TCR, receiver does not check CRC errors, CRC error bit always set in RSR (for address matching packets).
4. At end of receive, receive byte count written into FIFO, receive status register is updated. The PRX bit is typically set in the RSR even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the RS to be set.

### EXAMPLES

The following examples show what results can be expected from a properly operating AT/LANTIC Controller during loopback. The restrictions and results of each type of loopback are listed for reference. The loopback tests are divided into two sets of tests. One to verify the data path, CRC generation and byte count through all three paths. The second set of tests uses internal loopback to verify the receiver's CRC checking and address recognition. For all of the tests the DCR was programmed to 40H.

Path	TCR	RCR	TSR	RSR	ISR
AT/LANTIC Controller Internal	02	1F	53 (Note 1)	02 (Note 2)	02 (Note 3)

**Note 1:** Since carrier sense and collision detect are generated in the ENDEC module. They are blocked during internal loopback, carrier and CD heartbeat are not seen and the CRS and CDH bits are set.

**Note 2:** CRC errors are always indicated by receiver if CRC is appended by the transmitter.

**Note 3:** Only the PTX bit in the ISR is set, the PRX bit is only set if status is written to memory. In loopback this action does not occur and the PRX bit remains 0 for all loopback modes.

**Note 4:** All values are hex.

Path	TCR	RCR	TSR	RSR	ISR
AT/LANTIC Controller Internal	04	1F	43 (Note 1)	02	02

**Note 1:** CDH is set, CRS is not set since it is generated by the external encoder/decoder.

Path	TCR	RCR	TSR	RSR	ISR
AT/LANTIC Controller External	06	1F	03 (Note 1)	02	02 (Note 2)

**Note 1:** CDH and CRS should not be set. The TSR however, could also contain 01H,03H,07H and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** Will contain 08H if packet is not transmittable.

**Note 3:** During external loopback the AT/LANTIC Controller is now exposed to network traffic, it is therefore possible for the contents of both the Receive portion of the FIFO and the RSR to be corrupted by any other packet on the network. Thus in a live network the contents of the FIFO and RSR should not be depended on. The AT/LANTIC Controller will still abide by the standard CSMA/CD protocol in external loopback mode (i.e. the network will not be disturbed by the loopback packet).

**Note 4:** All values are hex.

### CRC and Address Recognition

The next three tests exercise the address recognition logic and CRC. These tests should be performed using internal loopback only so that the AT/LANTIC Controller is isolated from interference from the network. These tests also require the capability to generate CRC in software.

The address recognition logic cannot be directly tested. The CRC and FAE bits in the RSR are only set if the address in the packet matches the address filters. If errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch. The following sequence of packets will test the address recognition logic. The DCR should be set to 40H, the TCR should be set to 03H with a software generated CRC.

Packet Contents		Results	
Test	Address	CRC	RSR
Test A	Matching	Good	01 (Note 1)
Test B	Matching	Bad	02 (Note 2)
Test C	Non-Matching	Bad	01

**Note 1:** Status will read 21H if multicast address used.

**Note 2:** Status will read 22H if multicast address used.

**Note 3:** In test A, the RSR is set up. In test B the address is found to match since the CRC is flagged as bad. Test C proves that the address recognition logic can distinguish a bad address and does not notify the RSR of the bad CRC. The receiving CRC is proven to work in test A and test B.

**Note 4:** All values are hex.

## 6.0 Operation of AT/LANTIC Controller (Continued)

FIGURE 36. Tally Counters

### Network Management Functions

Network management capabilities are required for maintenance and planning of a local area network. The AT/LANTIC Controller supports the minimum requirement for network management in hardware, the remaining requirements can be met with software. Software alone can not track during reception of packets: CRC errors, Frame Alignment errors, and missed packets, *Figure 36*.

Since errored packets can be rejected, the status associated with these packets is lost unless the CPU can access the Receive Status Register before the next packer arrives. In situations where another packet arrives very quickly, the CPU may have no opportunity to do this. The AT/LANTIC Controller counts the number of packets with CRC errors and Frame Alignment errors. 8-bit counters have been selected to reduce overhead. The counters will generate interrupts whenever their MSBs are set so that a software routine can accumulate the network statistics and reset the counter before overflow occurs. The counters are sticky so that when they reach a count of 192 (COH) counting is halted. An additional counter is provided to count the number of packets the AT/LANTIC Controller misses due to buffer overflow or being offline.

The structure of the counters is shown in *Figure 36*.

Additional information required for network management is available in the Receive and Transmit Status Registers. Transmit status is available after each transmission for information regarding events during transmission.

Typically, the following statistics might be gathered in software:

- Traffic:
  - Frames Sent OK
  - Frames Received OK
  - Multicast Frames Received
  - Packets Lost Due to Lack of Resources
  - Retries/Packet
- Errors:
  - CRC Errors
  - Alignment Errors
  - Excessive Collisions
  - Packet with Length Errors
  - Heartbeat Failure

### 6.6 MEMORY ARBITRATION AND BUS OPERATION

The AT/LANTIC Controller will always operate as a slave device on its peripheral interface to the ISA bus. However on the memory bus, the AT/LANTIC Controller operates in three possible modes:

1. Bus Master of Local Packet Buffer RAM
2. Bus Slave when accessed by the CPU via the Bus Interface
3. Idle, when no activity is occurring.

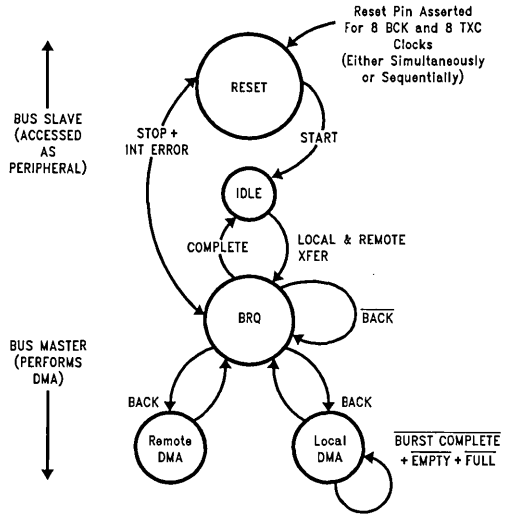

FIGURE 37. DP8390 Core Bus States

Upon power-up the AT/LANTIC Controller is in an indeterminate state. After receiving a hardware reset the AT/LANTIC Controller is a bus slave in the Reset State, the receiver and transmitter are both disabled in this state. The reset state can be re-entered under four conditions, soft reset (Stop Command), register reset (reset port in I/O mode, bit in Control Register 1 in shared memory mode), hard reset (RESET input) or an error that shuts down the receiver or transmitter (FIFO underflow or overflow, receive buffer ring overflow).

After initialization of registers, the AT/LANTIC Controller is issued a Start command and the AT/LANTIC Controller enters Idle state. Until the DMA is required the AT/LANTIC Controller remains in idle state.

The idle state is exited and the AT/LANTIC Controller will drive the local memory bus when a request from the FIFO in the DP8390 (NIC) core causes the memory bus interface logic to issue a read or write operation, such as when the AT/LANTIC Controller is transmitting or receiving data.

In I/O mode the NIC Core's Remote DMA also requests access from the memory bus. When software programs an I/O mode data transfer between the CPU and the buffer RAM, the Remote DMA controls this request.

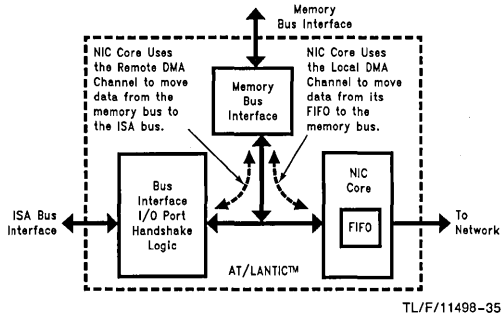

In Shared Memory Mode, the memory bus is accessed via the CPU interface directly.

All Local DMA transfers are burst transfers, the DMA will transfer an exact burst of bytes programmed in the Data Configuration Register (DCR) then relinquish the memory bus. If there are remaining bytes in the FIFO the next burst will not be initiated until the FIFO threshold is exceeded.

#### I/O Mode Operation

In I/O mode the AT/LANTIC Controller transfers data to and from the packet buffer RAM by utilizing the Remote DMA logic which is programmed by the main system CPU to transfer data through the AT/LANTIC Controller's internal data port register.

## 6.0 Operation of AT/LANTIC Controller (Continued)

**FIGURE 38. I/O Operation: All Data Transfers and Arbitration is Controlled by the NIC Core**

### INTERLEAVED LOCAL/REMOTE OPERATION

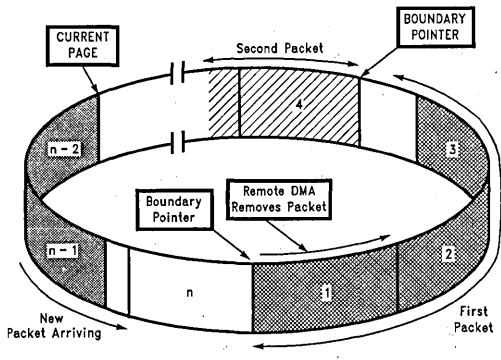

When in I/O mode the remote DMA is used to transfer data to/from the main system. If a remote DMA transfer is initiated or in progress when a packet is being received or transmitted, the Remote DMA transfers will be interrupted for higher priority Local DMA transfers. When the Local DMA transfer is completed the Remote DMA will re-arbitrate for the bus and continue its transfers.

If the FIFO requires service while a remote DMA is in progress the Local DMA burst is appended to the Remote Transfer. When switching from a local transfer to a remote transfer there is a break to allow the CPU to fairly contend for the bus.

### REMOTE DMA BI-DIRECTIONAL PORT

The Remote DMA transfers data between the local buffer memory and the internal bidirectional port (memory to I/O transfer).

This transfer is arbitrated on a transfer by transfer basis versus the burst transfer mode used for Local DMA transfers. This bidirectional port is integrated onto the AT/LANTIC Controller, and is read/written by the host. All transfers through this port are asynchronous. At any one time transfers are limited to one direction, either from the port to local buffer memory (Remote Write) or from local buffer memory to the port (Remote Read).

**FIGURE 39. 1st Received Packet Removed by Remote DMA**

### I/O MODE REMOVING PACKETS FROM RING

Network activity is isolated on a local bus, where the AT/LANTIC Controller's local DMA channel performs burst transfers between the buffer memory and the AT/LANTIC Controller's FIFO. The Remote DMA transfers data between the buffer memory and the host memory via the internal bidirectional I/O port. The Remote DMA provides local addressing capability and is used as a slave DMA by the host. The host system reads the I/O port to transfer data between the system and I/O port. The AT/LANTIC Controller allows Local and Remote DMA operations to be interleaved.

Packets are removed from the ring using the Remote DMA. When using the Remote DMA the Send Packet command can be used. This programs the Remote DMA to automatically remove the received packet pointed to by the Boundary Pointer. At the end of the transfer, the AT/LANTIC Controller moves the Boundary Pointer, freeing additional buffers for reception. The Boundary Pointer can also be moved manually by programming the Boundary Register. Care should be taken to keep the Boundary Pointer at least one buffer behind the Current Page Pointer.

Data transfer by the Remote DMA to the integrated I/O data port is dependent on whether the AT/LANTIC Controller is set into 8-bit mode or 16-bit mode. In 8-bit mode all transfers are 8 bits (1 byte) wide. When in 16-bit mode all transfers are 16 bits (1 word) wide. The data width is selected by setting the WTS bit in the Data Configuration Register and setting the DWID pin for the proper mode.

The following is a suggested method for maintaining the Receive Buffer Ring pointers if in shared memory mode or if remote read is used in I/O mode.

1. At initialization, set up a software variable (`next_pkt`) to indicate where the next packet will be read. At the beginning of each Remote Read DMA operation, the value of `next_pkt` will be loaded into RSAR0 and RSAR1.
2. When initializing the AT/LANTIC Controller set:
 

```
BNDRY = PSTART
CURR = PSTART + 1
next_pkt = PSTART + 1
```
3. After a packet is DMAed from the Receive Buffer Ring, the Next Page Pointer (second byte in the AT/LANTIC Controller buffer header is used to update BNDRY and `next_pkt`.
 

```
next_pkt = Next Page Pointer
BNDRY = Next Page Pointer - 1
```

If  $BNDRY < PSTART$  then  $BNDRY = PSTOP - 1$

Note the size of the Receive Buffer Ring is reduced by one 256 byte buffer, this will not, however, impede the operation of the AT/LANTIC Controller. The advantage of this scheme is that it easily differentiates between buffer full and buffer empty; it is full if  $BNDRY = CURR$ ; empty when  $BNDRY = CURR - 1$ . If, in I/O mode, send packet is used to empty the buffer ring this scheme cannot be used. BNDRY must be initialized equal to CURR, or the first executed send packet will not return data from the received packet, which will be written at CURR. The Overwrite Warning bit of the Interrupt Status Register must be used in this mode to differentiate between buffer full and buffer empty.

## 6.0 Operation of AT/LANTIC Controller (Continued)

FIGURE 40. Remote DMA Autoinitialization from Buffer Ring

TL/F/11498-37

### I/O MODE REMOTE DMA COMMANDS

The Remote DMA channel is used in the I/O Mode to both assemble packets for transmission, and to remove received packets from the Receive Buffer Ring. It may also be used for moving blocks of data or commands between host memory and local buffer memory. (In Shared Memory Mode, the Remote DMA should be disabled, and not used. Packet transfer to/from the system is accomplished by normal CPU read/write operations.)

There are three modes of Remote DMA operation: Remote Write, Remote Read, or Send Packet.

Two register pairs are used to control the Remote DMA, a Remote Start Address (RSAR0, RSAR1) and a Remote Byte Count (RBCR0, RBCR1) register pair. The Start Address Register pair points to the beginning of the block to be moved while the Byte Count Register pair is used to indicate the number of bytes to be transferred. Full handshake logic is provided to move data between local buffer memory and a bidirectional I/O port.

**Remote Write:** A Remote Write transfer is used to move a block of data from the host into local buffer memory. The Remote DMA will read data from the I/O port and sequentially write it to local buffer memory beginning at the Remote Start Address. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches a count of zero.

**Remote Read:** A Remote Read transfer is used to move a block of data from local buffer memory to the host. The Remote DMA will sequentially read data from the local buffer memory, beginning at the Remote Start Address, and write data to the I/O port. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

**Send Packet Command:** The Remote DMA channel can be automatically initialized to transfer a single packet from the Receive Buffer Ring. The CPU begins this transfer by issuing a "Send Packet" Command. The DMA will be initialized to the value of the Boundary Pointer Register and the Remote Byte Count Register pair (RBCR0, RBCR1) will be initialized to the value of the Receive Byte Count fields found in the Buffer Header of each packet. After the data is transferred, the Boundary Pointer is advanced to allow the buffers to be used for new receive packets. The Remote Read will terminate when the Byte Count equals zero. The Remote DMA is then prepared to read the next packet from the Receive Buffer Ring. If the DMA pointer crosses the Page Stop Register, it is reset to the Page Start Address. This allows the Remote DMA to remove packets that have wrapped around to the top of the Receive Buffer Ring.

**Note 1:** In order for the AT/LANTIC Controller to correctly execute the Send Packet command, the upper Remote Byte Count Register (RBCR1) must first be loaded with 0FH.

**Note 2:** The Send Packet command cannot be used with 680x0 type processors.

### I/O MODE READ TIMING

1. The DMA reads a word from local buffer memory and writes the word into the internal latch, increments the DMA address and decrements the byte count (RBCR0,1).
2. Internally a request line is asserted to enable the system to read the port. If the system reads this port before the data has been written, then the system is sent a wait signal to wait until the data has been written to the port. Once written the system's read is allowed to complete.
3. The system reads the port, the read strobe for the port is used as an acknowledgement to the Remote DMA and it goes back to step 1.

## 6.0 Operation of AT/LANTIC Controller (Continued)

Steps 1–3 are repeated until the remote DMA is complete (i.e. the byte count has gone to zero).

Note that in order for the Remote DMA to transfer a word from memory to the latch, it must arbitrate access to the local buffer RAM. After each word is transferred to the internal latch, access to the RAM is relinquished. If a Local DMA is in progress, the Remote DMA is held off until the local DMA is complete.

### I/O MODE WRITE TIMING

A Remote Write operation transfers data from the I/O port to the local buffer RAM. The system transfers a byte-word to the latch via  $\overline{IOWR}$ . This write strobe is detected by the AT/LANTIC Controller and the byte/word is transferred to local buffer memory. The Remote DMA holds off further transfers into the latch until the current byte/word has been transferred from the latch.

1. AT/LANTIC Controller awaits data to be written by the system. System writes byte/word into latch.
2. Remote DMA reads contents of port and writes byte/word to local buffer memory, increments address and decrements byte count (RBCRO,1).
3. Go back to step 1.

Steps 1–3 are repeated until the remote DMA is complete.

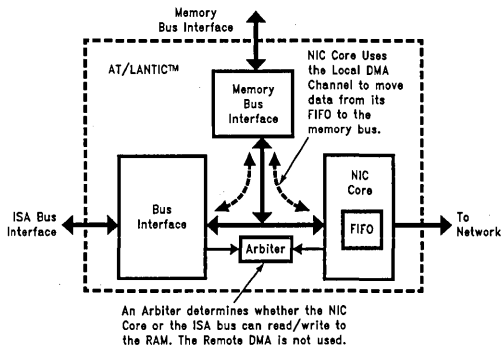

FIGURE 41. Shared Memory Mode the ISA Bus Directly Access the RAM

### Shared Memory Mode Operation

In shared memory mode the AT/LANTIC Controller transfers data to or from the packet buffer RAM directly from or to the ISA bus. The buffer RAM is mapped into system memory with the AT/LANTIC Controller doing all address decoding, synchronization and handshaking.

### INTERLEAVED SHARED/LOCAL OPERATION

When in shared memory mode the local DMA is used to transfer data to or from the FIFO in the NIC core and ultimately the network. If a local DMA transfer is in progress when a shared memory access occurs the system is sent a wait state signal until the local DMA has been completed. If the shared memory access begins first then it will be completed before any local DMA is allowed.

### SHARED MEMORY HOST DATA TRANSFER

In Shared Memory Mode the system reads data from the RAM directly, usually using memory string move instructions. The memory is enabled by setting D6 of Shared Memory Control Register 1. The base address of the memory is programmed by writing to the Control Registers.

If DWID is low only Control Register 1 is used to program base address, so the memory must exist in the lower 1 Mbytes of system memory. A19 is always compared to a 1 when DWID is low. The A13–18 bits are compared to the address lines, if there is 8k of memory. A13 is not compared in 16k mode, A13–14 are not compared in 32k mode (8-bit non-compatible) and A13–15 are not compared in 64k mode (16-bit non-compatible).

If DWID is high both Control Registers must be programmed to set the base address, so the memory can exist anywhere in up to 16 Gbytes of system memory. LA19 can be either 1 or 0. The same limited decode, as detailed above, also occurs depending on the memory size.

### SHARED MEMORY READ TIMING

The system executes a normal memory read cycle which the AT/LANTIC Controller will complete immediately, if idle, or insert wait states into if local DMA is current. The byte or word of data is fetched from the buffer RAM via the memory support bus.

### SHARED MEMORY WRITE TIMING

The system executes a normal memory write cycle which the AT/LANTIC Controller will complete immediately, if idle, or insert wait states into if local DMA is current. The byte or word of data is written to the buffer RAM via the memory support bus.

## 6.7 FUNCTIONAL BUS TIMING

This section describes the bus cycles that the AT/LANTIC Controller performs. These timings can be subdivided into 3 basic categories:

1. ISA I/O Access: There are register accesses in both modes, and I/O data accesses in I/O mode.
2. Shared RAM ISA Accesses: These are the timing for the ISA bus accesses through the AT/LANTIC Controller to the memory bus and buffer RAM.
3. Boot PROM ISA Accesses: These are the timing for the ISA bus accesses through the AT/LANTIC Controller to the memory bus and boot PROM.
4. Local and I/O RAM Accesses: This is the timing of the local DMA, accesses from the NIC Core FIFO to the RAM, and the Remote DMA accesses to the RAM over the memory bus.

### ISA Bus I/O Accesses

The AT/LANTIC Controller is designed to directly interface to the ISA bus (PC-AT backplane bus). The CPU can read or write any internal registers. All register accesses are byte wide. The functional timing for AT/LANTIC Controller accesses are shown in the following pages.

## 6.0 Operation of AT/LANTIC Controller (Continued)

8-Bit I/O Mode Slave Read

TL/F/11498-39

This is the type of cycle used to read from a register or, in 8-bit I/O mode, from a data transfer port. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IORD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will always appear on SD0-7.

8-Bit I/O Mode Slave Write

TL/F/11498-40

This is the type of cycle used to write to a register or, in 8-bit I/O mode, to a data transfer port. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IOWR}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The data will always be taken from SD0-7.

## 6.0 Operation of AT/LANTIC Controller (Continued)

### 16-Bit I/O Mode Slave Read

TL/F/11498-41

This is the type of cycle used to read from a data transfer port in 16-bit I/O mode. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IORD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{\text{IO16}}$  is generated, when an address within the AT/LANTIC Controller's data transfer port is decoded, to indicate to the system that this is a 16-bit transfer. If the  $\overline{\text{IO16CON}}$  bit in Configuration Register B is low then it will be a straight decode of the SA0-9 lines. If that bit is high the  $\overline{\text{IO16}}$  output will be generated after  $\overline{\text{IORD}}$  goes active.  $\overline{\text{SBHE}}$  must be low, to indicate that this is a 16-bit transfer, and the address should be even, SA0 low. The data will appear on SD0-15.

### 16-Bit I/O Mode Slave Write

TL/F/11498-42

This is the type of cycle used to write to a data transfer port in 16-bit I/O mode. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-9 and an  $\overline{\text{IOWR}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{\text{IO16}}$  is generated, when an address within the AT/LANTIC Controller's data transfer port is decoded, to indicate to the system that this is a 16-bit transfer. If the  $\overline{\text{IO16CON}}$  bit in Configuration Register B is low then it will be a straight decode of the SA0-9 lines. If that bit is high the  $\overline{\text{IO16}}$  output will be generated after  $\overline{\text{IOWR}}$  goes active.  $\overline{\text{SBHE}}$  must be low, to indicate that this is a 16-bit transfer, and the address should be even, SA0 low. The data will be taken from SD0-15.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-63

### 16-Bit I/O Cycle with CHRDY Fix

Some Chips and Technologies and VLSI Technologies PC-AT chip sets have timing requirements in 16-bit I/O cycles that cannot be achieved by the default AT/LANTIC cycle, described on the previous page. When that cycle is executed with these chip sets the system does not recognize the CHRDY signal and does not insert wait states. The system executes a standard cycle and deasserts IORD or IOW even if CHRDY is still deasserted. The AT/LANTIC recognizes if this situation has occurred, asserts CHRDY and sets a bus error bit in Configuration Register B to flag this error. Thus the user can test any new system to see if this error occurs and then take some remedial action. There are two ways of overcoming this problem, which are implemented by various board vendors. The AT/LANTIC supports both methods to allow the user to decide. Either fix can be selected by software, by writing to Configuration Register B.

The first fix is enabled by setting the IO16-bit of Configuration Register B. In normal operation any time a valid address exists on SA0-9 IO16 is generated. Delaying IO16 until after the IORD or IOW can cure the problem on non-compliant machines. The theory is that the system is fooled into thinking an 8-bit peripheral is responding, since IO16 is not generated for the valid address, and accepts 8-bit I/O cycle timings for CHRDY. It then rechecks IO16 after the IORD or IOW strobe and correctly determines it is a 16-bit peripheral. If a system did not recheck IO16 it would generate 2 8-bit cycles instead of 1 16-bit cycle. The AT/LANTIC would interpret each 8-bit access as a 16-bit transfer and decrement it's DMA byte count by 2. Eventually the system would attempt to access the data transfer port when the AT/LANTIC had finished transferring data and CHRDY would be deasserted indefinitely. To prevent misoperation, this fix should only be implemented on systems that require it.

The above figure shows the second fix to the problem with non-compliant machines. It is enabled by setting the CHRDY bit of Configuration Register B. This approach works on the theory that CHRDY deassertion is not fast enough and should be faster. In fact, it must be deasserted before the IORD or IOW strobe to operate correctly in some machines. All of the signals shown above are the same as a normal 16-bit I/O cycle, except CHRDY. BALE goes active and the address becomes valid after a falling edge of ISACK. This causes the AT/LANTIC to generate IO16 if the address decodes to the data transfer port. BALE goes inactive after the next rising edge of ISACK and IORD or IOW is asserted after the following falling edge. Normally CHRDY would be deasserted after the IORD or IOW strobe, if the AT/LANTIC was not ready. With this fix implemented CHRDY is deasserted as soon as the address becomes valid and BALE is active. If a memory cycle is in operation, instead of an I/O, CHRDY is asserted after the command strobe (MRD, MWR, SMRD or SMWR). If the address becomes invalid CHRDY is asserted. To prevent CHRDY being asserted for the half clock between BALE going inactive and IORD or IOW going active the AT/LANTIC holds CHRDY asserted as long as ISACK is high between these signals. If the delay between the falling edge of ISACK and the falling edge of IORD or IOW is too great, there may be a period where CHRDY is not held deasserted. This should not cause a problem. To prevent misoperation, this fix should only be implemented on systems that require it.

## 6.0 Operation of AT/LANTIC Controller (Continued)

### ISA Bus Shared Memory Access Timing

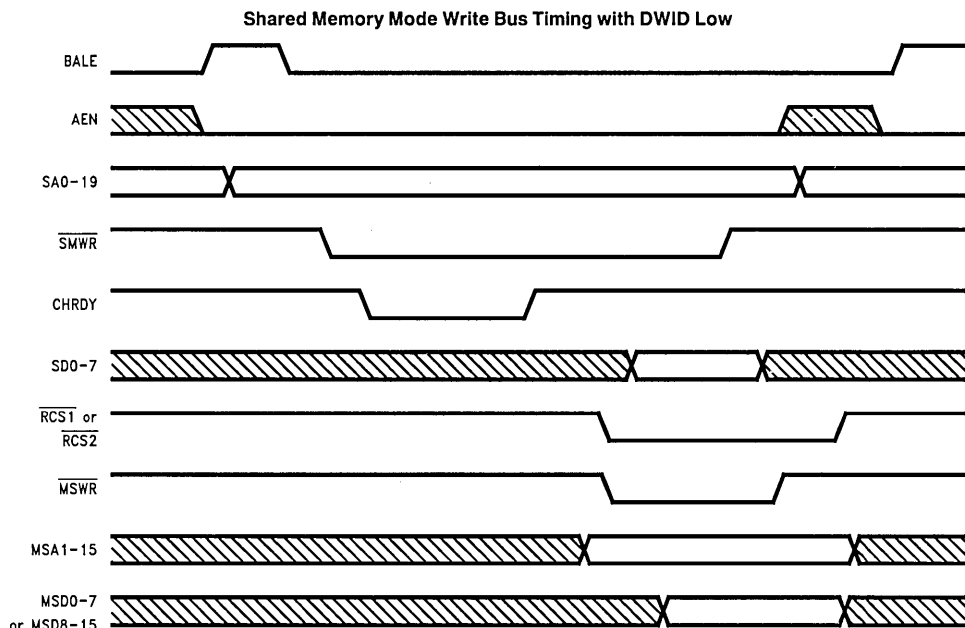

TL/F/11498-43

This is the type of cycle used to read from buffer RAM in shared memory mode when DWID is low. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the address on SA0-19 matches Control Register 1 and an  $\overline{\text{SMRD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. If the memory width bit in Control Register 2 is low then 8 kbytes of RAM are accessible, so only  $\overline{\text{RCS1}}$  is used to strobe data and the data is always on MSD0-7. If this bit is high 16 kbytes of RAM are accessible, so both chip selects and byte lanes are used. If the memory address is even  $\overline{\text{RCS1}}$  and MSD0-7 are used, if odd  $\overline{\text{RCS2}}$  and MSD8-15 are used. System data is always output on SD0-7.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-44

This is the type of cycle used to write to buffer RAM in shared memory mode when DWID is low. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the address on SA0-19 matches Control Register 1 and an  $\overline{SMWR}$ . If AEN is high the cycle will be ignored.  $\overline{CHRDY}$  is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately  $\overline{CHRDY}$  is not deasserted. If the memory width bit in Control Register 2 is low then 8 kbytes of RAM are accessible, so only  $\overline{RCS1}$  is used to strobe data and the data is always on MSD0-7. If this bit is high 16 kbytes of RAM are accessible, so both chip selects and byte lanes are used. If the memory address is even  $\overline{RCS1}$  and MSD0-7 are used, if odd  $\overline{RCS2}$  and MSD8-15 are used. System data is always taken from SD0-7.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-45

This is the type of cycle used to read 16 bits from buffer RAM in shared memory mode when DWID is high. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on LA17-23, SA0-19 and a MRD. If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The 8/16-bit in Control Register 2 must be set to allow generation of M16. This will be generated whenever the LA17-23 lines match the corresponding values in Control Register 2. It will therefore be generated for a full 128 kbytes of address space, although the AT/LANTIC Controller will occupy less than that. It may be preferable to only set the 8/16-bit for the duration of a transfer from the buffer RAM. The AT/LANTIC Controller will also compare the address line programmed in Control Register 1 before allowing accesses to buffer RAM and therefore do a complete decode. The system indicates that this is a 16-bit transfer by asserting SBHE and accessing an even address, SA0 low. The full 16 bits of data bus are used on both system and memory support busses.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-46

This is the type of cycle used to write 16 bits to buffer RAM in shared memory mode when DWID is high. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on LA17-23, SA0-19 and a MWR. If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The 8/16-bit in Control Register 2 must be set to allow generation of M16. This will be generated whenever the LA17-23 lines match the corresponding values in Control Register 2. It will therefore be generated for a full 128 kbytes of address space, although the AT/LANTIC Controller will occupy less than that. It may be preferable to only set the 8/16-bit for the duration of a transfer to the buffer RAM. The AT/LANTIC Controller will also compare the address line programmed in Control Register 1 before allowing accesses to buffer RAM and therefore do a complete decode. The system indicates that this is a 16-bit transfer by asserting SBHE and accessing an even address, SA0 low. The full 16 bits of data bus are used on both system and memory support busses.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-47

This is the type of cycle used to read 8 bits from buffer RAM in shared memory mode when DWID is high. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on LA17-23, SA0-19 and a MRD. If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The 8/16-bit in Control Register 2 must be set to allow generation of M16. This will be generated whenever the LA17-23 lines match the corresponding values in Control Register 2. It will therefore be generated for a full 128 kbytes of address space, although the AT/LANTIC Controller will occupy less than that. It may be preferable to only set the 8/16-bit for the duration of a transfer from the buffer RAM. The AT/LANTIC Controller will also compare the address line programmed in Control Register 1 before allowing accesses to buffer RAM and therefore do a complete decode. The system indicates that this is an 8-bit transfer by not asserting SBHE for an even address, SA0 low, or by accessing an odd address, SA0 high. If the 8/16-bit is low the AT/LANTIC Controller will only drive data onto SD0-7. Even addresses will use RCS1 and MSD0-7, odd addresses will use RCS2 and MSD8-15. If 8/16-bit is high the AT/LANTIC Controller can drive either SD0-7 or SD8-15. Even addresses are fetched using RCS1 and MSD0-7 and driven onto SD0-7. Odd addresses are fetched using RCS2 and MSD8-15 and driven onto SD8-15.

## 6.0 Operation of AT/LANTIC Controller (Continued)

8-Bit Shared Memory Mode Write Bus Timing with DWID High

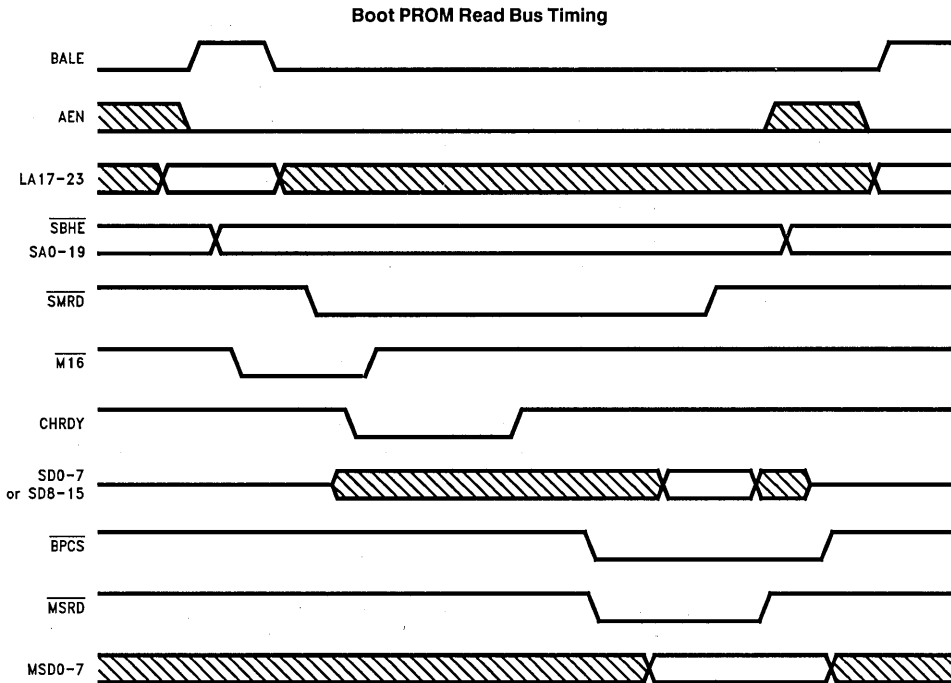

TL/F/11498-48

This is the type of cycle used to write 8 bits to buffer RAM in shared memory mode when DWID is high. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on LA17-23, SA0-19 and a  $\overline{IORD}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted. The 8/16-bit in Control Register 2 must be set to allow generation of M16. This will be generated whenever the LA17-23 lines match the corresponding values in Control Register 2. It will therefore be generated for a full 128 kbytes of address space, although the AT/LANTIC Controller will occupy less than that. It may be preferable to only set the 8/16-bit for the duration of a transfer to the buffer RAM. The AT/LANTIC Controller will also compare the address line programmed in Control Register 1 before allowing accesses to buffer RAM and therefore do a complete decode. The system indicates that this is an 8-bit transfer by not asserting SBHE for an even address, SA0 low, or by accessing an odd address, SA0 high. If the 8/16-bit is low the AT/LANTIC Controller will only read data from SD0-7. Even addresses will use RCS1 and MSD0-7, odd addresses will use RCS2 and MSD8-15. If 8/16-bit is high the AT/LANTIC Controller can read from either SD0-7 or SD8-15. Even addresses are read from SD0-7 and written to RAM using RCS1 and MSD0-7. Odd addresses are read from SD8-15 and written to RAM using RCS2 and MSD8-15.

## 6.0 Operation of AT/LANTIC Controller (Continued)

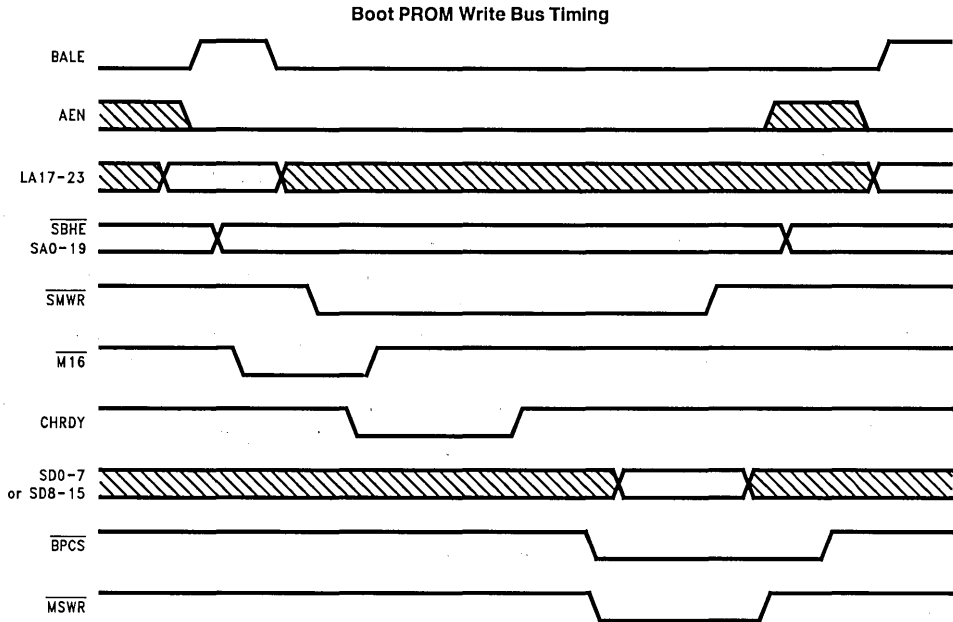

### ISA Bus Boot PROM Access Timing

TL/F/11498-49

This is the type of cycle used to read the boot PROM. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-19 and a  $\overline{\text{SMRD}}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{\text{M16}}$  is only generated if the AT/LANTIC Controller is 1) in shared memory mode AND 2) DWID is high AND 3) 8/16-bit in Control Register 2 is high AND 4) the LA17-23 lines match the corresponding values in Control Register 2. The data will normally be driven onto SD0-7. However, if  $\overline{\text{M16}}$  is generated and the access is to an odd address the data will be driven onto SD8-15. The data will always be taken from MSD0-7.

## 6.0 Operation of AT/LANTIC Controller (Continued)

TL/F/11498-50

This is the type of cycle used to write to the boot PROM. These accesses are entirely asynchronous, with the AT/LANTIC Controller responding when it decodes the correct address on SA0-19 and a  $\overline{SMWR}$ . If AEN is high the cycle will be ignored. CHRDY is deasserted if the AT/LANTIC Controller is not ready to respond and asserted when ready. If it is ready immediately CHRDY is not deasserted.  $\overline{M16}$  is only generated if the AT/LANTIC Controller is 1) in shared memory mode AND 2) DWID is high AND 3) 8/16-bit in Control Register 2 is high AND 4) the LA17-23 lines match the corresponding values in Control Register 2. The data will normally be taken from SD0-7. However, if  $\overline{M16}$  is generated and the access is to an odd address the data will be taken from SD8-15. The data will always be driven onto MSD0-7. The BPWR bit of Configuration Register B must be high to allow write cycles to the boot PROM.

## 6.0 Operation of AT/LANTIC Controller (Continued)

### RAM Access Timing

TL/F/11498-51

This is a memory read cycle executed by the AT/LANTIC Controller's internal DMA. This is used to either load the data transfer port, during a Remote Read in I/O mode, or to load the FIFO, for a transmission on the network, in both modes. This transfer is synchronized to BCLK, which can be either driven from the 20 MHz input on X1 or by the BCLK input. This is selected by the CLKSEL bit in Configuration Register C. If there is 8 kbytes of RAM only  $\overline{RCS1}$  is used, if 16 kbytes are available  $\overline{RCS1}$  and  $\overline{RCS2}$  are used.

TL/F/11498-52

This is a memory write cycle executed by the AT/LANTIC Controller's internal DMA. This is used to either write from the data transfer port, during a Remote Write in I/O mode, or to empty the FIFO, during a reception from the network, in both modes. This transfer is synchronized to BCLK, which can be either driven from the 20 MHz input on X1 or by the BCLK input. This is selected by the CLKSEL bit in Configuration Register C. If there is 8 kbytes of RAM only  $\overline{RCS1}$  is used, if 16 kbytes are available  $\overline{RCS1}$  and  $\overline{RCS2}$  are used.

T32	$\overline{\text{MSWR}}$ Deasserted to MA1–15 Invalid	10		10		ns
T33	$\overline{\text{MSWR}}$ Deasserted to MSD0–15 Invalid (Note 3)	0		0		ns
T34	MSA1–15 valid before $\overline{\text{MSWR}}$ Asserted	20		20		ns
T35a	$\overline{\text{RCS}}$ Asserted to CHRDY Asserted (Note 11, 12)	80		80		ns
T35b	$\overline{\text{BPCS}}$ Asserted to CHRDY Asserted (Note 13)	175		175		ns
T36a	$\overline{\text{MSRD}}$ , $\overline{\text{MSWR}}$ Asserted to CHRDY Asserted (Note 11)	15		15		ns
T36b	$\overline{\text{MSRD}}$ , $\overline{\text{MSWR}}$ Asserted to CHRDY Asserted (Note 13)	150		150		ns
T37	MSA1–15 Valid to CHRDY Asserted (Note 11)	75		75		ns
T38a	Driving Data from SD0–15 on to MSD0–15 to CHRDY Asserted (Note 11)	60		60		ns
T38b	Driving Data from SD0–15 on to MSD0–15 to CHRDY Asserted (Note 13)	260		260		ns

**Note 1:**  $\overline{\text{MT6}}$ ,  $\overline{\text{IOT6}}$  are only asserted for 16-bit transfers.

**Note 2:** CHRDY is only deasserted if the NIC core can not service the access immediately. It is held deasserted until the NIC core is ready, causing the system to insert wait states.

**Note 3:** On 8-bit transfers only 8 bits of MSD0–15 and D0–7 are driven.

**Note 4:** This is the early CHRDY timing, required by some machines, where CHRDY is referenced to BALE. In this mode of operation, under certain circumstances, CHRDY will be asserted for cycles which are not for this device, i.e. memory cycles or I/O cycles where SA0–9 match our address before reaching their valid state. In such a case the time to assert CHRDY, from  $\overline{\text{MRD}}$ ,  $\overline{\text{MWR}}$  or SA0–9 invalid, will be the same as the deassertion time specified.

**Note 5:** This is the standard CHRDY timing where CHRDY is asserted after  $\overline{\text{IORD}}$  or  $\overline{\text{IOWR}}$ .

**Note 6:** Read data valid is referenced to CHRDY when wait states have been inserted.

**Note 7:** If no wait states are inserted read data valid can be measured from  $\overline{\text{IORD}}$ .

**Note 8:** This is a minimum timing with no additional wait states.

**Note 9:** This is the standard  $\overline{\text{IOT6}}$  timing where  $\overline{\text{IOT6}}$  is asserted after a valid address decode.

**Note 10:** This is the late  $\overline{\text{IOT6}}$  timing, required by some machines, where  $\overline{\text{IOT6}}$  is asserted after a valid address decode and  $\overline{\text{IORD}}$  or  $\overline{\text{IOWR}}$  going active.

**Note 11:** This is a timing for a RAM access.

**Note 12:** RCS refers to  $\overline{\text{RCS1}}$  and  $\overline{\text{RCS2}}$ . Depending on the mode of operation either or both can be asserted. See the Functional Bus Timing section for a further explanation.

**Note 13:** This is a timing for a Boot PROM access.

## 8.0 Preliminary Switching Characteristics (Continued)

### RESET Timing

TL/F/11498-55

Symbol	Description	Min	Max	Units
T1	RESET Asserted Until IO Inactive Asserted (Note 1)	400		ns
T2	RESET Asserted Until RegLoad State Entered (Note 2)	415		μs
T3	RESET Deasserted Until RegLoad Deasserted (Note 3)	100		ns
T4	RESET Deasserted Until EELoad State Entered (Note 4)	0		μs
TS	EELoad Width (Note 4)		320	μs

**Note 1:** I/O inactive is not an external signal. It is used here to indicate the length of time RESET must be active before the AT/LANTIC Controller recognizes it, begins to drive the ISA outputs to their inactive state and ignores ISA inputs except RESET.

**Note 2:** RegLoad is not an external signal. It is used here to indicate the length of time RESET must be active before the AT/LANTIC Controller begins configuring. When IOinactive goes active the internal pull-down resistors on the memory support buses are enabled.

**Note 3:** If RegLoad is high the values on the memory support buses are latched into the configuration registers when RESET is deasserted. The pull-down resistors on this bus are enabled until RegLoad is deasserted.

**Note 4:** EELoad is not an external signal, it is used here to indicate when the EEPROM store is loading.

### Serial EEPROM Timing

TL/F/11498-56

Symbol	Description	Min	Max	Units
T1	EECS Setup to SK	150		ns
T2	EECS Hold after SK	250		ns
T3	MSD2 Low Time	450		ns
T4	MSD2 High Time	450		ns
T5	MSD2 Clock Period (Note 1)	1		μs
T6	Data In Setup to MSD2 High	100		ns
T7	Data In Hold from MSD2 High	100		ns
T8	Data Out Valid from MSD2 High		500	ns

**Note 1:** Derived from Crystal Oscillator Tolerance = ±0.01%.

### 8.0 Preliminary Switching Characteristics (Continued)

#### AUI Transmit Timing (End of Packet)

TL/F/11498-57

Symbol	Description	Min	Max	Units
$t_{TOH}$	Transmit Output High before Idle	200		ns
$t_{TOI}$	Transmit Output Idle Time	8000		ns

#### AUI/TPI Receive Timing (End of Packet)

TL/F/11498-58

Symbol	Description	Min	Max	Units
$t_{eop1}$	Receive End of Packet Hold Time after Logic "1" (Note 1)	225		ns
$t_{eop0}$	Receive End of Packet Hold Time after Logic "0" (Note 1)	225		ns

**Note 1:** This parameter is guaranteed by design and is not tested.

## 8.0 Preliminary Switching Characteristics (Continued)

### Link Pulse Timing

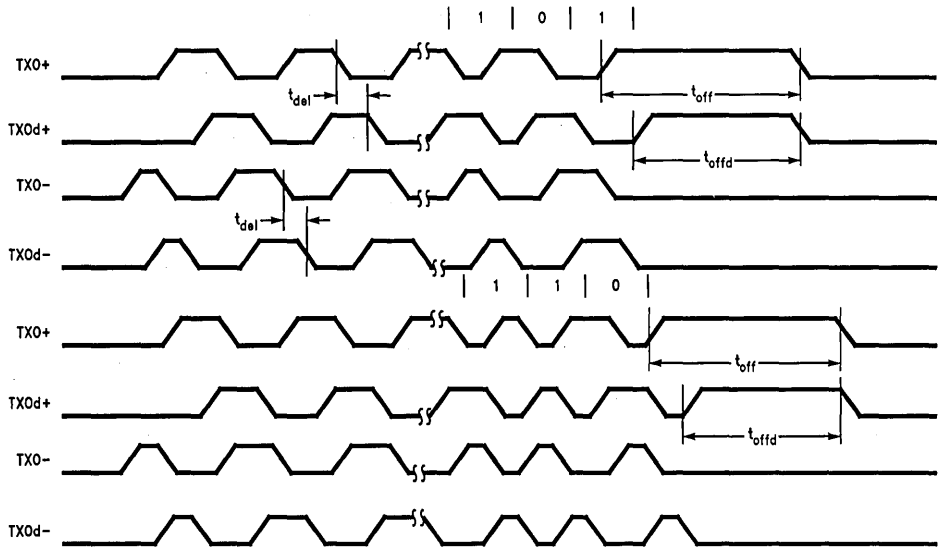

TL/F/11498-59

Symbol	Description	Min	Max	Units
$t_{lp}$	Time between Link Output Pulses	8	24	ns
$t_{lpw}$	Link Integrity Output Pulse Width	80	130	ns

## 8.0 Preliminary Switching Characteristics (Continued)

### TPI Transmit Timing (End of Packet)

TL/F/11498-60

Symbol	Description	Min	Max	Units
$t_{del}$	Pre-Emphasis Output Delay (TXO± to TXOd±) (Note 1)	46	54	ns
$t_{off}$	Transmit Hold Time at End of Packet (TXO±) (Note 1)	250		ns
$t_{offd}$	Transmit Hold Time at End of Packet (TXOd±) (Note 1)	200		ns

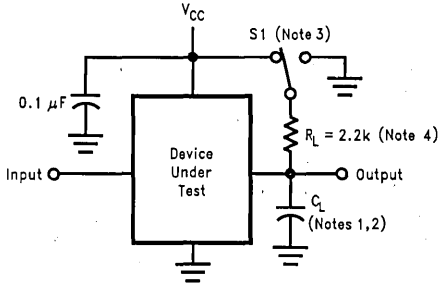

**Note 1:** This parameter is guaranteed by design and is not tested.

## 9.0 AC Timing Test Conditions

Input Pulse Levels (TTL/CMOS)	GND to 3.0V
Input Rise and Fall Times (TTL/CMOS)	5 ns
Input and Output Reference Levels (TTL/CMOS)	1.3V
Input Pulse Levels (Diff.)	-350 mV to -1315 mV
Input and Output Reference Levels (Diff.)	50% Point of the Differential
TRI-STATE Reference Levels	Float ( $\Delta V$ ) $\pm 0.5V$
Output Load (See Figure Below)	

All specifications are valid only if the mandatory isolation is employed and all differential signals are taken to be at the AUI side of the pulse transformer.

### Output Load (See Figure Below)

TL/F/11498-61

**Note 1:** Load Capacitance used depends on output type (includes scope and jig capacitance):  
 For 3SL, MOS, TPI, AUI:  $C_L = 50$  pF.  
 For 3SH, OCH:  $C_L = 240$  pF.

**Note 2:** Specifications which measure delays from an active state to a high impedance state are not guaranteed by production test, but are characterized using 70 pF, and are correlated to determine true driver turn-off time by eliminating inherent R-C delay times in measurements.

**Note 3:** S1 = Open for timing test for push pull outputs.  
 S1 =  $V_{CC}$  for  $V_{OL}$  test.  
 S1 = GND for  $V_{OH}$  test.  
 S1 =  $V_{CC}$  for High Impedance to active low and active low to High Impedance measurements.  
 = GND for High Impedance to active high and active high to High Impedance measurements.

**Note 4:** Pull-up load for CHRDY = 1 k $\Omega$ .  
 IO16 = 300 $\Omega$ .  
 M16 = 300 $\Omega$ .

## Pin Capacitance $T_A = 25^\circ C, f = 1$ MHz

Symbol	Parameter	Typ	Units
$C_{IN}$	Input Capacitance	7	pF
$C_{OUT}$	Output Capacitance	10	pF

### DERATING FACTOR

Output timing is measured with a purely capacitive load of 50 pF, or 240 pF. The following correction factor can be used for other loads (**Note:** This factor is preliminary):

Derating for 3SL, MOS =  $\sim 0.05$  ns/pF

Derating for 3SH, OCL, TPI =  $\sim 0.03$  ns/pF

### AUI Transmit Test Load

TL/F/11498-62

**Note:** In the above diagram, the TX+ and TX- signals are taken from the AUI side of the isolation (pulse transformer). The pulse transformer used for all testing is a 100  $\mu H \pm 0.1\%$  Pulse Engineering PE64103.

## DP83902A ST-NIC™

### Serial Network Interface Controller for Twisted Pair

#### General Description

The DP83902A Serial Network Interface Controller for Twisted Pair (ST-NIC) is a microCMOS VLSI device designed for easy implementation of CSMA/CD local area networks. These include Ethernet (10BASE5), Thin Ethernet (10BASE2) and Twisted-pair Ethernet (10BASE-T). The overall ST-NIC solution provides the Media Access Control (MAC) and Encode-Decode (ENDEC) with an AUI interface, and 10BASE-T transceiver functions in accordance with the IEEE 802.3 standards.

The DP83902A's 10BASE-T transceiver fully complies with the IEEE standard. This functional block incorporates the receiver, transmitter, collision, heartbeat, loopback, jabber, and link integrity blocks as defined in the standard. The transceiver when combined with equalization resistors, transmit/receive filters, and pulse transformers provides a complete physical interface from the DP83902A's ENDEC module and the twisted pair medium.

The integrated ENDEC module allows Manchester encoding and decoding via a differential transceiver and phase lock loop decoder at 10 Mbit/sec. Also included are collision detect translator and diagnostic loopback capability. The ENDEC module interfaces directly to the transceiver module, and also provides a fully IEEE compliant AUI (Attachment Unit Interface) for connection to other media transceivers.

(Continued)

#### Features

- Single chip solution for IEEE 802.3, 10BASE-T
- Integrated controller, ENDEC, and transceiver
- Full AUI interface
- No external precision components required
- 3 levels of loopback supported

#### Transceiver Module

- Integrates transceiver electronics, including:
  - Transmitter and receiver
  - Collision detect, heartbeat and jabber timer
  - Link integrity test
- Link disable and polarity detection/correction
- Integrated smart receive squelch
- Reduced squelch level for extended distance cable operation (100-pin QFP version)

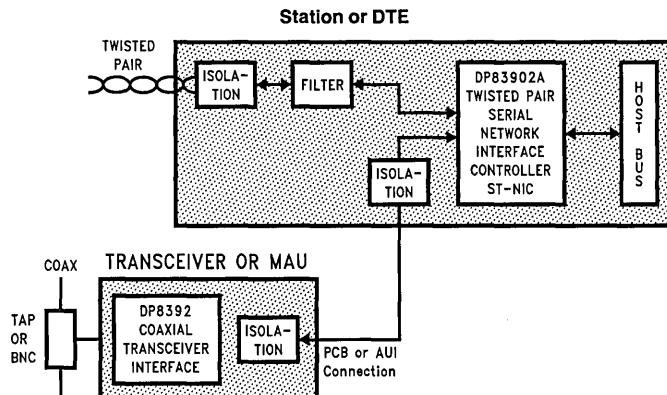

#### ENDEC Module

- 10 Mb/s Manchester encoding/decoding, plus clock recovery
- Transmitter half or full step mode
- Squelch on receive and collision pairs
- Lock time 5 bits typical
- Decodes Manchester data with up to  $\pm 18$  ns jitter

#### MAC/Controller Module

- 100% DP8390 software/hardware compatible
- Dual 16-bit DMA channels
- 16-byte internal FIFO
- Efficient buffer management implementation
- Independent system and network clocks
- Supports physical, multicast and broadcast address filtering
- Network statistics storage

#### 1.0 System Diagram

TL/F/11157-1

## General Description (Continued)

The Media Access Control function which is provided by the Network Interface Control module (NIC) provides simple and efficient packet transmission and reception control by means of unique dual DMA channels and an internal FIFO. Bus arbitration and memory control logic are integrated to reduce board cost and area overheads.

DP83902A provides a comprehensive single chip solution for 10BASE-T IEEE 802.3 networks and is designed for easy interface to other transceivers via the AUI interface.

Due to the inherent constraints of CMOS processing, isolation is required at the AUI differential signal interface for 10BASE5 and 10BASE2 applications. Capacitive or inductive isolation may be used.

## 2.0 Pin Description

PQFP Pin No.	PLCC Pin No.	AVJG Pin No.	Pin Name	I/O	Description
<b>BUS INTERFACE PINS</b>					
95	5	92	INT	O	<b>INTERRUPT:</b> Indicates that the DP83902A requires CPU attention after reception transmission or completion of DMA transfers. The interrupt is cleared by writing to the ISR (Interrupt Status Register). All interrupts are maskable.
96	6	93	WACK	I	<b>WRITE ACKNOWLEDGE:</b> Issued from system to DP83902A to indicate that data has been written to the external latch. The DP83902A will begin a write cycle to place the data in local memory.
98	7	95	PRD	O	<b>PORT READ:</b> Enables data from external latch on to local bus during a memory write cycle to local memory (remote write operation). This allows asynchronous transfer of data from the system memory to local memory.
99, 100, 1, 2	8-11	96, 98-100	RA3-RA0	I	<b>REGISTER ADDRESS:</b> These four pins are used to select a register to be read or written. The state of these inputs is ignored when the DP83902A is not in slave mode (CS high).

1

## 2.0 Pin Description (Continued)

PQFP Pin No.	PLCC Pin No.	AVJG Pin No.	Pin Name	I/O	Description
<b>BUS INTERFACE PINS (Continued)</b>					
4-8, 10-12, 14, 15, 17, 18, 22, 23, 25, 26	12-23, 28-31	2-4, 6, 7, 9-15, 20-23	AD0- AD15	I/O, Z	<b>MULTIPLEXED ADDRESS/DATA BUS:</b> <ul style="list-style-type: none"> <li>Register Access, with DMA inactive, <math>\overline{CS}</math> low and <math>\overline{ACK}</math> returned from DP83902A, pins AD0-AD7 are used to read and write register data. AD8-AD15 float during I/O transfers, <math>\overline{SRD}</math>, <math>\overline{SWR}</math> pins are used to select direction of transfer.</li> <li>Bus Master with BACK input asserted. During t1 of memory cycle AD0-AD15 contain address. During t2, t3, t4 AD0-AD15 contain data (word transfer mode). During t2, t3, t4 AD0-AD7 contain data, AD8-AD15 contain address (byte transfer mode). Direction of transfer is indicated by DP83902A on <math>\overline{MWR}</math>, <math>\overline{MRD}</math> lines.</li> </ul>
27	32	25	ADS0	I/O, Z	<b>ADDRESS STROBE 0:</b> <ul style="list-style-type: none"> <li>Input: with DMA inactive and <math>\overline{CS}</math> low, latches RA0-RA3 inputs on falling edge. If high, data present on RA0-RA3 will flow through latch.</li> <li>Output: When Bus Master, latches address bits (AD0-AD15) to external memory during DMA transfers.</li> </ul>
28	33	26	$\overline{CS}$	I	<b>CHIP SELECT:</b> Chip Select places controller in slave mode for $\mu P$ access to internal registers. Must be valid through data portion of bus cycle. RA0-RA3 are used to select the internal register. $\overline{SWR}$ and $\overline{SRD}$ select direction of data transfer.
29	34	27	$\overline{MWR}$	O, Z	<b>MASTER WRITE STROBE:</b> (Strobe for DMA transfers) Active low during write cycles (t2, t3, tw) to buffer memory. Rising edge coincides with the presence of valid output data. TRI-STATE® until BACK asserted.
30	35	28	$\overline{MRD}$	O, Z	<b>MASTER READ STROBE:</b> (Strobe for DMA transfers) Active during read cycles (t2, t3, tw) to buffer memory. Input data must be valid on rising edge of $\overline{MRD}$ . TRI-STATE until BACK asserted.
31	36	29	$\overline{SWR}$	I	<b>SLAVE WRITE STROBE:</b> Strobe from CPU to write an internal register selected by RA0-RA3. Data is latched into the DP83902A on the rising edge of this input.
32	37	30	$\overline{SRD}$	I	<b>SLAVE READ STROBE:</b> Strobe from CPU to read an internal register selected by RA0-RA3. The register data is output when $\overline{SRD}$ goes low.
33	38	31	$\overline{ACK}$	O	<b>ACKNOWLEDGE:</b> Active low when DP83902A grants access to CPU. Used to insert WAIT states to CPU until DP83902A is synchronized for a register read or write operation.
36	40	34	BSCK	I	<b>BUS CLOCK:</b> This clock is used to establish the period of the DMA memory cycle. Four clock cycles (t1, t2, t3, t4) are used per DMA cycle. DMA transfers can be extended by one BSCK increment using the $\overline{READY}$ input.
37	41	35	$\overline{RACK}$	I	<b>READ ACKNOWLEDGE:</b> Indicates that the system DMA or host CPU has read the data placed in the external latch by the DP83902A. The DP83902A will begin a read cycle to update the latch.
39	42	36	$\overline{PWR}$	O	<b>PORT WRITE:</b> Strobe used to latch data from the DP83902A into external latch for transfer to host memory during Remote Read transfers. The rising edge of $\overline{PWR}$ coincides with the presence of valid data on the local bus.
41	43	37	$\overline{READY}$	I	<b>READY:</b> This pin is set high to insert wait states during a DMA transfer. The DP83902A will sample this signal at t3 during DMA transfers.
42	44	39	PRQ/ ADS1	O, Z	<b>PORT REQUEST/ADDRESS STROBE 1</b> <ul style="list-style-type: none"> <li>32-BIT MODE: If LAS is set in the Data Configuration Register, this line is programmed as ADS1. It is used to strobe addresses A16-A31 into external latches. (A16-A31 are the fixed addresses stored in RSAR0, RSAR1). ADS1 will remain at TRI-STATE until BACK is received.</li> <li>16-BIT MODE: If LAS is not set in the Data Configuration Register, this line is programmed as PRQ and is used for Remote DMA Transfers. The DP83902A initiates a single remote DMA read or write operation by asserting this pin. In this mode PRQ will be a standard logic output.</li> </ul> <p>Note: This line will power up as TRI-STATE until the Data Configuration Register is programmed.</p>

PQFP Pin No.	PLCC Pin No.	AVJG Pin No.	Pin Name	I/O	Description
<b>BUS INTERFACE PINS (Continued)</b>					
43	45	40	BACK	I	<b>BUS ACKNOWLEDGE:</b> Bus Acknowledge is an active high signal indicating that the CPU has granted the bus to the DP83902A. If immediate bus access is desired, BREQ should be tied to BACK. <b>Tying BACK to V<sub>CC</sub> will result in a deadlock.</b>
45	46	42	BREQ	O	<b>BUS REQUEST:</b> Bus Request is an active high signal used to request the bus for DMA transfers. This signal is automatically generated when the FIFO needs servicing.
52	53	50	RESET	I	<b>RESET:</b> Reset is active low and places the DP83902A in a reset mode immediately. No packets are transmitted or received by the DP83902A until STA bit is set. Affects Command Register, Interrupt Mask Register, Data Configuration Register and Transmit Configuration Register. The DP83902A will execute reset within 10 BSCK cycles.
<b>NETWORK INTERFACE PINS</b>					
47	48	45	POL	O	<b>POLARITY:</b> A TTL/MOS active high output. This signal is normally in the low state. When the TPI module detects seven consecutive link pulses or three consecutive received packets with reversed polarity POL, is asserted.
49	50	47	TXE/TX	O	<b>TRANSMIT ENABLE/TRANSMIT:</b> A TTL/MOS active high output. It is asserted for approximately 50 ms whenever the DP83902A transmits data in either AUI or TPI modes.
50	51	48	COL	O	<b>COLLISION:</b> A TTL/MOS active high output. It is asserted for approximately 50 ms whenever the DP83902A detects a collision in either the AUI or TPI modes.
51	52	49	TEST	I	<b>FACTORY TEST INPUT:</b> Used to check the chip's internal functions. This should be tied low during normal operation.
55, 56, 58, 59	54, 55, 56, 57	54, 55, 56, 57	TXO <sub>d-</sub> , TXO <sub>+</sub> , TXO <sub>-</sub> , TXO <sub>d+</sub>	O	<b>TWISTED PAIR TRANSMIT OUTPUTS:</b> These high drive CMOS level outputs are resistively combined external to the chip to produce a differential output signal with equalization to compensate for Intersymbol Interference (ISI) on the twisted pair medium.
64, 65	61, 62	61, 62	RXI <sub>+</sub> , RXI <sub>-</sub>	I	<b>TWISTED PAIR RECEIVE INPUTS:</b> These inputs feed a differential amplifier which passes valid data to the ENDEC module.
69	67	65	GDLNK/ LNKDIS	I/O	<b>GOOD LINK/LINK DISABLE:</b> This pin has a dual function both input and output. The function is latched by the DP83902A on the rising edge of the Reset signal i.e.: on the chip returning to normal operation after reset. As an output this pin is configured as an open drain N-channel device and is suitable for driving a LED. It will be latched as output on removal of chip reset if connected to a LED or left open circuit. Under normal conditions (the twisted pair link is not broken) the output will be low, and the LED will be lit. The open drain output will be switched off if the twisted pair link has been detected to be broken. It is recommended that the color of the LED be green. This output will be pulled high in AUI mode, by an internal resistor of approximately 15 k $\Omega$ . When this pin, which has an internal pull-up resistor to V <sub>DD</sub> , is tied low it becomes an input and the link integrity checking is disabled.
73	—	70	SQSEL	I	<b>TPI SQUELCH SELECT:</b> This pin selects the TPI module input squelch thresholds. When tied low, the input squelch threshold on the RXI $\pm$ inputs complies to 10BASE-T specification. When set high, the RXI $\pm$ input operates with reduced squelch levels, allowing its use with longer lengths of cable or cable with higher losses. If this pin is left unconnected, an internal pulldown causes the ST-NIC's TPI to default to the higher squelch level.
70	68	66	20 MHz	O	<b>20 MHz:</b> This is a TTL/MOS level signal. It is a buffered version of the oscillator X2. It is suitable to drive external logic.
71	69	67	X1	I	<b>EXTERNAL OSCILLATOR INPUT</b>
72	70	69	GND/ X2	I	<b>GROUND/X2:</b> If an oscillator is used, this pin should be tied to ground and if a crystal is used, this pin should be tied directly to the crystal.
74	71	71	SEL	I	<b>MODE SELECT:</b> When high, TX <sub>+</sub> and TX <sub>-</sub> are the same voltage in the idle state. When low, Transmit <sub>+</sub> is positive with respect to Transmit <sub>-</sub> in the idle state, at the transformer's primary.

  - 3) Valor FL1012.

### ST-NIC Twisted Pair Interface

## 4.0 Functional Description (Refer to Figure 1)

### TWISTED PAIR INTERFACE (TPI) MODULE

The TPI consists of five main logical functions:

- The Smart Squelch, responsible for determining when valid data is present on the differential receive inputs (RXI $\pm$ ).
- The Collision function checks for simultaneous transmission and reception of data on the TXO $\pm$  and RXI $\pm$  pins.
- The Link Detector/Generator checks the integrity of the cable connecting the two twisted pair MAUs.
- The Jabber disables the transmitter if it attempts to transmit a longer than legal packet.
- The Tx Driver & Pre-emphasis transmits Manchester encoded data to the twisted pair network via the summing resistors and transformer/filter.

#### SMART SQUELCH

The ST-NIC implements an intelligent receive squelch on the RXI $\pm$  differential inputs to ensure that impulse noise on the receive inputs will not be mistaken for a valid signal.

The squelch circuitry employs a combination of amplitude and timing measurements to determine the validity of data on the twisted pair inputs. There are two squelch levels which are selectable via the SQSEL pin. One mode is 10BASE-T compatible, and the second is reduced squelch mode.

The diagram shows the 10BASE-T mode operation of the smart squelch.

The signal at the start of packet is checked by the smart squelch and any pulses not exceeding the squelch level (either positive or negative, depending upon polarity) will be rejected. Once this first squelch level is overcome correctly the opposite squelch level must then be exceeded within 150 ns. Finally the signal must exceed the original squelch level within a further 150 ns to ensure that the input waveform will not be rejected. The checking procedure results in the loss of typically three bits at the beginning of each packet.

Only after all these conditions have been satisfied will a control signal be generated to indicate to the remainder of the circuitry that valid data is present. At this time the smart squelch circuitry is reset.

Valid data is considered to be present until either squelch level has not been generated for a time longer than 150 ns, indicating End of Packet. Once good data has been detected the squelch levels are reduced to minimize the effect of noise causing premature End of Packet detection.

TL/F/11157-5

The reduced squelch mode functions the same as the 10BASE-T mode except that only the lower level is used for both turn-on and turn-off.

#### COLLISION

A collision is detected by the TPI module when the receive and transmit channels are active simultaneously. If the TPI is receiving when a collision is detected it is reported to the controller immediately. If, however, the TPI is transmitting when a collision is detected the collision is not reported until seven bits have been received while in the collision state. This prevents a collision being reported incorrectly due to noise on the network. The signal to the controller remains for the duration of the collision.

Approximately  $1 \mu\text{s}$  after the transmission of each packet a signal called the Signal Quality Error (SQE) consisting of typically 10 cycles of 10 MHz is generated. This 10 MHz signal, also called the Heartbeat, ensures the continued functioning of the collision circuitry.

#### LINK DETECTOR/GENERATOR

The link generator is a timer circuit that generates a link pulse as defined by the 10BASE-T specification that will be generated by the transmitter section. The pulse which is 100 ns wide is transmitted on the TXO+ output, every 16 ms, in the absence of transmit data.

The pulse is used to check the integrity of the connection to the remote MAU. The link detection circuit checks for valid pulses from the remote MAU and if valid link pulses are not received the link detector will disable the transmit, receive and collision detection functions.

The GDLNK output can directly drive a LED to show that there is a good twisted pair link. For normal conditions the LED will be on. The link integrity function can be disabled as described in the Pin Description Section.

#### JABBER

The jabber timer monitors the transmitter and disables the transmission if the transmitter is active for greater than 26 ms. The transmitter is then disabled for the whole time that the ENDEC module's internal transmit enable is asserted. This signal has to be deasserted for approximately 750 ms (the unjab time) before the Jabber re-enables the transmit outputs.

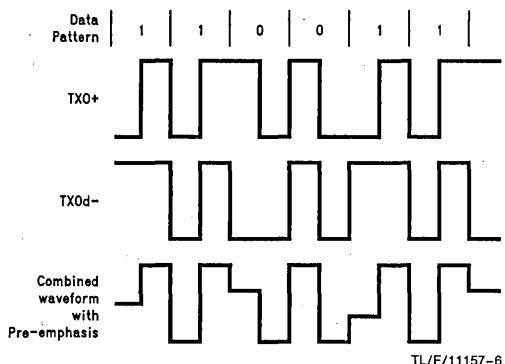

#### TRANSMIT DRIVER

The transmitter consists of four signals, the true and complement Manchester encoded data (TXO $\pm$ ) and these signals delayed by 50 ns (TXOd $\pm$ ).

## 4.0 Functional Description (Continued)

These four signals are resistively combined, TXO+ with TXOd- and TXO- with TXOd+. This is known as digital pre-emphasis and is required to compensate for the twisted pair cable which acts like a low pass filter causing greater attenuation to the 10 MHz (50 ns) pulses of the Manchester encoded waveform than the 5 MHz (100 ns) pulses.

An example of how these signals are combined is shown in the following diagram.

The signal with pre-emphasis shown above is generated by resistively combining TXO+ and TXOd-. This signal along with its complement is passed to the transmit filter.

### STATUS INFORMATION

Status information is provided by the ST-NIC on the CRS/RX, TXE/TX, COL and POL outputs as described in the pin description table. These outputs are suitable for driving status LEDs via an appropriate driver circuit.

The POL output is normally low, and will be driven high when seven consecutive link pulses or three consecutive receive packets are detected with reversed polarity. A polarity reversal can be caused by a wiring error at either end of the TPI cable. On detection of a polarity reversal the condition is latched and POL is asserted. The TPI corrects for this error internally and will decode received data correctly, eliminating the need to correct the wiring error.

### ENCODER/DECODER (ENDEC) MODULE

The ENDEC consists of three main logical blocks:

- The Manchester encoder accepts NRZ data from the controller, encodes the data to Manchester, and transmits it differentially to the transceiver, through the differential transmit driver.
- The Manchester decoder receives Manchester data from the transceiver, converts it to NRZ data and clock pulses, and sends it to the controller.
- The collision translator indicates to the controller the presence of a valid 10 MHz collision signal to the PLL.

### MANCHESTER ENCODER AND DIFFERENTIAL DRIVER

The differential transmit pair, on the secondary of the transformer, drives up to 50 meters of twisted pair AUI cable. These outputs are source followers which require two 270 $\Omega$  pull-down resistors to ground.

The DP83902A allows both half-step and full-step to be compatible with Ethernet and IEEE 802.3. With the SEL pin low (for Ethernet I). Transmit+ is positive with respect to

Transmit- during idle; with SEL high (for IEEE 802.3), Transmit+ and Transmit- are equal in the idle state. This provides zero differential voltage to operate with transformer coupled loads.

### MANCHESTER DECODER

The decoder consists of a differential receiver and a PLL to separate a Manchester decoded data stream into internal clock signals and data. The differential input must be externally terminated with two 39 $\Omega$  resistors connected in series if the standard 78 $\Omega$  transceiver drop cable is used. In thin Ethernet applications, these resistors are optional. To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with levels less than -175 mV. Signals more negative than -300 mV are decoded. Data becomes valid typically within 5 bit times. The DP83902A may tolerate bit jitter up to 18 ns in the received data. The decoder detects the end of a frame when no more mid-bit transitions are detected.

### COLLISION TRANSLATOR

When in AUI mode, when the Ethernet transceiver (DP8392 CT) detects a collision, it generates a 10 MHz signal to the differential collision inputs (CD $\pm$ ) of the DP83902A. When these inputs are detected active, the DP83902A uses this signal to back off its current transmission and reschedule another one.

The collision differential inputs are terminated the same way as the differential receive inputs. The squelch circuitry is also similar, rejecting pulses with levels less than -175 mV.

### CRYSTAL/OSCILLATOR OPERATION

#### OSCILLATOR

The oscillator is controlled by a 20 MHz parallel resonant crystal connected between X1 and X2 or by an external clock on X1. The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock for the controller. The oscillator also provides internal clock signals to the encoding and decoding circuits.

**Note:** When X1 is being driven by an external oscillator, X2 MUST be grounded.

#### Crystal Specifications

Resonant Frequency	20 MHz
Tolerance	$\pm 0.005\%$ at 25°C
Stability	$\pm 0.005\%$ at 0°C-70°C
Type	AT Cut
Circuit	Parallel Resonance
Max ESR	25 $\Omega$
Crystal Load Capacitor	20 pF

The 20 MHz crystal connection to the DP83902 requires special care. The IEEE 802.3 standard requires the transmitted signal frequency to be accurate within  $\pm 0.01\%$ . Stray capacitance can shift the crystal's frequency out of range and cause transmitted frequency to exceed its 0.01% tolerance. The frequency marked on the crystal is usually measured with a fixed load capacitance specified in the crystal's data sheet, typically 20 pF.

## 4.0 Functional Description (Continued)

In order to prevent distortion on the transmitted frequency, the total capacitance seen by the crystal should equal the total load capacitance. On a standard parallel set-up as shown in the diagram below, the 2 load caps C1 and C2 should equal 2C1, the spec load cap, (due to the capacitors acting in series) less any stray capacitances.

Thus the trim capacitors required can be calculated as follows:

$C1 = 2XC1 - (Cb1 + Cd1)$  Where Cb1 = Board cap on X1 and Cd1 = X1 dev cap

$C2 = 2XC1 - (Cb2 + Cd2)$  Where Cb2 = Board cap on X2 and Cd2 = X2 dev cap

The value of STNIC pins X1 and X2 is in the region of 5 pF.

### NIC (Media Access Control) MODULE

#### RECEIVE DESERIALIZER

The Receive Deserializer is activated when the input signal Carrier Sense is asserted to allow incoming bits to be shifted into the shift register by the receive clock. The serial receive data is also routed to the CRC generator/checker. The Receive Deserializer includes a synch detector which detects the SFD (Start of Frame Delimiter) to establish where byte boundaries within the serial bit stream are located. After every eight receive clocks, the byte wide data is transferred to the 16-byte FIFO and the Receive Byte Count is incremented. The first six bytes after the SFD are checked for valid comparison by the Address Recognition Logic. If the Address Recognition Logic does not recognize the packet, the FIFO is cleared.

#### CRC GENERATOR/CHECKER

During transmission, the CRC logic generates a local CRC field for the transmitted bit sequence. The CRC encodes all fields after the SFD. The CRC is shifted out MSB first following the last transmit byte. During reception the CRC logic generates a CRC field from the incoming packet. This local CRC is serially compared to the incoming CRC appended to the end of the packet by the transmitting node. If the local and received CRC match, a specific pattern will be generated and decoded to indicate no data errors. Transmission errors result in different pattern and are detected, resulting in rejection of a packet (if so programmed).

#### TRANSMIT SERIALIZER

The Transmit Serializer reads parallel data from the FIFO and serializes it for transmission. The serializer is clocked by the transmit clock generated internally. The serial data is also shifted into the CRC generator/checker. At the beginning of each transmission, the Preamble and Synch Generator append 62 bits of 1,0 preamble and a 1,1 synch pattern. After the last data byte of the packet has been serialized the 32-bit FCS field is shifted directly out of the CRC generator. In the event of a collision the Preamble and Synch generators are used to generate a 32-bit JAM pattern of all 1's.

#### ADDRESS RECOGNITION LOGIC

The address recognition logic compares the Destination Address Field (first 6 bytes of the received packet) to the Physical address registers stored in the Address Register Array. If any one of the six bytes does not match the pre-programmed physical address, the Protocol Control Logic rejects the packet. All multicast destination addresses are filtered using a hashing technique. (See register description.) If the multicast address indexes a bit that has been set in the filter bit array of the Multicast Address Register Array the packet is accepted, otherwise it is rejected by the Protocol Control Logic. Each destination address is also checked for all 1's which is the reserved broadcast address.

#### FIFO AND BUS OPERATIONS

##### Overview

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the ST-NIC contains a 16-byte FIFO for buffering data between the media. The FIFO threshold is programmable. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

FIFO underruns or overruns are caused by two conditions: (1) the bus latency is so long that the FIFO has filled (or emptied) from the network before the local DMA has serviced the FIFO and (2) the bus latency has slowed the throughput of the local DMA to a point where it is slower than the network data rate (10 Mbit/sec). This second condition is also dependent upon DMA clock and word width (byte wide or word wide). The worst case condition ultimately limits the overall bus latency which the ST-NIC can tolerate.

##### Beginning of Receive

At the beginning of reception, the ST-NIC stores the entire Address field of each incoming packet in the FIFO to determine whether the address matches the ST-NIC's Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time to when BREQ is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu$ s. This operation affects the bus latencies at 2- and 4-byte thresholds during the first receive BREQ since the FIFO must be filled to 8 bytes (or 4 words) before issuing a BREQ.

##### End of Receive

When the end of a packet is detected by the ENDEC module, the ST-NIC enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet. The ST-NIC holds onto the bus for the entire sequence. The longest time BREQ may be extended occurs when a packet ends just as the ST-NIC performs its last FIFO burst. The ST-NIC, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completes by writing the header information to memory. The following steps occur during this sequence.

1. ST-NIC issues BREQ because the FIFO threshold has been reached.
2. During the burst, packet ends, resulting in BREQ extended.

### 4.0 Functional Description (Continued)

3. ST-NIC flushes remaining bytes from FIFO.
4. ST-NIC performs internal processing to prepare for writing the header.
5. ST-NIC writes 4-byte (2-word) header.
6. ST-NIC de-asserts BREQ.

#### FIFO Threshold Detection

To assure that no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the  $n + 1$  byte has entered the FIFO; thus, with an 8-byte threshold, the ST-NIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until  $n + 2$  bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to an 8-byte threshold), BREQ is issued when the 10th byte has entered the FIFO.

#### Beginning of Transmit

Before transmitting, the ST-NIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next BREQ is not issued until after the ST-NIC actually begins transmitting data, i.e., after SFD.

#### Reading the FIFO

During normal operation, the FIFO must not be read. The ST-NIC will not issue an ACKnowledge back to the CPU if the FIFO is read. The FIFO should only be read during loop-back diagnostics.

#### PROTOCOL PLA

The protocol PLA is responsible for implementing the IEEE 802.3 protocol, including collision recovery with random backoff. The Protocol PLA also formats packets during transmission and strips preamble and synch during reception.

#### DMA AND BUFFER CONTROL LOGIC

The DMA and Buffer Control Logic is used to control two 16-bit DMA channels. During reception, the local DMA stores packets in a receive buffer ring, located in buffer memory. During transmission the Local DMA uses programmed pointer and length registers to transfer a packet from local buffer memory to the FIFO. A second DMA channel is used as a slave DMA to transfer data between the local buffer memory and the host system. The Local DMA and Remote DMA are internally arbitrated, with the Local DMA channel having highest priority. Both DMA channels use a common external bus clock to generate all required

bus timing. External arbitration is performed with a standard bus request, bus acknowledge handshake protocol.

### 5.0 Transmit/Receive Packet Encapsulation/Decapsulation

A standard IEEE 802.3 packet consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data, and Frame Check Sequence (FCS). The typical format is shown in *Figure 2*. The packets are Manchester encoded and decoded by the ENDEC module and transferred serially to the NIC module using NRZ data with a clock. All fields are of fixed length except for the data field. The ST-NIC generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

#### PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted each packet contains 62 bits of alternating 1,0 preamble. Some of this preamble will be lost as the packet travels through the network. The preamble field is stripped by the NIC module. Byte alignment is performed with the Start of Frame Delimiter (SFD) pattern which consists of two consecutive 1's. The ST-NIC does not treat the SFD pattern as a byte, it detects only the two bit pattern. This allows any preceding preamble within the SFD to be used for phase locking.

#### DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted packets from reaching a node. There are three types of address formats supported by the ST-NIC: physical, multicast and broadcast. The physical address is a unique address that corresponds only to a single node. All physical addresses have an MSB of "0". These addresses are compared to the internally stored physical address registers. Each bit in the destination address must match in order for the ST-NIC to accept the packet. Multicast addresses begin with an MSB of "1". The ST-NIC filters multicast addresses using a standard hashing algorithm that maps all multicast addresses into a 6-bit value. This 6-bit value indexes a 64-bit array that filters the value. If the address consists of all 1's it is a broadcast address, indicating that the packet is intended for all nodes. A promiscuous mode allows reception of all packets: the destination address is not required to match any filters. Physical, broadcast, multicast, and promiscuous address modes can be selected.

TL/F/11157-7

FIGURE 2

## 5.0 Transmit/Receive Packet Encapsulation/Decapsulation

(Continued)

### SOURCE ADDRESS

The source address is the physical address of the node that sent the packet. Source addresses cannot be multicast or broadcast addresses. This field is simply passed to buffer memory.

### LENGTH/TYPE FIELD

The 2-byte length field indicates the number of bytes that are contained in the data field of the packet. This field is not interpreted by the ST-NIC.

### DATA FIELD

The data field consists of anywhere from 46 to 1500 bytes. Messages longer than 1500 bytes need to be broken into multiple packets. Messages shorter than 46 bytes will require appending a pad to bring the data field to the minimum length of 46 bytes. If the data field is padded, the number of valid data bytes is indicated in the length field. **The ST-NIC does not strip or append pad bytes for short packets, or check for oversize packets.**

### FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of errors when a packet is received. During reception, error free packets result in a specific pattern in the CRC generator. Packets with improper CRC will be rejected. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X^1 + 1$ ) polynomial is used for the CRC calculations.

## 6.0 Direct Memory Access Control (DMA)

The DMA capabilities of the ST-NIC greatly simplify the use of the DP83902A in typical configurations. The local DMA channel transfers data between the FIFO and memory. On transmission, the packet is DMAed from memory to the FIFO in bursts. Should a collision occur (up to 15 times), the packet is retransmitted with no processor intervention. On reception, packets are DMAed from the FIFO to the receive buffer ring (as explained below).

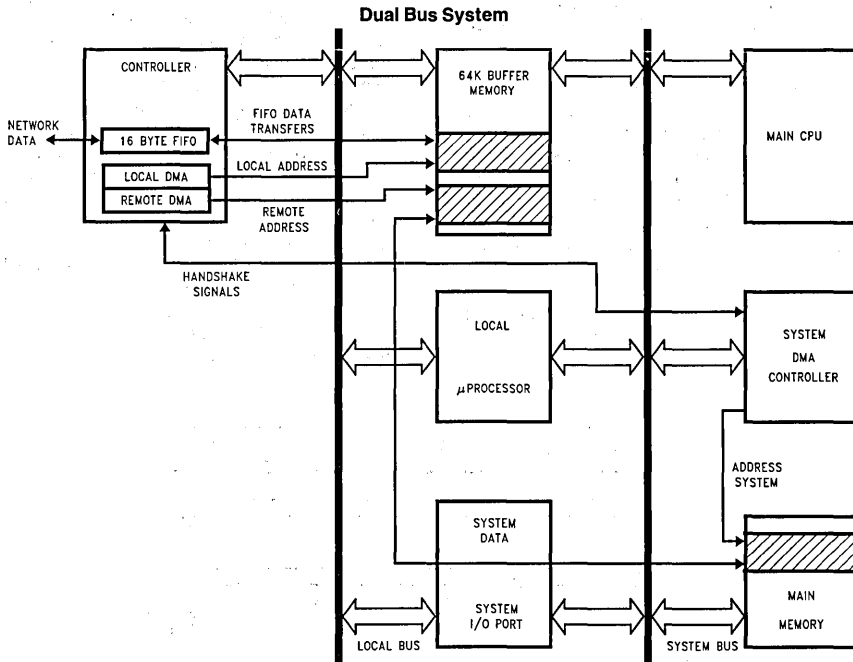

dA remote DMA channel is also provided on the ST-NIC to accomplish transfers between a buffer memory and system memory. The two DMA channels can alternatively be combined to form a single 32-bit address with 8- or 16-bit data.

### DUAL DMA CONFIGURATION

An example configuration using both the local and remote DMA channels is shown below. Network activity is isolated on a local bus, where the ST-NIC's local DMA channel performs burst transfers between the buffer memory and the ST-NIC's FIFO. The Remote DMA transfers data between the buffer memory and the host memory via a bidirectional I/O port. The Remote DMA provides local addressing capability and is used as a slave DMA by the host. Host side addressing must be provided by a host DMA or the CPU. The ST-NIC allows Local and Remote DMA operations to be interleaved.

### SINGLE CHANNEL DMA OPERATION

If desirable, the two DMA channels can be combined to provide a 32-bit DMA address. The upper 16 bits of the 32-bit address are static and are used to point to a 64 kbyte (or 32k word) page of memory where packets are to be received and transmitted.

## 7.0 Packet Reception

The Local DMA receive channel uses a Buffer Ring Structure comprised of a series of contiguous fixed length 256-byte (128 word) buffers for storage of received packets. The location of the Receive Buffer Ring is programmed in two registers, a Page Start and a Page Stop Register. Ethernet packets consist of a distribution of shorter link control packets and longer data packets, the 256-byte buffer length provides a good compromise between short packets and longer packets to most efficiently use memory. In addition these buffers provide memory resources for storage of back-to-back packets in loaded networks. The assignment of buffers for storing packets is controlled by Buffer Management Logic in the ST-NIC. The Buffer Management Log-

ic provides three basic functions: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of buffer pages that have been read by the host.

At initialization, a portion of the 64 kbyte (or 32k word) address space is reserved for the receive buffer ring. Two 8-bit registers, the Page Start Address Register (PSTART) and the Page Stop Address Register (PSTOP) define the physical boundaries of where the buffers reside. The ST-NIC treats the list of buffers as a logical ring; whenever the DMA address reaches the Page Stop Address, the DMA is reset to the Page Start Address.

TL/F/11157-9

## 7.0 Packet Reception (Continued)

### INITIALIZATION OF THE BUFFER RING

Two static registers and two working registers control the operation of the Buffer Ring. These are the Page Start Register, Page Stop Register (both described previously), the Current Page Register and the Boundary Pointer Register. The Current Page Register points to the first buffer used to store a packet and is used to restore the DMA for writing status to the Buffer Ring or for restoring the DMA address in the event of a Runt packet, a CRC, or Frame Alignment error. The Boundary Register points to the first packet in the Ring not yet read by the host. If the local DMA address ever reaches the Boundary, reception is aborted. The Boundary Pointer is also used to initialize the Remote DMA for remov-

ing a packet and is advanced when a packet is removed. A simple analogy to remember the function of these registers is that the Current Page Register acts as a Write Pointer and the Boundary Pointer acts as a Read Pointer.

**Note:** At initialization, the Page Start Register value should be loaded into both Current Page Register and the Boundary Pointer Register.

**Note:** The Page Start Register must not be initialized to 00H.

### BEGINNING OF RECEPTION

When the first packet begins arriving the ST-NIC begins storing the packet at the location pointed to by the Current Page Register. An offset of 4 bytes is saved in this first buffer to allow room for storing receive status corresponding to this packet.

TL/F/11157-10

TL/F/11157-11

## 7.0 Packet Reception (Continued)

### LINKING RECEIVE BUFFER PAGES

If the length of the packet exhausts the first 256-byte buffer, the DMA performs a forward link to the next buffer to store the remainder of the packet. For a maximum length packet the buffer logic will link six buffers to store the entire packet. Buffers cannot be skipped when linking, therefore a packet will always be stored in contiguous buffers. Before the next buffer can be linked, the Buffer Management Logic performs two comparisons. The first comparison tests for equality between the DMA address of the next buffer and the contents of the Page Stop Register. If the buffer address equals the Page Stop Register, the buffer management logic will restore the DMA to the first buffer in the

Receive Buffer Ring value programmed in the Page Start Address Register. The second comparison tests for equality between the DMA address of the next buffer address and the contents of the Boundary Pointer Register. If the two values are equal the reception is aborted. The Boundary Pointer Register can be used to protect against overwriting any area in the receive buffer ring that has not yet been read. When linking buffers, buffer management will never cross this pointer, effectively avoiding any overwrites. If the buffer address does not match either the Boundary Pointer or Page Stop Address, the link to the next buffer is performed.

- 1) Check for = to PSTOP
- 2) Check for = to Boundary

TL/F/11157-12

## 7.0 Packet Reception (Continued)

### Buffer Ring Overflow

If the Buffer Ring has been filled and the DMA reaches the Boundary Pointer Address, reception of the incoming packet will be aborted by the ST-NIC. Thus, the packets previously received and still contained in the Ring will not be destroyed.

In heavily loaded network which cause overflows of the Receive Buffer Ring, the ST-NIC may disable the local DMA and suspend further receptions even if the Boundary register is advanced beyond the Current register. To guarantee this will not happen, a software reset must be issued during all Receive Buffer Ring overflows (indicated by the OVW bit in the Interrupt Status Register). The following procedure is required to recover from a Receiver Buffer Ring Overflow.

If this routine is not adhered to, the ST-NIC may act in an unpredictable manner. It should also be noted that it is not permissible to service an overflow interrupt by continuing to empty packets from the receive buffer without implementing the prescribed overflow routine. A flow chart of the ST-NIC's overflow routine follows.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

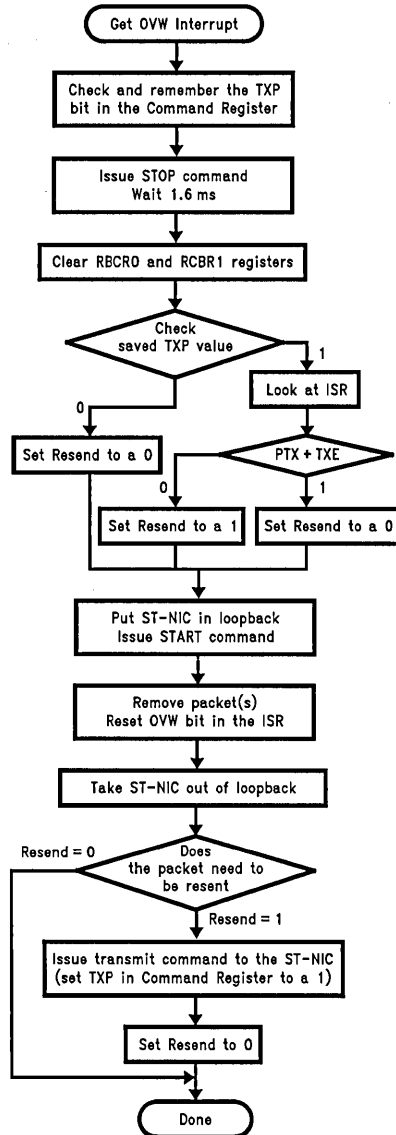

1. Read and store the value of the TXP bit in the ST-NIC Command Register.
2. Issue the STOP command to the ST-NIC. This is accomplished by setting the STP bit in the ST-NIC's Command Register. Writing 21H to the Command Register will stop the ST-NIC.
3. Wait for at least 1.6 ms. Since the ST-NIC will complete any transmission or reception that is in progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommended that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.
4. Clear the ST-NIC's Remote Byte Count registers (RBCR0 and RBCR1).
5. Read the stored value of the TXP bit from step 1, above. If this value is a 0, set the "Resend" variable to a 0 and jump to step 6. If this value is a 1, read the ST-NIC's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 1 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

If this value is a 1, read the ST-NIC's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 1 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the ST-NIC's ISR is read to determine whether or not the packet was recognized by the ST-NIC. If neither the PTX nor TXE bit was set, then the packet will essentially be lost and re-transmitted only after a time-out takes place in the upper level software. By determining that the packet was lost at the driver level, a transmit command can be reissued to

the ST-NIC once the overflow routine is completed (as in step 11). Also, it is possible for the ST-NIC to defer indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the ST-NIC to operate correctly.

**Overflow Routine Flow Chart**

TL/F/11157-57

## 7.0 Packet Reception (Continued)

6. Place the ST-NIC in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to "0,1" or "1,0", respectively.
  7. Issue the START command to the ST-NIC. This can be accomplished by writing 22H to the Command Register. This is necessary to activate the ST-NIC's Remote DMA channel.
  8. Remove one or more packets from the receive buffer ring.
  9. Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.
  10. Take the ST-NIC out of loopback. This is done by writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)
  11. If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by writing a value of 26H to the Command Register. If the "Resend" variable is 0, nothing needs to be done.
- Note 1:** If Remote DMA is not being used, the ST-NIC does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7.
- Note 2:** When the ST-NIC is in STOP mode, the Missed Talley Counter is disabled

TL/F/11157-13

## 7.0 Packet Reception (Continued)

### Enabling the ST-NIC On An Active Network

After the ST-NIC has been initialized the procedure for disabling and then re-enabling the ST-NIC on the network is similar to handling Receive Buffer Ring overflow as described previously.

1. Program Command Register for page 0 (Command Register = 21H)
2. Initialize Data Configuration Register (DCR)
3. Clear Remote Byte Count Registers (RBCR0, RBCR1)
4. Initialize Receive Configuration Register (RCR)
5. Place the ST-NIC in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
6. Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
7. Clear Interrupt Status Register (ISR) by writing 0FFH to it.
8. Initialize Interrupt Mask Register (IMR)
9. Program Command Register for page 1 (Command Register = 61H)
  - i. Initialize Physical Address Registers (PAR0-PAR5)
  - ii. Initialize Multicast Address Registers (MAR0-MAR7)
  - iii. Initialize CURRENT pointer

10. Put ST-NIC in START mode (Command Register = 22H). The local receive DMA is still not active since the ST-NIC is in LOOPBACK.

11. Initialize the Transmit Configuration for the intended value. The ST-NIC is now ready for transmission and reception.

### END OF PACKET OPERATIONS

At the end of the packet the ST-NIC determines whether the received packet is to be accepted or rejected. It either branches to a routine to store the Buffer Header or to another routine that recovers the buffers used to store the packet.

### SUCCESSFUL RECEPTION

If the packet is successfully received, the DMA is restored to the first buffer used to store the packet (pointed to by the Current Page Register). The DMA then stores the Receive Status, a Pointer to where the next packet will be stored (Buffer 4) and the number of received bytes. Note that the remaining bytes in the last buffer are discarded and reception of the next packet begins on the next empty 256-byte buffer boundary. The Current Page Register is then initialized to the next available buffer in the Buffer Ring. (The location of the next buffer had been previously calculated and temporarily stored in an internal scratchpad register.)

Termination of Received Packet—Packet Accepted

TL/F/11157-14

## 7.0 Packet Reception (Continued)

### BUFFER RECOVERY FOR REJECTED PACKETS

If the packet is a runt packet or contains CRC or Frame Alignment errors, it is rejected. The buffer management logic resets the DMA back to the first buffer page used to store the packet (pointed to by CURR), recovering all buffers that had been used to store the rejected packet. This operation will not be performed if the ST-NIC is programmed to accept either runt packets or packets with CRC or Frame Alignment

errors. The received CRC is always stored in buffer memory after the last byte of received data for the packet.

### Error Recovery

If the packet is rejected as shown, the DMA is restored by the ST-NIC by reprogramming the DMA starting address pointed to by the Current Page Register.

Termination of Receive Packet—Packet Reject

TL/F/11157-15

## 7.0 Packet Reception (Continued)

### REMOVING PACKETS FROM THE RING

Packets are removed from the ring using the Remote DMA or an external device. When using the Remote DMA the Send Packet command can be used. This programs the Remote DMA to automatically remove the received packet pointed to by the Boundary Pointer. At the end of the transfer, the ST-NIC moves the Boundary Pointer, freeing additional buffers for reception. The Boundary Pointer can also be moved manually by programming the Boundary Register.

The ST-NIC knows the difference between an empty buffer ring and a full buffer ring. This situation is seen when the Boundary Pointer (BNDRY) and the Current Page Pointer (CURR) point to the same address. If BNDRY caught up with CURR the buffer is empty and if CURR caught up with BNDRY the buffer is full.

### STORAGE FORMAT FOR RECEIVED PACKETS

The following diagrams describe the format for how received packets are placed into memory by the local DMA channel. These modes are selected in the Data Configuration Register.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 0		Receive Byte Count 1	
Byte 1		Byte 2	

BOS = 1, WTS = 1 in Data Configuration Register. This format is used with 680x0 type processors. (Note: The Receive Count ordering remains the same for BOS = 0 or 1.)

Receive Status
Next Packet Pointer
Receive Byte Count 0
Receive Byte Count 1
Byte 0
Byte 1

BOS = 0, WTS = 0 in Data Configuration Register. This format is used with general 8-bit processors.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 1		Receive Byte Count 0	
Byte 2		Byte 1	

BOS = 0, WTS = 1 in Data Configuration Register. This format is used with Series 32xxx, or 680x0 processors.

TL/F/11157-16

## 8.0 Packet Transmission

The Local DMA is also used during transmission of a packet. Three registers control the DMA transfer during transmission, a Transmit Page Start Address Register (TPSR) and the Transmit Byte Count Registers (TBCR0, 1). When the ST-NIC receives a command to transmit the packet pointed to by these registers, buffer memory data will be moved into the FIFO as required during transmission. The ST-NIC will generate and append the preamble, synch and CRC fields.

### General Transmit Packet Format

Transmit	Destination Address	6 Bytes
Byte	Source Address	6 Bytes
Count	Type/Length	2 Bytes
TBCR0, 1	Data Pad (If Data < 46 Bytes)	≥ 46 Bytes

### TRANSMIT PACKET ASSEMBLY

The ST-NIC requires a contiguous assembled packet with the format shown. The transmit byte count includes the Destination Address, Source Address, Length Field and Data. It does not include preamble and CRC. When transmitting data smaller than 46 bytes, the packet must be padded to a minimum size of 64 bytes. The programmer is responsible for adding and stripping pad bytes.

### TRANSMISSION

Prior to transmission, the TPSR (Transmit Page Start Register) and TBCR0, TBCR1 (Transmit Byte Count Registers) must be initialized. To initiate transmission of the packet the TXP bit in the Command Register is set. The Transmit Status Register (TSR) is cleared and the ST-NIC begins to prefetch transmit data from memory (unless the ST-NIC is currently receiving). If the interframe gap has timed out the ST-NIC will begin transmission.

### CONDITIONS REQUIRED TO BEGIN TRANSMISSION

In order to transmit a packet, the following three conditions must be met:

1. The Interframe Gap Timer has timed out the first 6.4  $\mu$ s of the Interframe Gap.
2. At least one byte has entered the FIFO. (This indicates that the burst transfer has been started.)
3. If a collision has been detected the backoff timer has expired.

In typical systems the ST-NIC prefetches the first burst of bytes before the 6.4  $\mu$ s timer expires. The time during which ST-NIC transmits preamble can also be used to load the FIFO.

**Note:** If carrier sense is asserted before a byte has been loaded into the FIFO, the ST-NIC will become a receiver.

### COLLISION RECOVERY

During transmission, the Buffer Management logic monitors the transmit circuitry to determine if a collision has occurred. If a collision is detected, the Buffer Management logic will reset the FIFO and restore the Transmit DMA pointers for retransmission of the packet. The COL bit will be set in the TSR and the NCR (Number of Collisions Register) will be incremented. If 15 retransmissions each result in a collision the transmission will be aborted and the ABT bit in the TSR will be set.

**Note:** NCR reads as zeroes if excessive collisions are encountered.

### TRANSMIT PACKET ASSEMBLY FORMAT

The following diagrams describe the format for how packets must be assembled prior to transmission for different byte ordering schemes. The various formats are selected in the Data Configuration Register.

D15	D8 D7	D0
Destination Address 1	Destination Address 0	
Destination Address 3	Destination Address 2	
Destination Address 5	Destination Address 4	
Source Address 1	Source Address 0	
Source Address 3	Source Address 2	
Source Address 5	Source Address 4	
Type/Length 1	Type/Length 0	
Data 1	Data 0	

BOS = 0, WTS = 1 in Data Configuration Register.

This format is used with Series 32xxx, or 808xx processors.

D15	D8 D7	D0
Destination Address 0	Destination Address 1	
Destination Address 2	Destination Address 3	
Destination Address 4	Destination Address 5	
Source Address 0	Source Address 1	
Source Address 2	Source Address 3	
Source Address 4	Source Address 5	
Type/Length 0	Type/Length 1	
Data 0	Data 1	

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with 680x0 type processors.

D1	D0
Destination Address 0	
Destination Address 1	
Destination Address 2	
Destination Address 3	
Destination Address 4	
Destination Address 5	
Source Address 0	
Source Address 1	
Source Address 2	
Source Address 3	
Source Address 4	
Source Address 5	

BOS = 0, WTS = 0 in Data Configuration Register.

This format is used with general 8-bit processors.

**Note:** All examples above will result in a transmission of a packet in order of DA0, DA1, DA2, DA3 ... bits within each byte will be transmitted least significant bit first.

DA = Destination Address.

## 9.0 Remote DMA

The Remote DMA channel is used to both assemble packets for transmission, and to remove received packets from the Receive Buffer Ring. It may also be used as a general purpose slave DMA channel for moving blocks of data or commands between host memory and local buffer memory. There are three modes of operation, Remote Write, Remote Read, or Send Packet.

Two register pairs are used to control the Remote DMA, a Remote Start Address (RSAR0, RSAR1) register pair and a Remote Byte Count (RBCR0, RBCR1) register pair. The Start Address Register pair points to the beginning of the block to be moved while the Byte Count Register pair is used to indicate the number of bytes to be transferred. Full handshake logic is provided to move data between local buffer memory and a bidirectional I/O port.

### REMOTE WRITE

A Remote Write transfer is used to move a block of data from the host into local buffer memory. The Remote DMA will read data from the I/O port and sequentially write it to local buffer memory beginning at the Remote Start Address. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

### REMOTE READ

A Remote Read transfer is used to move a block of data from local buffer memory to the host. The Remote DMA will

sequentially read data from the local buffer memory, beginning at the Remote Start Address, and write data to the I/O port. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

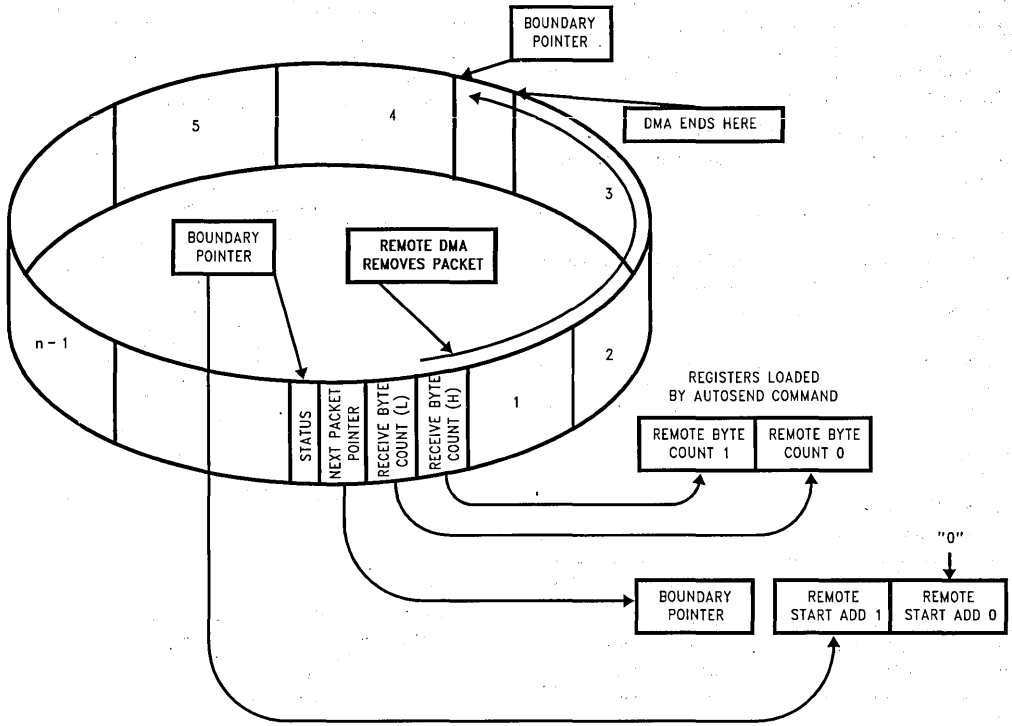

### SEND PACKET COMMAND

The Remote DMA channel can be automatically initialized to transfer a single packet from the Receive Buffer Ring. The CPU begins this transfer by issuing a "Send Packet" Command. The DMA will be initialized to the value of the Boundary Pointer Register and the Remote Byte Count Register pair (RBCR0, RBCR1) will be initialized to the value of the Receive Byte Count fields found in the Buffer Header of each packet. After the data is transferred, the Boundary Pointer is advanced to allow the buffers to be used for new receive packets. The Remote Read will terminate when the Byte Count equals zero. The Remote DMA is then prepared to read the next packet from the Receive Buffer Ring. If the DMA pointer crosses the Page Stop Register, it is reset to the Page Start Address. This allows the Remote DMA to remove packets that have wrapped around to the top of the Receive Buffer Ring.

**Note 1:** In order for the ST-NIC to correctly execute the Send Packet Command, the upper Remote Byte Count Register (RBCR1) must first be loaded with 0FH.

**Note 2:** The Send Packet command cannot be used with 680x0 type processors.

Remote DMA Autoinitialization from Buffer Ring

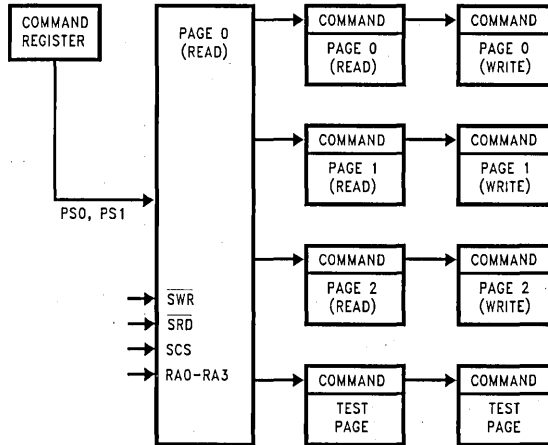

## 10.0 Internal Registers

All registers are 8-bit wide and mapped into four pages which are selected in the Command Register (PS0, PS1). Pins RA0-RA3 are used to address registers within each page. Page 0 registers are those registers which are com-

monly accessed during ST-NIC operation while page 1 registers are used primarily for initialization. The registers are partitioned to avoid having to perform two write/read cycles to access commonly used registers.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS

#### COMMAND REGISTER (CR) 00H (READ/WRITE)

The Command Register is used to initiate transmissions, enable or disable Remote DMA operations and to select register pages. To issue a command the microprocessor sets the corresponding bit(s) (RD2, RD1, RD0, TXP). Further commands may be overlapped, but with the following rules: (1) If a transmit command overlaps with a remote DMA operation, bits RD0, RD1, and RD2 must be maintained for the remote DMA command when setting the TXP bit. Note, if a remote DMA command is re-issued when giving the transmit command, the DMA will complete immediately if the remote byte count register has not been reinitialized. (2) If a remote DMA operation overlaps a transmission, RD0, RD1, and RD2 may be written with the desired values and a "0" written to the TXP bit. Writing a "0" to this bit has no effect. (3) A remote write DMA may not overlap remote read operation or vice versa. Either of these operations must either complete or be aborted before the other operation may start. Bits PS1, PS0, RD2, and STP may be set any time.

7	6	5	4	3	2	1	0
PS1	PS0	RD2	RD1	RD0	TXP	STA	STP

Bit	Symbol	Description																								
D0	STP	<p><b>Stop:</b> Software reset command, takes the controller offline, no packets will be received or transmitted. Any reception or transmission in progress will continue to completion before entering the reset state. To exit this state, the STP bit must be reset and the STA bit must be set high. To perform a software reset, this bit should be set high. The software reset has executed only when indicated by the RST bit in the ISR being set to 1. <b>STP powers up high.</b></p> <p><b>Note:</b> If the ST-NIC has previously been in start mode and the STP is set, both the STP and STA bits will remain set.</p>																								
D1	STA	<p><b>Start:</b> This bit is used to activate the ST-NIC after either power up, or when the ST-NIC has been placed in a reset mode by software command or error. <b>STA powers up low.</b></p>																								
D2	TXP	<p><b>Transmit Packet:</b> This bit must be set to initiate the transmission of a packet. TXP is internally reset either after the transmission is completed or aborted. This bit should be set only after the Transmit Byte Count and Transmit Page Start registers have been programmed.</p>																								
D3, D4, and D5	RD0, RD1, and RD2	<p><b>Remote DMA Command:</b> These three encoded bits control operation of the Remote DMA channel. RD2 can be set to abort any Remote DMA command in progress. The Remote Byte Count Registers should be cleared when a Remote DMA has been aborted. The Remote Start Addresses are not restored to the starting address if the Remote DMA is aborted.</p> <table style="margin-left: 20px;"> <tr> <td style="text-align: center;">RD2</td> <td style="text-align: center;">RD1</td> <td style="text-align: center;">RD0</td> <td></td> </tr> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">0</td> <td style="text-align: center;">0</td> <td>Not Allowed</td> </tr> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">0</td> <td style="text-align: center;">1</td> <td>Remote Read</td> </tr> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">1</td> <td style="text-align: center;">0</td> <td>Remote Write (Note 2)</td> </tr> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">1</td> <td style="text-align: center;">1</td> <td>Send Packet</td> </tr> <tr> <td style="text-align: center;">1</td> <td style="text-align: center;">X</td> <td style="text-align: center;">X</td> <td>Abort/Complete Remote DMA (Note 1)</td> </tr> </table> <p><b>Note 1:</b> If a remote DMA operation is aborted and the remote byte count has not decremented to zero, PRQ will remain high. A read acknowledge (RACK) on a write acknowledge (WACK) will reset PRQ low.</p> <p><b>Note 2:</b> For proper operation of the Remote Write DMA, there are two steps which must be performed before using the Remote Write DMA. The steps are as follows:</p> <ol style="list-style-type: none"> <li>I) Write a non-zero value into RBCR0.</li> <li>II) Set bits RD2, RD1, and RD0 to 0, 0, and 1.</li> <li>III) Set RBCR0, 1 and RSAR0, 1.</li> <li>IV) Issue the Remote Write DMA Command (RD2, RD1, RD0 = 0, 1, 0).</li> </ol>	RD2	RD1	RD0		0	0	0	Not Allowed	0	0	1	Remote Read	0	1	0	Remote Write (Note 2)	0	1	1	Send Packet	1	X	X	Abort/Complete Remote DMA (Note 1)

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### INTERRUPT STATUS REGISTER (ISR) 07H (READ/WRITE)

This register is accessed by the host processor to determine the cause of an interrupt. Any interrupt can be masked in the Interrupt Mask Register (IMR). Individual interrupt bits are cleared by writing a "1" into the corresponding bit of the ISR. The INT signal is active as long as any unmasked signal is set, and will not go low until all unmasked bits in this register have been cleared. The ISR must be cleared after power up by writing it with all 1's.

7	6	5	4	3	2	1	0
RST	RDC	CNT	OVW	TXE	RXE	PTX	PRX

Bit	Symbol	Description
D0	PRX	<b>Packet Received:</b> Indicates packet received with no errors.
D1	PTX	<b>Packet Transmitted:</b> Indicates packet transmitted with no errors.
D2	RXE	<b>Receive Error:</b> Indicates that a packet was received with one or more of the following errors: — CRC Error — Frame Alignment Error — FIFO Overrun — Missed Packet
D3	TXE	<b>Transmit Error:</b> Set when packet transmitted with one or more of the following errors: — Excessive Collisions — FIFO Underrun
D4	OVW	<b>Overwrite Warning:</b> Set when receive buffer ring storage resources have been exhausted. (Local DMA has reached Boundary Pointer)
D5	CNT	<b>Counter Overflow:</b> Set when MSB of one or more of the Network Tally Counters has been set.
D6	RDC	<b>Remote DMA Complete:</b> Set when Remote DMA operation has been completed.
D7	RST	<b>Reset Status:</b> Set when ST-NIC enters reset state and cleared when a Start Command is issued to the CR. This bit is also set when a Receive Buffer Ring overflow occurs and is cleared when one or more packets have been removed from the ring. Writing to this bit has no effect.  <b>Note:</b> This bit does not generate an interrupt, it is merely a status indicator.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### INTERRUPT MASK REGISTER (IMR) 0FH (WRITE)

The Interrupt Mask Register is used to mask interrupts. Each interrupt mask bit corresponds to a bit in the Interrupt Status Register (ISR). If an interrupt mask bit is set, an interrupt will be issued whenever the corresponding bit in the ISR is set. If any bit in the IMR is set low, an interrupt will not occur when the bit in the ISR is set. **The IMR powers up to all zeroes.**

#### DATA CONFIGURATION REGISTER (DCR) 0EH (WRITE)

This Register is used to program the ST-NIC for 8- or 16-bit memory interface, select byte ordering in 16-bit applications and establish FIFO thresholds. **The DCR must be initialized prior to loading the Remote Byte Count Registers. LAS is set on power up.**

Bit	Symbol	Description																				
D0	WTS	<p><b>Word Transfer Select</b>                      0: Selects byte-wide DMA transfers                      1: Selects word-wide DMA transfers</p> <p>; WTS establishes byte or word transfers for both Remote and Local DMA transfers  <b>Note:</b> When word-wide mode is selected up to 32k words are addressable; A0 remains low.</p>																				
D1	BOS	<p><b>Byte Order Select</b>                      0: MS byte placed on AD15–AD8 and LS byte on AD7–AD0. (32xxx, 80x86)                      1: MS byte placed on AD7–AD0 and LS byte on AD15–A8. (680x0)</p> <p>; Ignored when WTS is low</p>																				
D2	LAS	<p><b>Long Address Select</b>                      0: Dual 16-bit DMA mode                      1: Single 32-bit DMA mode</p> <p>; When LAS is high, the contents of the Remote DMA registers RSAR0, 1 are issued as A16–A31 Power up high</p>																				
D3	LS	<p><b>Loopback Select</b>                      0: Loopback mode selected. Bits D1 and D2 of the TCR must also be programmed for Loopback operation                      1: Normal Operation</p>

D6	Reserved	Reserved																				
D7	Reserved	Reserved																				

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### TRANSMIT STATUS REGISTER (TSR) 04H (READ)

This register records events that occur on the media during transmission of a packet. It is cleared when the next transmission is initiated by the host. All bits remain low unless the event that corresponds to a particular bit occurs during transmission. Each transmission should be followed by a read of this register. The contents of this register are not specified until after the first transmission.

7	6	5	4	3	2	1	0
OWC	CDH	FU	CRS	ABT	COL	—	PTX

Bit	Symbol	Description
D0	PTX	<b>Packet Transmitted:</b> Indicates transmission without error. (No excessive collisions or FIFO underrun) (ABT = "0", FU = "0")
D1	Reserved	Reserved
D2	COL	<b>Transmit Collided:</b> Indicates that the transmission collided at least once with another station on the network. The number of collisions is recorded in the Number of Collisions Registers (NCR).
D3	ABT	<b>Transmit Aborted:</b> Indicates the ST-NIC aborted transmission because of excessive collisions. (Total number of transmissions including original transmission attempt equals 16.)
D4	CRS	<b>Carrier Sense Lost:</b> This bit is set when carrier is lost during transmission of the packet. Transmission is not aborted on loss of carrier.
D5	FU	<b>FIFO Underrun:</b> If the ST-NIC cannot gain access of the bus before the FIFO empties, this bit is set. Transmission of the packet will be aborted.
D6	CDH	<b>CD Heartbeat:</b> Failure of the transceiver to transmit a collision signal after transmission of a packet will set this bit. The Collision Detect (CD) heartbeat signal must commence during the first 6.4 $\mu$ s of the Interframe Gap following a transmission. In certain collisions, the CD Heartbeat bit will be set even though the transceiver is not performing the CD heartbeat test.
D7	OWC	<b>Out of Window Collision:</b> Indicates that a collision occurred after a slot time (51.2 $\mu$ s). Transmissions rescheduled as in normal collisions.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### RECEIVE CONFIGURATION REGISTER (RCR) OCH (WRITE)

This register determines operation of the ST-NIC during reception of a packet and is used to program what types of packets to accept.

Bit	Symbol	Description
D0	SEP	<p><b>Save Errored Packets</b></p> <p>0: Packets with receive errors are rejected.                      1: Packets with receive errors are accepted. Receive errors are CRC and Frame Alignment errors.</p>
D1	AR	<p><b>Accept Runt Packets:</b> This bit allows the receiver to accept packets that are smaller than 64 bytes. The packet must be at least 8 bytes long to be accepted as a runt.</p> <p>0: Packets with fewer than 64 bytes rejected.                      1: Packets with fewer than 64 bytes accepted.</p>
D2	AB	<p><b>Accept Broadcast:</b> Enables the receiver to accept a packet with an all 1's destination address.</p> <p>0: Packets with broadcast destination address rejected.                      1: Packets with broadcast destination address accepted.</p>
D3	AM	<p><b>Accept Multicast:</b> Enables the receiver to accept a packet with a multicast address. All multicast addresses must pass the hashing array.</p> <p>0: Packets with multicast destination address not checked.                      1: Packets with multicast destination address checked.</p>
D4	PRO	<p><b>Promiscuous Physical:</b> Enables the receiver to accept all packets with a physical address.</p> <p>0: Physical address of node must match the station address programmed in PAR0–PAR5.                      1: All packets with physical addresses accepted.</p>
D5	MON	<p><b>Monitor Mode:</b> Enables the receiver to check addresses and CRC on incoming packets without buffering to memory. The Missed Packet Tally counter will be incremented for each recognized packet.</p> <p>0: Packets buffered to memory.                      1: Packets checked for address match, good CRC and Frame Alignment but not buffered to memory.</p>
D6	Reserved	Reserved
D7	Reserved	Reserved

**Note:** D2 and D3 are "OR'd" together, i.e., if D2 and D3 are set the ST-NIC will accept broadcast and multicast addresses as well as its own physical address. To establish full promiscuous mode, bits D2, D3, and D4 should be set. In addition the multicast hashing array must be set to all 1's in order to accept all multicast addresses.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### RECEIVE STATUS REGISTER (RSR) OCH (READ)

This register records status of the received packet, including information on errors and the type of address match, either physical or multicast. The contents of this register are written to buffer memory by the DMA after reception of a good packet. If packets with errors are to be saved the receive status is written to memory at the head of the erroneous packet if an erroneous packet is received. If packets with errors are to be rejected the RSR will not be written to memory. The contents will be cleared when the next packet arrives. CRC errors, Frame Alignment errors and missed packets are counted internally by the ST-NIC which relinquishes the Host from reading the RSR in real time to record errors for Network Management Functions. The contents of this register are not specified until after the first reception.

7	6	5	4	3	2	1	0
DFR	DIS	PHY	MPA	FO	FAE	CRC	PRX

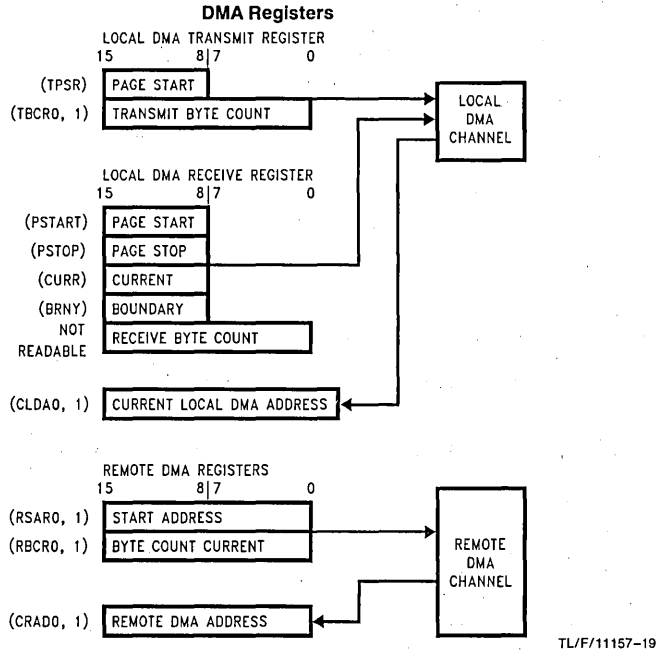

Bit	Symbol	Description
D0	PRX	<b>Packet Received Intact:</b> Indicates packet received without error. (Bits CRC, FAE, FO, and MPA are zero for the received packet.)
D1	CRC	<b>CRC Error:</b> Indicates packet received with CRC error. Increments Tally Counter (CNTR1). This bit will also be set for Frame Alignment errors.
D2	FAE	<b>Frame Alignment Error:</b> Indicates that the incoming packet did not end on a byte boundary and the CRC did not match at the last byte boundary. Increments Tally Counter (CNTR0).
D3	FO	<b>FIFO Overrun:</b> This bit is set when the FIFO is not serviced causing overflow during reception. Reception of the packet will be aborted.
D4	MPA	<b>Missed Packet:</b> Set when a packet intended for node cannot be accepted by ST-NIC because of a lack of receive buffers or if the controller is in monitor mode and did not buffer the packet to memory. Increments Tally Counter (CNTR2).
D5	PHY	<b>Physical/Multicast Address:</b> Indicates whether received packet had a physical or multicast address type. 0: Physical Address Match 1: Multicast/Physical Address Match
D6	DIS	<b>Receiver Disabled:</b> Set when receiver disabled by entering Monitor mode. Reset when receiver is re-enabled when exiting Monitor mode.
D7	DFR	<b>Deferring:</b> Set when internal Carrier Sense or Collision signals are generated in the ENDEC module. If the transceiver has asserted the CD line as a result of the jabber, this bit will stay set indicating the jabber condition.

**Note:** Following coding applies to CRC and FAE bits.

FAE	CRC	Type of Error
0	0	No Error (Good CRC and <6 Dribble Bits)
0	1	CRC Error
1	0	Illegal, Will Not Occur
1	1	Frame Alignment Error and CRC Error

# 10.0 Internal Registers (Continued)

## 10.4 DMA REGISTERS

The DMA Registers are partitioned into groups; Transmit, Receive and Remote DMA Registers. The Transmit registers are used to initialize the Local DMA Channel for transmission of packets while the Receive Registers are used to initialize the Local DMA Channel for packet Reception. The Page Stop, Page Start, Current and Boundary Registers are used by the Buffer Management Logic to supervise the Receive Buffer Ring. The Remote DMA Registers are used to initialize the Remote DMA.

**Note:** In the figure above, registers are shown as 8 or 16 bits wide. Although some registers are 16-bit internal registers, all registers are accessed as 8-bit registers. Thus the 16-bit Transmit Byte Count Register is broken into two 8-bit registers, TBCR0, TBCR1. Also TPSR, PSTART, PSTOP, CURR and BRNY only check or control the upper 8 bits of address information on the bus. Thus, they are shifted to positions 15-8 in the diagram above.

### 10.5 TRANSMIT DMA REGISTERS

#### TRANSMIT PAGE START REGISTER (TPSR)

This register points to the assembled packet to be transmitted. Only the eight higher order addresses are specified since all transmit packets are assembled on 256-byte page boundaries. The bit assignment is shown below. The values placed in bits D7-D0 will be used to initialize the higher order address (A8-A15) of the Local DMA for transmission. The lower order bits (A7-A0) are initialized to zero.

#### Bit Assignment

	7	6	5	4	3	2	1	0
TPSR	A15	A14	A13	A12	A11	A10	A9	A8

(A7-A0 Initialized to Zero)

#### TRANSMIT BYTE COUNT REGISTER 0, 1 (TBCR0, TBCR1)

These two registers indicate the length of the packet to be transmitted in bytes. The count must include the number of bytes in the source, destination, length and data fields. The maximum number of transmit bytes allowed is 64 Kbytes. The ST-NIC will not truncate transmissions longer than 1500 bytes. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
TBCR1	L15	L14	L13	L12	L11	L10	L9	L8

	7	6	5	4	3	2	1	0
TBCR0	L7	L6	L5	L4	L3	L2	L1	L0

## 10.0 Internal Registers (Continued)

### 10.6 LOCAL DMA RECEIVE REGISTERS

#### PAGE START AND STOP REGISTERS (PSTART, PSTOP)

The Page Start and Page Stop Registers program the starting and stopping address of the Receive Buffer Ring. Since the ST-NIC uses fixed 256-byte buffers aligned on page boundaries only the upper 8 bits of the start and stop address are specified.

#### PSTART, PSTOP Bit Assignment

	7	6	5	4	3	2	1	0
PSTART, PSTOP	A15	A14	A13	A12	A11	A10	A9	A8

#### BOUNDARY (BNRY) REGISTER

This register is used to prevent overflow of the Receive Buffer Ring. Buffer management compares the contents of this register to the next buffer address when linking buffers together. If the contents of this register match the next buffer address the Local DMA operation is aborted.

	7	6	5	4	3	2	1	0
BNRY	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT PAGE REGISTER (CURR)

This register is used internally by the Buffer Management Logic as a backup register for reception. CURR contains the address of the first buffer to be used for a packet reception and is used to restore DMA pointers in the event of receive errors. This register is initialized to the same value as PSTART and should not be written to again unless the controller is Reset.

	7	6	5	4	3	2	1	0
CURR	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT LOCAL DMA REGISTER 0,1 (CLDA0, 1)

These two registers can be accessed to determine the current local DMA address.

	7	6	5	4	3	2	1	0
CLDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CLDA0	A7	A6	A5	A4	A3	A2	A1	A0

### 10.7 REMOTE DMA REGISTERS

#### REMOTE START ADDRESS REGISTERS (RSAR0, 1)

Remote DMA operations are programmed via the Remote Start Address (RSAR0, 1) and Remote Byte Count (RBCR0, 1) registers. The Remote Start Address is used to point to the start of the block of data to be transferred and the Remote Byte Count is used to indicate the length of the block (in bytes).

	7	6	5	4	3	2	1	0
RSAR1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
RSAR0	A7	A6	A5	A4	A3	A2	A1	A0

#### REMOTE BYTE COUNT REGISTERS (RBCR0, 1)

	7	6	5	4	3	2	1	0
RBCR1	BC15	BC14	BC13	BC12	BC11	BC10	BC9	BC8

	7	6	5	4	3	2	1	0
RBCR0	BC7	BC6	BC5	BC4	BC3	BC2	BC1	BC0

**Note:** RSAR0 programs the start address bits A0-A7.

RSAR1 programs the start address bits A8-A15.

Address incremented by two for word transfers, and by one for byte transfers. Byte Count decremented by two for word transfers and by one for byte transfers.

RBCR0 programs LSB byte count.

RBCR1 programs MSB byte count.

#### CURRENT REMOTE DMA ADDRESS (CRDA0, CRDA1)

The Current Remote DMA Registers contain the current address of the Remote DMA. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
CRDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CRDA0	A7	A6	A5	A4	A3	A2	A1	A0

### 10.8 PHYSICAL ADDRESS REGISTERS (PAR0-PAR5)

The physical address registers are used to compare the destination address of incoming packets for rejecting or accepting packets. Comparisons are performed on a byte-wide basis. The bit assignment shown below relates the sequence in PAR0-PAR5 to the bit sequence of the received packet.

	D7	D6	D5	D4	D3	D2	D1	D0
PAR0	DA7	DA6	DA5	DA4	DA3	DA2	DA1	DA0
PAR1	DA15	DA14	DA13	DA12	DA11	DA10	DA9	DA8
PAR2	DA23	DA22	DA21	DA20	DA19	DA18	DA17	DA16
PAR3	DA31	DA30	DA29	DA28	DA27	DA26	DA25	DA24
PAR4	DA39	DA38	DA37	DA36	DA35	DA34	DA33	DA32
PAR5	DA47	DA46	DA45	DA44	DA43	DA42	DA41	DA40

	Destination Address						Source		
P/S	DA0	DA1	DA2	DA3	...	DA46	DA47	SA0	...

**Note:** P/S = Preamble, Sync

DA0 = Physical/Multicast Bit

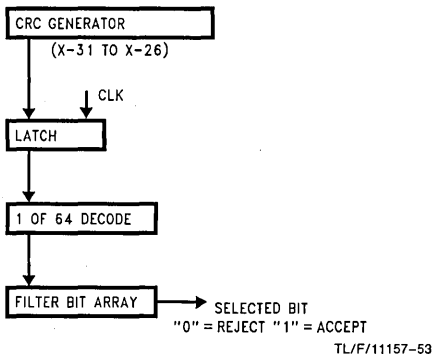

### 10.9 MULTICAST ADDRESS REGISTERS (MAR0-MAR7)

The multicast address registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 most signifi-

## 10.0 Internal Registers (Continued)

cant bits of the CRC generator are latched. These 6 bits are then decoded by a 1 of 64 decode to index a unique filter bit (FB0-63) in the multicast address registers. If the filter bit selected is set, the multicast packet is accepted. The system designer would use a program to determine which filter bits to set in the multicast registers. All multicast filter bits that correspond to multicast address accepted by the node are then set to one. To accept all multicast packets all of the registers are set to all ones.

**Note:** Although the hashing algorithm does not guarantee perfect filtering of multicast address, it will perfectly filter up to 64 multicast addresses if these addresses are chosen to map into unique locations in the multicast filter.

	D7	D6	D5	D4	D3	D2	D1	D0
MAR0	FB7	FB6	FB5	FB4	FB3	FB2	FB1	FB0
MAR1	FB15	FB14	FB13	FB12	FB11	FB10	FB9	FB8
MAR2	FB23	FB22	FB21	FB20	FB19	FB18	FB17	FB16
MAR3	FB31	FB30	FB29	FB28	FB27	FB26	FB25	FB24
MAR4	FB39	FB38	FB37	FB36	FB35	FB34	FB33	FB32
MAR5	FB47	FB46	FB45	FB44	FB43	FB42	FB41	FB40
MAR6	FB55	FB54	FB53	FB52	FB51	FB50	FB49	FB48
MAR7	FB63	FB62	FB61	FB60	FB59	FB58	FB57	FB56

If address Y is found to hash to the value 32 (20H), then FB32 in MAR4 should be initialized to "1". This will cause the ST-NIC to accept any multicast packet with the address Y.

### 10.10 NETWORK TALLY COUNTERS

Three 8-bit counters are provided for monitoring the number of CRC errors, Frame Alignment Errors and Missed Packets. The maximum count reached by any counter is 192 (COH). These registers will be cleared when read by the CPU. The count is recorded in binary in CT0-CT7 of each Tally Register.

#### Frame Alignment Error Tally (CNTR0)

This counter increments every time a packet is received with a Frame Alignment Error. The packet must have been recognized by the address recognition logic. The counter is cleared after it is read by the processor.

#### CRC Error Tally (CNTR1)

This counter is incremented every time a packet is received with a CRC error. The packet must first be recognized by the address recognition logic. The counter is cleared after it is read by the processor.

#### Frames Lost Tally Register (CNTR2)

This counter is incremented if a packet cannot be received due to lack of buffer resources. In monitor mode, this counter will count the number of packets that pass the address recognition logic.

#### FIFO

This is an 8-bit register that allows the CPU to examine the contents of the FIFO after loopback. The FIFO will contain the last 8 data bytes transmitted in the loopback packet. Sequential reads from the FIFO will advance a pointer in the FIFO and allow reading of all 8 bytes.

**Note:** The FIFO should only be read when the ST-NIC has been programmed in loopback mode.

#### NUMBER OF COLLISIONS (NCR)

This register contains the number of collisions a node experiences when attempting to transmit a packet. If no collisions are experienced during a transmission attempt, the COL bit of the TSR will not be set and the contents of NCR will be zero. If there are excessive collisions, the ABT bit in the TSR will be set and the contents of NCR will be zero. The NCR is cleared after the TXP bit in the CR is set.

## 11.0 Initialization Procedures

The ST-NIC must be initialized prior to transmission or reception of packets from the network. Power on reset is applied to the ST-NIC's reset pin. This clears/sets the following bits:

Register	Reset Bits	Set Bits
Command Register (CR)	TXP, STA	RD2, STP
Interrupt Status (ISR)		RST
Interrupt Mask (IMR)	All Bits	
Data Control (DCR)		LAS
Transmit Config. (TCR)	LB1, LB0	

The ST-NIC remains in its reset state until a Start Command is issued. This guarantees that no packets are transmitted or received and that the ST-NIC remains a bus slave until all appropriate internal registers have been programmed. After initialization the STP bit of the command register is reset and packets may be received and transmitted.

### Initialization Sequence

The following initialization procedure is mandatory.

1. Program Command Register for Page 0 (Command Register = 21H)
2. Initialize Data Configuration Register (DCR)
3. Clear Remote Byte Count Registers (RBCR0, RBCR1)
4. Initialize Receive Configuration Register (RCR)
5. Place the ST-NIC in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
6. Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
7. Clear Interrupt Status Register (ISR) by writing 0FFH to it.
8. Initialize Interrupt Mask Register (IMR)
9. Program Command Register for page 1 (Command Register = 61H)
  - I) Initialize Physical Address Registers (PAR0-PAR5)
  - II) Initialize Multicast Address Registers (MAR0-MAR5)
  - III) Initialize CURRent pointer
10. Put ST-NIC in START mode (Command Register = 22H).
11. Initialize the Transmit Configuration Register for the intended value. The ST-NIC is now ready for transmission and reception.

Before receiving packets, the user must specify the location of the Receive Buffer Ring. This is programmed in the Page Start and Page Stop Registers. In addition, the Boundary and Current Page Register must be initialized to the value of the Page Start Register. These registers will be modified during reception of packets.

## 12.0 Loopback Diagnostics

Three forms of local loopback are provided on the ST-NIC. The user has the ability to loopback through the deserializer on the controller, through the ENDEC module or the Transceiver. **Because of the half duplex architecture of the ST-NIC, loopback testing is a special mode of operation with the following restrictions:**

### Restrictions During Loopback

The FIFO is split into two halves, one half is used for transmission and the other for reception. Only 8-bit fields can be fetched from memory so two tests are required for 16-bit systems to verify integrity of the entire data path. During loopback the maximum latency from the assertion of BREQ to BACK is 2.0  $\mu$ s. Systems that wish to use the loopback test but do not meet this latency can limit the loopback to 7 bytes without experiencing underflow. Only the last 8 bytes of the loopback packet are retained in the FIFO. The last 8 bytes can be read through the FIFO register which will advance through the FIFO to allow reading the receive packet sequentially.

Destination Address	= (6 Bytes) Station Physical Address
Source Address	
Length	2 Bytes
Data	= 46 to 1500 Bytes
CRC	Appended by ST-NIC if CRC = "0" in TCR

When in word-wide mode with Byte Order Select set, the loopback packet must be assembled in the even byte location as shown below. (Loopback only operates with byte wide transfers.)

TL/F/11157-54

When in word-wide mode with Byte Order Select low, the following format must be used for the loopback packet.

TL/F/11157-55

**Note:** When using loopback in word mode 2n bytes must be programmed in TBCR0, 1. Where n = actual number of bytes assembled in even or odd location.

## 12.0 Loopback Diagnostics (Continued)

To initiate a loopback the user first assembles the loopback packet then selects the type of loopback using the Transmit Configuration register bits LB0, LB1. The transmit configuration register must also be set to enable or disable CRC generation during transmission. The user then issues a normal transmit command to send the packet. During loopback the receiver checks for an address match and if CRC bit in the TCR is set, the receiver will also check the CRC. The last 8 bytes of the loopback packet are buffered and can read out of the FIFO using the FIFO read port.

### Loopback Modes

**MODE 1:** Loopback through the NIC Module (LB1 = 0, LB0 = 1): If this loopback is used, the NIC Modules's serial-izer is connected to the deserializer.

**MODE 2:** Loopback through the ENDEC Module (LB1 = 1, LB0 = 0): If the loopback is to be performed through the SNI, the ST-NIC provides a control (LPBK) that forces the ENDEC module to loopback all signals.

**MODE 3:** Loopback to cable (LB1 = 1, LB0 = 1). Packets can be transmitted to the cable in loopback mode to check all of the transmit and receive paths and the cable itself.

**Note:** Collision and Carrier Sense can be generated by the ENDEC module and are masked by the NIC module. It is not possible to go directly between the loopback modes, it is necessary to return to normal operation (00H) when changing modes.

### Reading the Loopback Packet

The last 8 bytes of a received packet can be examined by 8 consecutive reads of the FIFO register. The FIFO pointer is incremented after the rising edge of the CPU's read strobe by internally synchronizing and advancing the pointer. This may take up to four bus clock cycles, if the pointer has not been incremented by the time the CPU reads the FIFO register again, the ST-NIC will insert wait states.

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the ST-NIC to malfunction.

### Alignment of the Received Packet in the FIFO

Reception of the packet in the FIFO begins at location zero, after the FIFO pointer reaches the last location in the FIFO, the pointer wraps to the top of the FIFO overwriting the previously received data. This process is continued until the last byte is received. The ST-NIC then appends the received byte count in the next two locations of the FIFO. The contents of the Upper Byte Count are also copied to the next FIFO location. The number of bytes used in the loopback packet determines the alignment of the packet in the FIFO.

The alignment for a 64-byte packet is shown below.

FIFO Location	FIFO Contents	
0	Lower Byte Count	First Byte Read
1	Upper Byte Count	Second Byte Read
2	Upper Byte Count	•
3	Last Byte	•
4	CRC1	•
5	CRC2	•
6	CRC3	•
7	CRC4	Last Byte Read

For the following alignment in the FIFO the packet length should be  $(N \times 8) + 5$  Bytes. Note that if the CRC bit in the TCR is set, CRC will not be appended by the transmitter. If the CRC is appended by the transmitter, the 1st four bytes, bytes N-3 to N, correspond to the CRC.

FIFO Location	FIFO Contents	
0	Byte N-4	First Byte Read
1	Byte N-3 (CRC1)	Second Byte Read
2	Byte N-2 (CRC2)	•
3	Byte N-1 (CRC3)	•
4	Byte N (CRC4)	•
5	Lower Byte Count	•
6	Upper Byte Count	Last Byte Read
7	Upper Byte Count	

### LOOPBACK TESTS

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the DP83902A ST-NIC prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

1. Verify integrity of data path. Received data is checked against transmitted data.
2. Verify the CRC logic's capability to generate good CRC on transmit, verify CRC on receive (good or bad CRC).

## 12.0 Loopback Diagnostics (Continued)

3. Verify that the Address Recognition Logic can

- a) Recognize address match packets
- b) Reject packets that fail to match an address

### LOOPBACK OPERATION IN THE ST-NIC

Loopback is a modified form of transmission using only half of the FIFO. This places certain restrictions on the use of loopback testing. When loopback mode is selected in the TCR, the FIFO is split. A packet should be assembled in memory with programming of TPSR and TBCR0, TBCR1 registers. When the transmit command is issued the following operations occur:

#### Transmitter Actions

1. Data is transferred from memory by the DMA until the FIFO is filled. For each transfer TBCR0 and TBCR1 are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
2. The ST-NIC generates 56 bits of preamble followed by an 8-bit synch pattern.
3. Data transferred from FIFO to serializer.
4. If CRC = 1 in TCR, the CRC is not calculated by ST-NIC, and the last byte transmitted is the last byte from the FIFO (Allows software CRC to be appended). If CRC = 0, ST-NIC calculates and appends four bytes of CRC.
5. At end of Transmission PTX bit set in ISR.

#### Receiver Actions

1. Wait for synch, all preamble stripped.
2. Store packet in FIFO, increment receive byte count for each incoming byte.
3. If CRC = 1 in TCR, receiver checks incoming packet for CRC errors. If CRC = 0 in TCR, receiver does not check CRC errors, CRC error bit always set in RSR (for address matching packets).
4. At the end of receive, the receive byte count is written into the FIFO, and the receive status register is updated. The PRX bit is typically set in the RSR even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the RSR to be set.

#### EXAMPLES

The following examples show what results can be expected from a properly operating ST-NIC during loopback. The restrictions and results of each type of loopback are listed for reference. The loopback tests are divided into two sets of tests. One to verify the data path, CRC generation and byte count through all three paths. The second set of tests uses internal loopback to verify the receiver's CRC checking and address recognition. For all of the tests the DCR was programmed to 40H.

Path	TCR	RCR	TSR	RSR	ISR
ST-NIC Internal	02	1F	53 (Note 1)	02 (Note 2)	02 (Note 3)

**Note 1:** Since carrier sense and collision detect are generated in the ENDEC module, they are blocked during NIC loopback. Carrier and CD heartbeat are not seen and the CRS and CDH bits are set.

**Note 2:** CRC errors are always indicated by the receiver if CRC is appended by the transmitter.

**Note 3:** Only the PTX bit in the ISR is set, the PRX bit is only set if status is written to memory. In loopback this action does not occur and the PRX bit remains 0 for all loopback modes.

**Note 4:** All values are hex.

Path	TCR	RCR	TSR	RSR	ISR
ST-NIC Internal	04	1F	43 (Note 1)	02	02

**Note 1:** CDH is set, CRS is not set since it is generated by the external encoder/decoder.

Path	TCR	RCR	TSR	RSR	ISR
ST-NIC External	06	1F	03 (Note 1)	02	02 (Note 2)

**Note 1:** CDH and CRS should not be set. The TSR however, could also contain 01H, 03H, 07H and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** The ISR will contain 08H if packet is not transmittable.

**Note 3:** During external loopback the ST-NIC is now exposed to network traffic. It is therefore possible for the contents of both the Receive portion of the FIFO and the RSR to be corrupted by any other packet on the network. Thus in a live network the contents of the FIFO and RSR should not be depended on. The ST-NIC will still abide by the standard CSMA/CD protocol in external loopback mode. (i.e., The network will not be disturbed by the loopback packet.)

**Note 4:** All values are hex.

### CRC AND ADDRESS RECOGNITION

The next three tests exercise the address recognition logic and CRC. These tests should be performed using internal loopback only so that the ST-NIC is isolated from interference from the network. These tests also require the capability to generate CRC in software.

The address recognition logic cannot be directly tested. The CRC and FAE bits in the RSR are only set if the address in the packet matches the address filters. If errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch. The following sequence of packets will test the address recognition logic. The DCR should be set to 40H and the TCR should be set to 03H with a software generated CRC.

Packet Contents			Results
Test	Address	CRC	RSR
Test A	Matching	Good	01 (Note 1)
Test B	Matching	Bad	02 (Note 2)
Test C	Non-Matching	Bad	01

**Note 1:** Status will read 21H if multicast address used.

**Note 2:** Status will read 22H if multicast address used.

**Note 3:** In test A, the RSR is set up. In test B the address is found to match since the CRC is flagged as bad. Test C proves that the address recognition logic can distinguish a bad address and does not notify the RSR of the bad CRC. The receiving CRC is proven to work in test A and test B.

**Note 4:** All values are hex.

### NETWORK MANAGEMENT FUNCTIONS

Network management capabilities are required for maintenance and planning of a local area network. The ST-NIC supports the minimum requirement for network management in hardware, the remaining requirements can be met with software counts. There are three events that software alone can not track during reception of packets: CRC errors, Frame Alignment errors, and missed packets.

### 12.0 Loopback Diagnostics (Continued)

Since errored packets can be rejected, the status associated with these packets is lost unless the CPU can access the Receive Status Register before the next packer arrives. In situations where another packet arrives very quickly, the CPU may have no opportunity to do this. The ST-NIC counts the number of packets with CRC errors and Frame Alignment errors. 8-Bit counters have been selected to reduce overhead. The counters will generate interrupts whenever their MSBs are set so that a software routine can accumulate the network statistics and reset the counter before overflow occurs. The counters are sticky so that when they reach a count of 192 (C0H) counting is halted. An additional counter is provided to count the number of packets the ST-NIC misses due to buffer overflow or being offline.

The structure of the counters is shown below:

Additional information required for network management is available in the Receive and Transmit Status Registers. Transmit status is available after each transmission for information regarding events during transmission.

Typically, the following statistics might be gathered in software:

- Traffic: Frames Sent OK
- Frames Received OK
- Multicast Frames Received
- Packets Lost Due to Lack of Resources
- Retries/Packet
  
- Errors: CRC Errors
- Alignment Errors
- Excessive Collisions
- Packet with Length Errors
- Heartbeat Failure

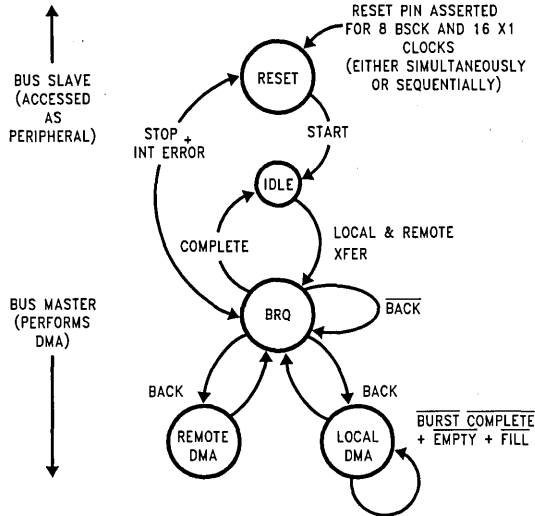

TL/F/11157-20

### 13.0 Bus Arbitration and Timing

The ST-NIC operates in three possible modes:

- BUS MASTER (WHILE PERFORMING DMA)
- BUS SLAVE (WHILE BEING ACCESSED BY CPU)
- IDLE

TL/F/11157-21

Upon power-up the ST-NIC is in an indeterminate state. After receiving a hardware reset the ST-NIC is a bus slave in the Reset State, the receiver and transmitter are both disabled in this state. The reset state can be re-entered under three conditions, soft reset (Stop Command), hard reset (RESET input) or an error that shuts down the receiver of transmitter (FIFO underflow or overflow). After initialization of registers, the ST-NIC is issued a Start command and the ST-NIC enters Idle state. Until the DMA is required the ST-NIC remains in idle state. The idle state is exited by a request from the FIFO on the case of receiver or transmit, or from the Remote DMA in the case of Remote DMA

operation. After acquiring the bus in a BREQ/BACK handshake the Remote or Local DMA transfer is completed and the ST-NIC re-enters the idle state.

#### DMA TRANSFERS TIMING

The DMA can be programmed for the following types of transfers:

- 16-Bit Address, 8-bit Data Transfer
- 16-Bit Address, 16-bit Data Transfer
- 32-Bit Address, 8-bit Data Transfer
- 32-Bit Address, 16-bit Data Transfer

All DMA transfers use BSCK for timing. 16-Bit Address modes require 4 BSCK cycles as shown below:

TL/F/11157-22

### 13.0 Bus Arbitration and Timing (Continued)

16-Bit Address, 16-Bit Data

TL/F/11157-23

32-Bit Address, 8-Bit Data

TL/F/11157-24

32-Bit Address, 16-Bit Data

TL/F/11157-25

Note: In 32-bit address mode, ADS1 is at TRI-STATE after the first T1-T4 states; thus, a 4.7k pull-down resistor is required for 32-bit address.

### 13.0 Bus Arbitration and Timing (Continued)

When in 32-bit mode four additional BSKC cycles are required per burst. The first bus cycle (T1'-T4') of each burst is used to output the upper 16-bit addresses. This 16-bit address is programmed in RSAR0 and RSAR1 and points to a 64k page of system memory. All transmitted or received packets are constrained to reside within this 64k page.

#### FIFO BURST CONTROL

All Local DMA transfers are burst transfers, once the DMA requests the bus and the bus is acknowledged, the DMA will transfer an exact burst of bytes programmed in the Data Configuration Register (DCR) then relinquish the bus. If there are remaining bytes in the FIFO the next burst will not be initiated until the FIFO threshold is exceeded. If BACK is removed during the transfer, the burst transfer will be aborted. **(DROPPING BACK DURING A DMA CYCLE IS NOT RECOMMENDED.)**

TL/F/11157-26

where N = 1, 2, 4, or 6 Words or N = 2, 4, 8, or 12 Bytes when in byte mode.

#### INTERLEAVED LOCAL OPERATION

If a remote DMA transfer is initiated or in progress when a packet is being received or transmitted, the Remote DMA transfer will be interrupted for higher priority Local DMA

transfers. When the Local DMA transfer is completed the Remote DMA will re-arbitrate for the bus and continue its transfers. This is illustrated below:

TL/F/11157-27

Note that if the FIFO requires service while a remote DMA is in progress, BREQ is not dropped and the Local DMA burst is appended to the Remote Transfer. When switching from a local transfer to a remote transfer, however, BREQ is dropped and raised again. This allows the CPU or other devices to fairly contend for the bus.

#### FIFO AND BUS OPERATIONS

##### Overview

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the ST-NIC contains a 16-byte FIFO for buffering data between the bus and the media. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO at different rates. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

To understand FIFO underruns or overruns, there are two causes which produce this condition—

1. the bus latency is so long that the FIFO has filled (or emptied) from the network before the local DMA has serviced the FIFO.
2. the bus latency or bus data rate has slowed the throughput of the local DMA to a point where it is slower than the network data rate (10 Mb/s). This second condition is also dependent upon DMA clock and word width (byte wide or word wide).

The worst case condition ultimately limits the overall bus latency which the ST-NIC can tolerate.

#### FIFO Underrun and Transmit Enable

During transmission, if a FIFO underrun occurs, the Transmit enable (TXE) output may remain high (active). Generally, this will cause a very large packet to be transmitted onto the network. The jabber feature of the transceiver will terminate the transmission, and reset TXE.

To prevent this problem, a properly designed system will not allow FIFO underruns by giving the ST-NIC a bus acknowledge within time shown in the maximum bus latency curves shown and described later.

#### FIFO at the Beginning of Receive

At the beginning of reception, the ST-NIC stores entire Address field of each incoming packet in the FIFO to deter-

### 13.0 Bus Arbitration and Timing (Continued)

mine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that BREQ is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu$ s. This operation affects the bus latencies at 2- and 4-byte thresholds during the first receive BREQ since the FIFO must be filled to 8 bytes (or 4 words) before issuing a BREQ.

#### FIFO Operation at the End of Receive

When Carrier Sense goes low, the ST-NIC enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet, *Figure 5*. The ST-NIC holds onto the bus for the entire sequence. The longest time BREQ may be extended occurs when a packet ends just as the ST-NIC performs its last FIFO burst. The ST-NIC, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completes by writing the header information to memory. The following steps occur during this sequence.

1. ST-NIC issues BREQ because the FIFO threshold has been reached
2. During the burst, packet ends, resulting in BREQ extended.
3. ST-NIC flushes remaining bytes from FIFO
4. ST-NIC performs internal processing to prepare for writing the header.
5. ST-NIC writes 4-byte (2-word) header
6. ST-NIC deasserts BREQ

End of Packet Processing (EOPP) times for 10 MHz and 20 MHz have been tabulated in the table below.

Mode	Threshold	Bus Clock	EOPP
Byte	2 Bytes	10 MHz	7.0 $\mu$ s
	4 Bytes		8.6 $\mu$ s
	8 Bytes		11.0 $\mu$ s
Byte	2 Bytes	20 MHz	3.6 $\mu$ s
	4 Bytes		4.2 $\mu$ s
	8 Bytes		5.0 $\mu$ s
Word	2 Bytes	10 MHz	5.4 $\mu$ s
	4 Bytes		6.2 $\mu$ s
	8 Bytes		7.4 $\mu$ s
Word	2 Bytes	20 MHz	3.0 $\mu$ s
	4 Bytes		3.2 $\mu$ s
	8 Bytes		3.6 $\mu$ s

**End of Packet Processing Times for Various FIFO Thresholds, Bus Clocks and Transfer Modes**

#### Threshold Detection (Bus Latency)

To assure that no overwriting of data in the FIFO occurs, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the  $n + 1$  byte has entered the FIFO; thus, with an 8-byte threshold, the ST-NIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until the  $n + 2$  bytes have entered the FIFO. Thus, with a 4-word threshold (equivalent to 8-byte threshold), BREQ is issued when the 10th byte has entered the FIFO. The two graphs, following, indicate the maximum allowable bus latency for Word and Byte transfer modes.

TL/F/11157-58

### 13.0 Bus Arbitration and Timing (Continued)

#### The FIFO at the Beginning of Transmit

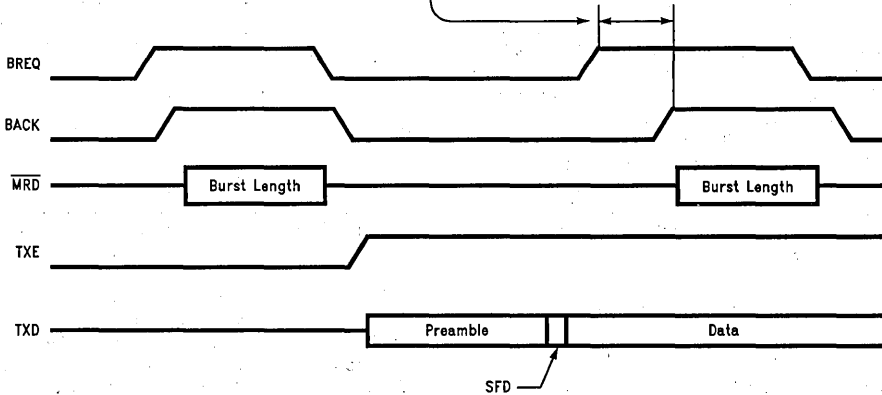

Before transmitting, the ST-NIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched

is the programmed FIFO threshold. The next BREQ is not issued until after the ST-NIC actually begins transmitting data, i.e., after SFD. The Transmit Prefetch diagram illustrates this process.

**Transmit Prefetch Timing**

$$\text{Tolerated Bus Latency} = [(\text{No. of Bytes Stored in FIFO}) \times 800] - 400 \text{ ns}$$

$$\text{or } (12 \text{ Bytes} - \text{FIFO Threshold}) \text{ whichever is less}$$

TL/F/11157-59

TL/F/11157-60

**Maximum Bus Latency for Word Mode**

TL/F/11157-61

### 13.0 Bus Arbitration and Timing (Continued)

#### REMOTE DMA-BIDIRECTIONAL PORT CONTROL

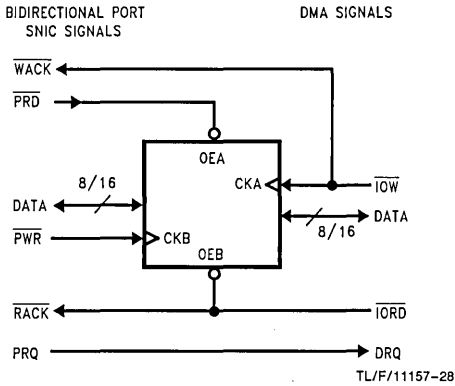

The Remote DMA transfers data between the local buffer memory and a bidirectional port (memory to I/O transfer). This transfer is arbitrated on a byte by byte basis versus the burst transfer used for Local DMA transfers. This bidirectional port is also read/written by the host. All transfers through this port are asynchronous. At any one time transfers are limited to one direction, either from the port to local buffer memory (Remote Write) or from local buffer memory to the port (Remote Read).

#### REMOTE READ TIMING

1. The DMA reads byte/word from local buffer memory and writes byte/word into latch, increments the DMA address and decrements the byte count (RBCR0, 1).
2. A Request Line (PRQ) is asserted to inform the system that a byte is available.
3. The system reads the port, the read strobe ( $\overline{RACK}$ ) is used as an acknowledge by the Remote DMA and it goes back to step 1.

Steps 1–3 are repeated until the remote DMA is complete. Note that in order for the Remote DMA to transfer a byte from memory to the latch, it must arbitrate access to the bus via a BREQ, BACK handshake. After each byte or word is transferred to the latch, BREQ is dropped. If a Local DMA is in progress, the Remote DMA is held off until the local DMA is complete.

#### Bus Handshake Signals for Remote DMA Transfers

## 13.0 Bus Arbitration and Timing (Continued)

### REMOTE WRITE TIMING

A Remote Write operation transfers data from the I/O port to the local buffer RAM. The ST-NIC initiates a transfer by requesting a byte/word via the PRQ. The system transfers a byte-word to the latch via  $\overline{OW}$ . This write strobe is detected by the ST-NIC and PRQ is removed. By removing the PRQ, the Remote DMA holds off further transfers into the latch until the current byte/word has been transferred from the latch, PRQ is reasserted and the next transfer can begin.

1. ST-NIC asserts PRQ. System writes byte/word into latch. ST-NIC removes PRQ.
  2. Remote DMA reads contents of port and writes byte/word to local buffer memory, increments address and decrements byte count (RBCR0, 1).
  3. Go back to step 1.
- Steps 1-3 are repeated until the remote DMA is complete.

TL/F/11157-30

### REMOTE DMA WRITE SPECIAL CONSIDERATIONS

#### Setting PRQ Using the Remote Read

Under certain conditions the ST-NIC bus state machine may issue  $\overline{MWR}$  and  $\overline{PRD}$  before PRQ for the first DMA transfer of a Remote Write Command. If this occurs this could cause data corruption, or cause the remote DMA count to be different from the main CPU count causing the system to "lock up".

To prevent this condition when implementing a Remote DMA Write, the Remote DMA Write command should first be preceded by a Remote DMA Read command to insure that the PRQ signal is asserted before the ST-NIC starts its port read cycle. The reason for this is that the state machine that asserts PRQ runs independently of the state machine that controls the DMA signals. The DMA machine assumes that PRQ is asserted, but actually may not be. To remedy this situation, a single Remote Read cycle should be inserted before the actual DMA Write Command is given. This will ensure that PRQ is asserted when the Remote DMA Write is subsequently executed. This single Remote Read cycle is called a "dummy Remote Read". In order for the dummy Remote Read cycle to operate correctly, the Start Address should be programmed to a known, safe location in the buffer memory space, and the Remote Byte count should be programmed to a value greater than 1. This will ensure that

the master read cycle is performed safely, eliminating the possibility of data corruption.

#### Remote Write with High Speed Buses

When implementing the Remote DMA Write solution with high speed buses and CPU's, timing may cause the system to hang. Therefore additional considerations are required.

A problem occurs when the system can execute the dummy Remote Read and then start the Remote Write before the ST-NIC has had a chance to execute the Remote Read. If this happens the PRQ signal will not get set, and the Remote Byte Count and Remote Start Address for the Remote Write operation could be corrupted. This is shown by the hatched waveforms in the following timing diagram. The execution of the Remote Read can be delayed by the local DMA operations (particularly during end-of-packet processing).

To ensure the dummy Remote Read does execute, a delay must be inserted between writing the Remote Read Command, and starting to write the Remote Write Start Address. (This time is designated in the next figure by the delay arrows.) The recommended method to avoid this problem is after the Remote Read command is given, to poll both bytes of the Current Remote DMA Address Registers. When the address has incremented PRQ has been set. Software should recognize this and then start the Remote Write.

### 13.0 Bus Arbitration and Timing (Continued)

An additional caution for high speed systems is that the polling must follow guidelines specified in the Time Between Chip Selects section. That is, there must be at least 4 bus clocks between chip selects. (For example when BSCK = 20 MHz, then this time should be 200 ns).

The general flow for executing a Remote Write is:

1. Set Remote Byte Count to a value > 1 and Remote Start Address to unused RAM (one location before the transmit start address is usually a safe location).
2. Issue the "dummy" Remote Read command.
3. Read the Current Remote DMA Address (CRDA) (both bytes).
4. Compare to previous CRDA value if different go to 6.
5. Delay and jump to 3.
6. Set up for the Remote Write command, by setting the Remote Byte Count and the Remote Start Address (note that if the Remote Byte count in step 1 can be set to the transmit byte count plus one, and the Remote Start Address to one less, these will now be incremented to the correct values.)
7. Issue the Remote Write command.

TL/F/11157-62

Note: The dashed lines indicate incorrect timing as described in text.

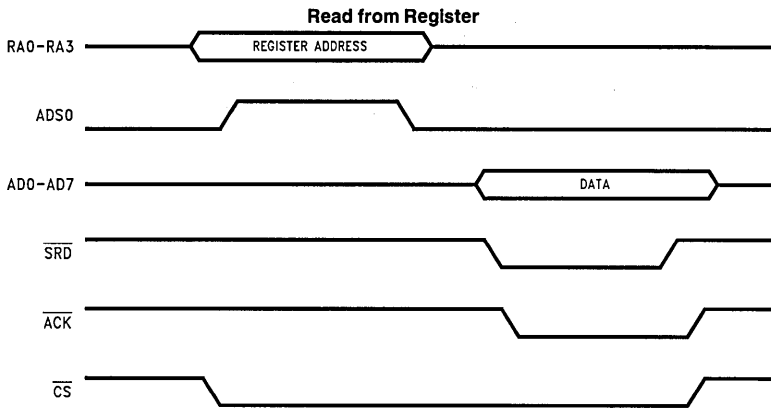

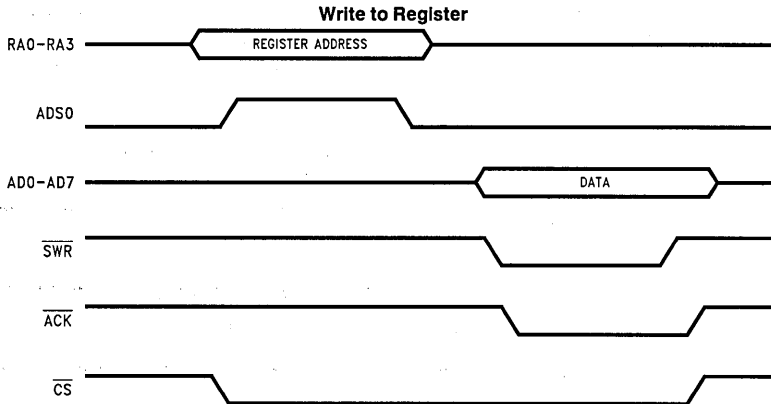

Timing Diagram for Dummy Remote Read

### 13.0 Bus Arbitration and Timing (Continued)

#### SLAVE MODE TIMING

When  $\overline{CS}$  is low, the ST-NIC becomes a bus slave. The CPU can then read or write any internal registers. All register accesses are byte wide. The timing for register access is shown below. The host CPU accesses internal registers with four address lines, RA0-RA3, SRD and SWR strobes.

ADS0 is used to latch the address when interfacing to a multiplexed, address data bus. Since the ST-NIC may be a local bus master when the host CPU attempts to read or write to the controller, an  $\overline{ACK}$  line is used to hold off the CPU until the ST-NIC leaves master mode. Some number of BSCK cycles is also required to allow the ST-NIC to synchronize to the read or write cycles.

#### TIME BETWEEN CHIP SELECTS

The ST-NIC requires that successive chip selects be no closer than 4 bus clocks (BSCK) together. If the condition is violated, the ST-NIC may glitch  $\overline{ACK}$ . CPUs that operate from pipelined instructions (i.e., 386) or have a cache (i.e.,

486) can execute consecutive I/O cycles very quickly. The solution is to delay the execution of consecutive I/O cycles by either breaking the pipeline or forcing the CPU to access outside its cache.

## 14.0 Preliminary Electrical Characteristics

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to +7.0V
DC Input Voltage ( $V_{IN}$ )	-0.5V to $V_{CC} + 0.5V$
DC Output Voltage ( $V_{OUT}$ )	-0.5V to $V_{CC} + 0.5V$
Storage Temperature Range ( $T_{STG}$ )	-65°C to +150°C
Power Dissipation (PD)	800 mW
Lead Temp. (TL) (Soldering, 10 sec.)	260°C
ESD Rating ( $R_{ZAP} = 1.5k$ , $C_{ZAP} = 100$ pF)	1.5 kV
Pin to Pin	
Pin to GND	
Pin to $V_{CC}$ ( $\pm 1$ ZAP)	
Clamp Diode Current	$\pm 20$ mA

Note: Absolute Maximum ratings are those values beyond which the safety of the device cannot be guaranteed. They are not meant to imply that the device should be operated at these limits.

Note: All specifications in this datasheet are valid only if the mandatory isolation is employed and all differential signals are taken to exist at the AUI or TPI side of the isolation.

### Preliminary DC Specifications $T_A = 0^\circ\text{C}$ to $70^\circ\text{C}$ , $V_{CC} = 5V \pm 5\%$ , unless otherwise specified.

Symbol	Parameter	Conditions	Min	Max	Units
$V_{OH}$	Minimum High Level Output Voltage (Notes 1, 4)	$I_{OH} = -20 \mu\text{A}$	$V_{CC} - 0.1$		V
		$I_{OH} = -2.0 \text{ mA}$			
$V_{OL}$	Minimum Low Level Output Voltage (Notes 1, 4)	$I_{OL} = 20 \mu\text{A}$		0.1	V
		$I_{OL} = 2.0 \text{ mA}$		0.4	V
$V_{IH}$	Minimum High Level Input Voltage (Note 2)		2.0		V
$V_{IH2}$	Minimum High Level Input Voltage For RACK WACK (Note 2)		2.7		V
$V_{IL}$	Maximum Low Level Input Voltage (Note 2)			0.8	V
$V_{IL2}$	Maximum Low Level Input Voltage For RACK, WACK (Note 2)			0.6	V
$V_{LOL}$	Good Link Output Voltage	$I_{OL} = 16 \text{ mA}$		0.4	V
$I_{IN}$	Input Current	$V_I = V_{CC}$ or GND	-1.0	+1.0	$\mu\text{A}$
$I_{INSEL}$	Input Current	$V_{IN} = V_{CC}$	50	2000	$\mu\text{A}$
		$V_{IN} = \text{GND}$	-1	+1	$\mu\text{A}$
$I_{OZ}$	Minimum TRI-STATE Output Leakage Current (Note 5)	$V_{OUT} = V_{CC}$ or GND	-10	+10	$\mu\text{A}$
$I_{CC}$	Average Supply Current (Note 3)	X1 = 20 MHz Clock $I_{OUT} = 0 \mu\text{A}$ $V_{IN} = V_{CC}$ or GND		140	mA

**Note 1:** These levels are tested dynamically using a limited amount of functional test patterns, please refer to AC test load.

**Note 2:** Limited functional test patterns are performed at these input levels. The majority of functional tests are performed at levels of 0V and 3V.

**Note 3:** This is measured with a 0.1  $\mu\text{F}$  bypass capacitor between  $V_{CC}$  and GND.

**Note 4:** The low drive CMOS compatible  $V_{OH}$  and  $V_{OL}$  limits are not tested directly. Detailed device characterization validates that this specification can be guaranteed by testing the high drive TTL compatible  $V_{OL}$  and  $V_{OH}$  specification.

**Note 5:** RA0-RA3, PRD, WACK, BREQ and INT pins are used as outputs in test mode and as a result are tested as if they are TRI-STATE input/outputs. For these pins the input leakage specification is  $I_{OZ}$ .

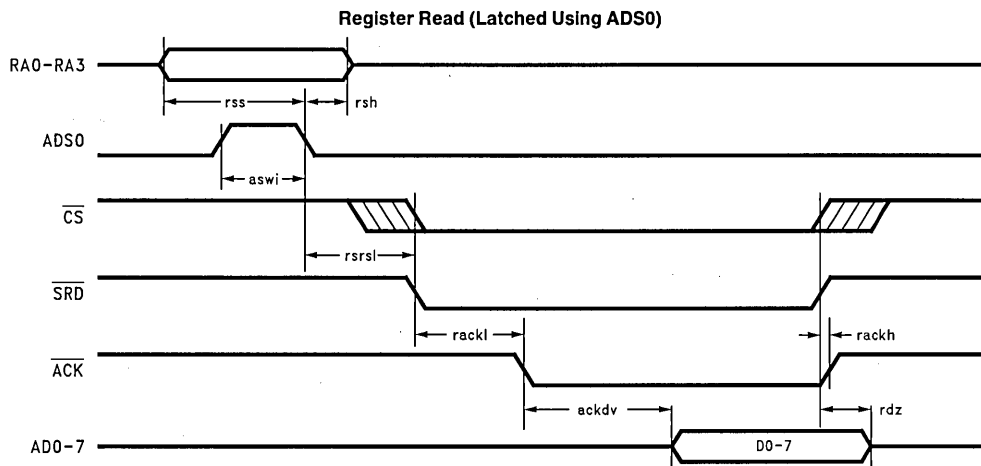

## 14.0 Preliminary Electrical Characteristics (Continued)

**Preliminary DC Specifications**  $T_A = 0^\circ\text{C to }70^\circ\text{C}$ ,  $V_{CC} = 5\text{V} \pm 5\%$ , unless otherwise specified. (Continued)

**Note 1:** This parameter is guaranteed by design and is not tested.

### 15.0 Switching Characteristics AC Specs DP83902A Note: All Timing is Preliminary

TL/F/11157-33

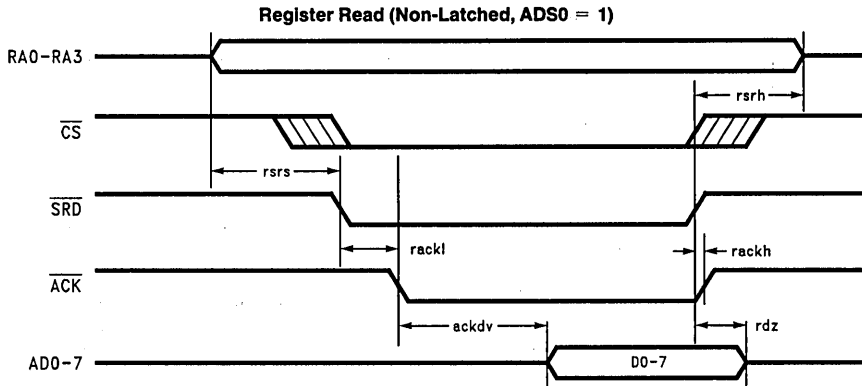

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	13		ns
aswi	Address Strobe Width In	15		ns
ackdv	Acknowledge Low to Data Valid		55	ns
rdz	Read Strobe to Data TRI-STATE (Note 3)	15	70	ns
rackl	Read Strobe to $\overline{\text{ACK}}$ Low (Notes 1, 2)		$n \cdot \text{bcyc} + 30$	ns
rackh	Read Strobe to $\overline{\text{ACK}}$ High		30	ns
rsrsl	Register Select to Slave Read Low, Latched RS0-3	10		ns

**Note 1:**  $\overline{\text{ACK}}$  is not generated until  $\overline{\text{CS}}$  and  $\overline{\text{SRD}}$  are low and the ST-NIC has synchronized to the register access. The ST-NIC will insert an integral number of Bus Clock cycles until it is synchronized. In Dual Bus systems additional cycles will be used for a local or remote DMA to complete. Wait states must be issued to the CPU until  $\overline{\text{ACK}}$  is asserted low.

**Note 2:**  $\overline{\text{CS}}$  may be asserted before or after  $\overline{\text{SRD}}$ . If  $\overline{\text{CS}}$  is asserted after  $\overline{\text{SRD}}$ , rackl is referenced from falling edge of  $\overline{\text{CS}}$ .  $\overline{\text{CS}}$  can be de-asserted concurrently with  $\overline{\text{SRD}}$  or after  $\overline{\text{SRD}}$  is de-asserted.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns, enabling other devices to drive these lines with no contention.

**15.0 Switching Characteristics** AC Specs DP83902A Note: All Timing is Preliminary (Continued)

TL/F/11157-34

Symbol	Parameter	Min	Max	Units
rsrc	Register Select to Read Setup (Notes 1, 3)	10		ns
rsrh	Register Select Hold from Read	0		ns
ackdv	ACK Low to Valid Data		55	ns
rdz	Read Strobe to Data TRI-STATE (Note 2)	15	70	ns
rackl	Read Strobe to ACK Low (Note 3)		$n \cdot bcyc + 30$	ns
rackh	Read Strobe to ACK High		30	ns

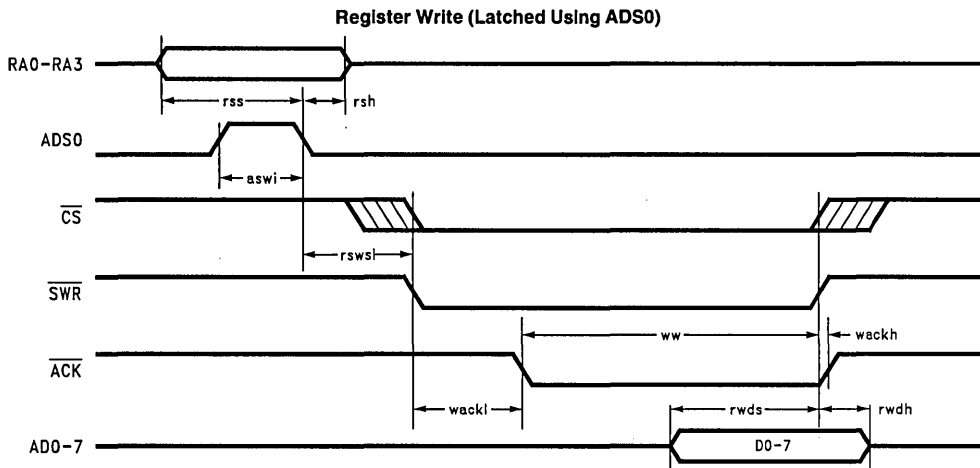

**Note 1:** rsrc includes flow-through time of latch.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns enabling other devices to drive these lines with no contention.

**Note 3:** CS may be asserted before or after RA0-3, and SRD, since address decode begins when ACK is asserted. If CS is asserted after RA0-3, and SRD, rackl is referenced from falling edge of CS.

**15.0 Switching Characteristics** AC Specs DP83902A **Note:** All Timing is Preliminary (Continued)

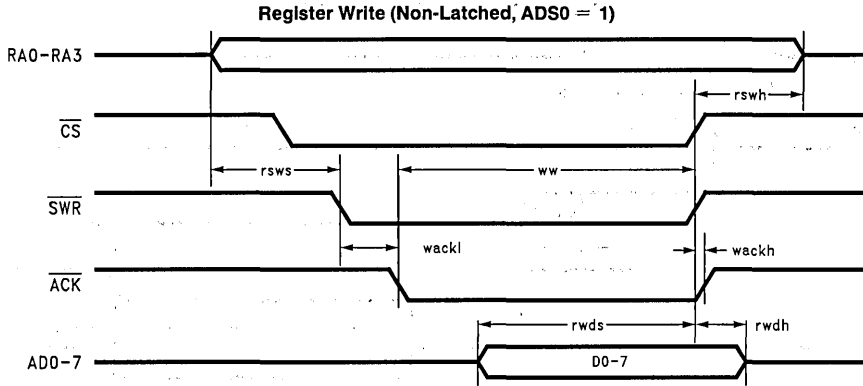

TL/F/11157-35

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	17		ns
aswi	Address Strobe Width In	15		ns
rwds	Register Write Data Setup	20		ns
rwdh	Register Write Data Hold	21		ns
ww	Write Strobe Width from $\overline{ACK}$	50		ns
wackh	Write Strobe High to $\overline{ACK}$ High		30	ns
wackl	Write Low to $\overline{ACK}$ Low (Notes 1, 2)		$n \cdot \text{bcyc} + 30$	ns
rswsl	Register Select to Write Strobe Low	10		ns

**Note 1:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SWR}$  are low and the ST-NIC has synchronized to the register access. In Dual Bus Systems additional cycles will be used for a local DMA or Remote DMA to complete.

**Note 2:**  $\overline{CS}$  may be asserted before or after  $\overline{SWR}$ . If  $\overline{CS}$  is asserted after  $\overline{SWR}$ , wackl is referenced from falling edge of  $\overline{CS}$ .

**15.0 Switching Characteristics** AC Specs DP83902A Note: All Timing is Preliminary (Continued)

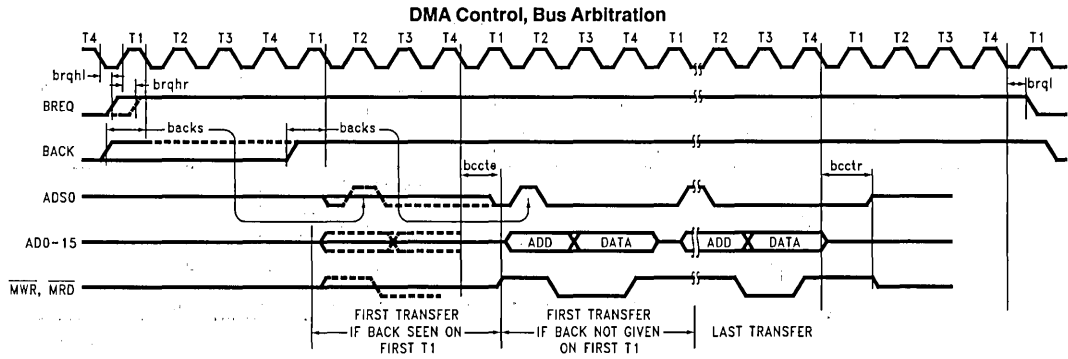

TL/F/11157-36

Symbol	Parameter	Min	Max	Units
rsws	Register Select to Write Setup (Note 1)	15		ns
rswh	Register Select Hold from Write	0		ns
rws	Register Write Data Setup	20		ns
rwdh	Register Write Data Hold	21		ns
wackl	Write Low to ACK Low (Note 2)		$n \cdot \text{bcyc} + 30$	ns
wackh	Write High to ACK High		30	ns
ww	Write Width from ACK	50		ns

**Note 1:** Assumes ADS0 is high when RA0-3 changing.

**Note 2:** ACK is not generated until CS and SWR are low and the ST-NIC has synchronized to the register access. In Dual Bus systems additional cycles will be used for a local DMA or remote DMA to complete.

**15.0 Switching Characteristics** AC Specs DP83902A **Note:** All Timing is Preliminary (Continued)

TL/F/11157-37

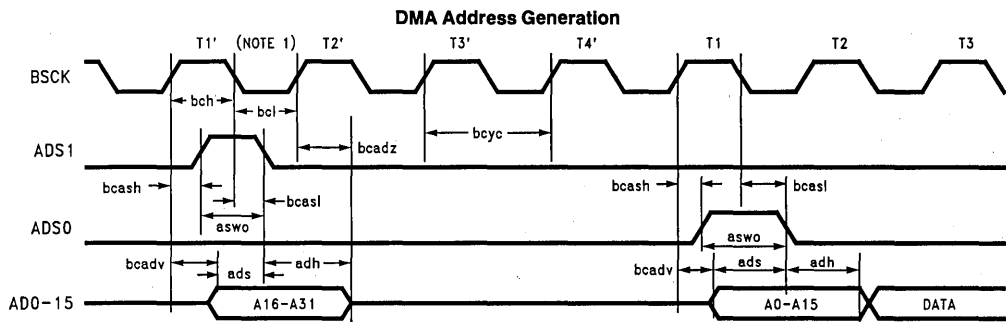

Symbol	Parameter	Min	Max	Units
brqhl	Bus Clock to Bus Request High for Local DMA		50	ns
brqhr	Bus Clock to Bus Request High for Remote DMA		45	ns
brql	Bus Request Low from Bus Clock		60	ns
backs	Acknowledge Setup to Bus Clock (Note 1)	2		ns
bccte	Bus Clock to Control Enable		60	ns
bcctr	Bus Clock to Control Release (Notes 2, 3)		70	ns

**Note 1:** BACK must be setup before T1 after BREQ is asserted. Missed setup will slip the beginning of the DMA by four bus clocks. The Bus Latency will influence the allowable FIFO threshold.

**Note 2:** During remote DMA transfers only, a single bus transfer is performed. During local DMA operations burst mode transfers are performed.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns enabling other devices to drive these lines with no contention.

# 15.0 Switching Characteristics AC Specs DP83902A Note: All Timing is Preliminary (Continued)

TL/F/11157-38

Symbol	Parameter	Min	Max	Units
bcyc	Bus Clock Cycle Time (Note 2)	50	125	ns

asds	Address Strobe to Data Strobe		$bcl + 10$	ns
aswd	Address Strobe to Write Data Valid		$bcl + 30$	ns

**Note 1:** When using byte mode transfers A8-A15 are only TRI-STATE on the last transfer, waz timing is only valid for last transfer in a burst.  
**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within  $bch + 15$  ns, enabling other devices to drive these lines with no contention.

# 15.0 Switching Characteristics AC Specs DP83902A Note: All Timing is Preliminary (Continued)

TL/F/11157-41

Symbol	Parameter	Min	Max	Units
ews	External Wait Setup to T3 0Clock (Note 1)	10		ns
ewr	External Wait Release Time (Note 1)	15		ns

**Note 1:** The addition of wait states affects the count of deserialized bytes and is limited to a number of bus clock cycles depending on the bus clock and network rates. The allowable wait states are found in the table below. (Assumes 10 Mbit/sec data rate.)

BSCCK (MHz)	Max # of Wait States	
	Byte Transfer	Word Transfer
8	0	1
10	0	1
12	1	2
14	1	2
16	1	3
18	2	3
20	2	4

Table assumes 10 MHz network clock.

The number of allowable wait states in byte mode can be calculated using:

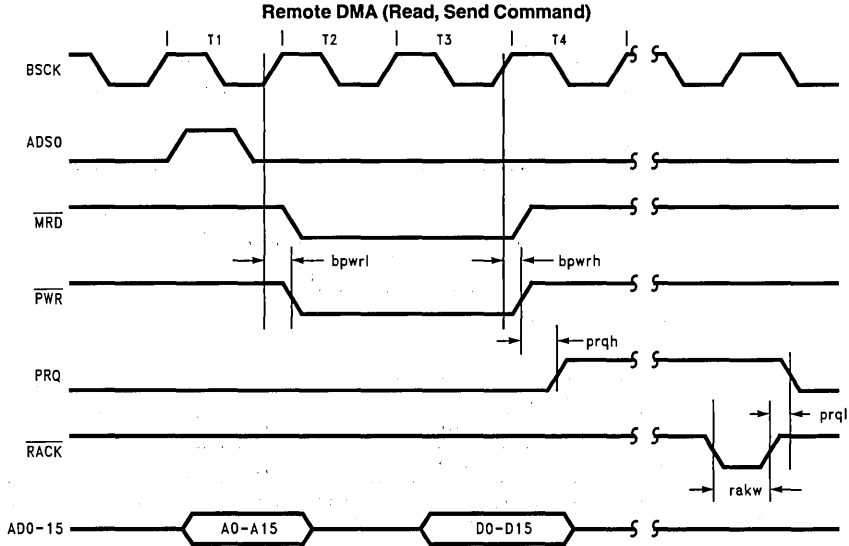

$$\#W_{(\text{byte mode})} = \left( \frac{8 \text{tnw}}{4.5 \text{tbsck}} - 1 \right)$$

- #W = Number of Wait States
- tnw = Network Clock Period
- tbsck = BSCCK Period

The number of allowable wait states in word mode can be calculated using:

$$\#W_{(\text{word mode})} = \left( \frac{5 \text{tnw}}{2 \text{tbsck}} - 1 \right)$$

bpwrh	Bus Clock to Port Write High		40	ns
prqh	Port Write High to Port Request High (Note 1)		30	ns
prql	Port Request Low from Read Acknowledge High		60	ns
rakw	Remote Acknowledge Read Strobe Pulse Width	20		ns

Note 1: Start of next transfer is dependent on where RACK is generated relative to BSCCK and whether a local DMA is pending.

**15.0 Switching Characteristics** AC Specs DP83902A **Note:** All Timing is Preliminary (Continued)

Symbol	Parameter	Min	Max	Units
bpwrl	Bus Clock to Port Write Low		43	ns
bpwrh	Bus Clock to Port Write High		40	ns
prqh	Port Write High to Port Request High (Note 1)		30	ns
prql	Port Request Low from Read Acknowledge High		60	ns
rakw	Remote Acknowledge Read Strobe Pulse Width	20		ns
rhpwh	Read Acknowledge High to Next Port Write Cycle (Notes 2, 3, 4)	11		BSCK

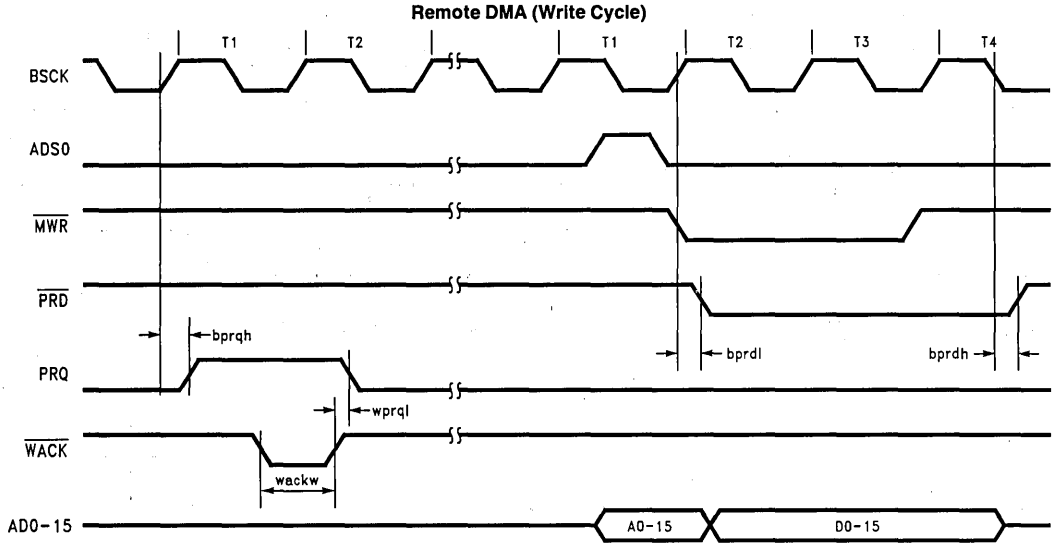

**Note 1:** Start of next transfer is dependent on where RACK is generated relative to BSCK and whether or not a local DMA is pending.

**Note 2:** This is not a measured value but guaranteed by design.

**Note 3:** RACK must be high for a minimum of 7 BSCK.

**Note 4:** Assumes no local DMA interleave, no CS, and immediate BACK.

**15.0 Switching Characteristics** AC Specs DP83902A **Note:** All Timing is Preliminary (Continued)

TL/F/11157-44

Symbol	Parameter	Min	Max	Units
bprqh	Bus Clock to Port Request High (Note 1)		42	ns
wprql	WACK to Port Request Low		52	ns
wackw	WACK Pulse Width	25		ns
bprdl	Bus Clock to Port Read Low (Note 2)		55	ns
bprdh	Bus Clock to Port Read High		40	ns

**Note 1:** The first port request is issued in response to the remote write command. It is subsequently issued on T1 clock cycles following completion of remote DMA cycles.

**Note 2:** The start of the remote DMA write following WACK is dependent on where WACK is issued relative to BSCk and whether a local DMA is pending.

### 15.0 Switching Characteristics AC Specs DP83902A Note: All Timing is Preliminary (Continued)

Remote DMA (Write Cycle) Recovery Time

TL/F/11157-45

Symbol	Parameter	Min	Max	Units
bprqh	Bus Clock to Port Request High (Note 1)		42	ns
wprql	$\overline{WACK}$ to Port Request Low		50	ns
wackw	$\overline{WACK}$ Pulse Width	25		ns
bprdl	Bus Clock to Port Read Low (Note 2)		55	ns
bprdh	Bus Clock to Port Read High		40	ns
wprq	Remote Write Port Request to Port Request Time (Notes 3, 4, 5)	12		BSCK

**Note 1:** The first port request is issued in response to the remote write command. It is subsequently issued on T1 clock cycles following completion of remote DMA cycles.

**Note 2:** The start of the remote DMA write following  $\overline{WACK}$  is dependent on where  $\overline{WACK}$  is issued relative to BSKC and whether a local DMA is pending.

**Note 3:** Assuming wackw < 1 BSCK, and no local DMA interleave, no  $\overline{CS}$ , immediate  $\overline{BACK}$ , and  $\overline{WACK}$  goes high before T4.

**Note 4:**  $\overline{WACK}$  must be high for a minimum of 7 BSCK.

**Note 5:** This is not a measured value but guaranteed by design.

Reset Timing

TL/F/11157-64

Symbol	Parameter	Min	Max	Units
rstw	Reset Pulse Width (Note 1)	8		BSCK Cycles or TXC Cycles (Note 2)

**Note 1:** The RESET pulse requires that BSKC and TXC be stable. On power up,  $\overline{RESET}$  should not be raised until BSKC and TXC have become stable. Several registers are affected by  $\overline{RESET}$ . Consult the register descriptions for details.

**Note 2:** The slower of BSKC or TXC clocks will determine the minimum time for the  $\overline{RESET}$  signal to be low.

If BSKC < TXC then  $\overline{RESET} = 8 \times \text{BSCK}$

If TXC < BSKC then  $\overline{RESET} = 8 \times \text{TXC}$

$teop0$	Receive End of Packet Hold Time after Logic "0" (Note 1)	225		ns

**Note 1:** This parameter is guaranteed by design and is not tested.

**15.0 Switching Characteristics** AC Specs DP83902A Note: All Timing is Preliminary (Continued)

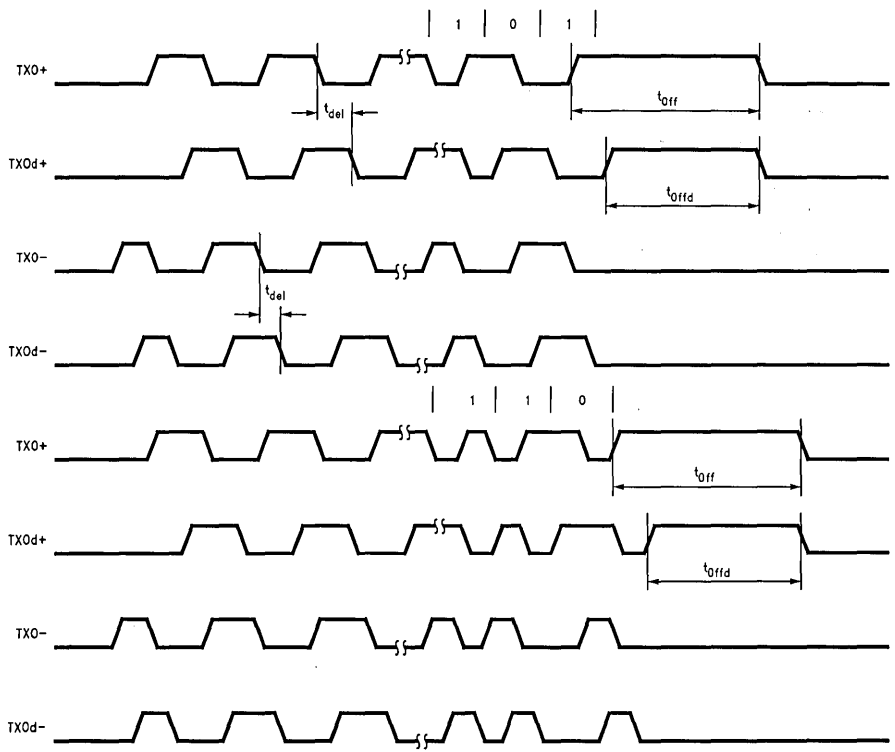

**Link Pulse Timing**

TL/F/11157-48

Symbol	Parameter	Min	Max	Units
tip	Time between Link Output Pulses	8	24	ms
tipw	Link Integrity Output Pulse Width	80	130	ns

**TPI Transmit and End of Packet Timing**

TL/F/11157-49

Symbol	Parameter	Min	Max	Units
tdel	Pre-Emphasis Output Delay (TX0± to TX0d±) (Note 1)	46	54	ns
toff	Transmit Hold Time at End of Packet (TX0±) (Note 1)	250		ns
toffd	Transmit Hold Time at End of Packet (TX0d±) (Note 1)	200		ns

**Note 1:** This parameter is guaranteed by design and is not tested.

## 16.0 AC Timing Test Conditions

All specifications are valid only if the mandatory isolation is employed and all differential signals are taken to be at the AUI side of the pulse transformer.

Input Pulse Levels (TTL/CMOS)	GND to 3.0V
Input Rise and Fall Times (TTL/CMOS)	5 ns
Input and Output Reference Levels (TTL/CMOS)	1.3V
Input Pulse Levels (Diff.)	-350 mV to -1315 mV
Input and Output Reference Levels (Diff.)	50% Point of the Differential
TRI-STATE Reference Levels	Float ( $\Delta V$ ) $\pm 0.5V$
Output Load (See Figure Below)	

TL/F/11157-50

**Note 1:** 50 pF, includes scope and jig capacitance.

**Note 2:** S1 = Open for timing tests for push pull outputs.

S1 = V<sub>CC</sub> for V<sub>OL</sub> test.

S1 = GND for V<sub>OH</sub> test.

S1 = V<sub>CC</sub> for High Impedance to active low and active low to High Impedance measurements.

S1 = GND for High Impedance to active high and active high to High Impedance measurements.

## Pin Capacitance $T_A = 25^\circ C, f = 1 \text{ MHz}$

Symbol	Parameter	Typ	Units
C <sub>IN</sub>	Input Capacitance	7	pF
C <sub>OUT</sub>	Output Capacitance	7	pF

### DERATING FACTOR

Output timing is measured with a purely capacitive load of 50 pF. The following correction factor can be used for other loads:  $C_L \geq 50 \text{ pF} + 0.3 \text{ ns/pF}$ .

### AUI Transmit Test Load

TL/F/11157-51

**Note:** In the above diagram, the TX+ and TX- signals are taken from the AUI side of the isolation (pulse transformer). The pulse transformer used for all testing is the Pulse Engineering PE64103.

# DP83901A SNIC

## Serial Network Interface Controller

### General Description

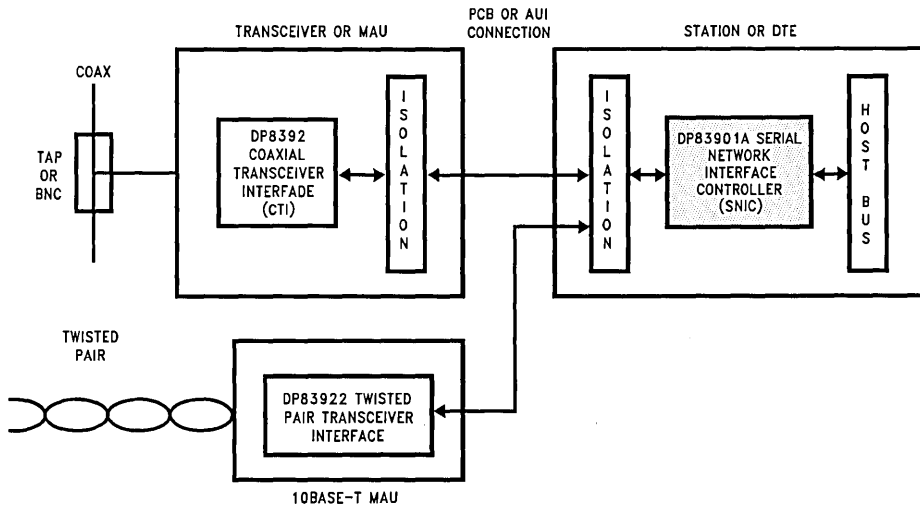

The DP83901A Serial Network Interface Controller (SNIC) is a microCMOS VLSI device designed for easy implementation of CSMA/CD local area networks. These include Ethernet (10BASE5), Thin Ethernet (10BASE2) and Twisted-pair Ethernet (10BASE-T). The overall SNIC solution provides the Media Access Control (MAC) and Encode-Decode (ENDEC) functions in accordance with the IEEE 802.3 standard.

The integrated ENDEC module allows Manchester encoding and decoding via a differential transceiver and phase lock loop at 10 Mbit/sec. Also included is a collision detect translator and diagnostic loopback capability. (Continued)

### Features

- Compatible with IEEE 802.3, 10BASE5, 10BASE2, 10BASE-T
- Dual 16-byte DMA channels
- 16-byte internal FIFO
- Network statistics storage
- Supports physical, multicast and broadcast address filtering
- 10 Mbit/sec Manchester encoding and decoding plus clock recovery
- No external precision components required
- Efficient buffer management implementation
- Transmitter can be selected for half or full step mode
- Integrated squelch on receive and collision pairs
- 3 levels of loopback supported
- Utilizes independent system and network clocks
- Lock Time 5 bits typical
- Decodes Manchester data with up to  $\pm 18$  ns jitter

### 1.0 System Diagram

TL/F/10469-1

## General Description (Continued)

The MAC function (NIC) provides simple and efficient packet transmission and reception control by means of unique dual DMA channels and an internal FIFO. Bus arbitration and memory control logic are integrated to reduce board cost and area overheads.

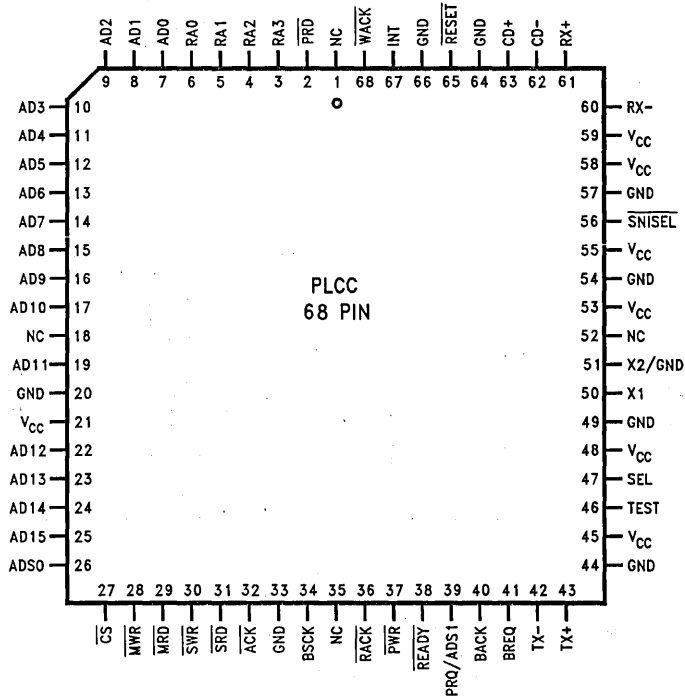

SNIC used in conjunction with the DP8392 Coaxial Transceiver Interface (CTI) provides a comprehensive 2 chip solution for IEEE 802.3 networks and is designed for easy interface to the latest 10BASE-T transceivers.

Due to the inherent constraints of CMOS processing, isolation is required at the differential signal interfaces for 10BASE5 and 10BASE2 applications. Capacitive or inductive isolation may be used.

## Pin Description

Pin No	Pin Name	I/O	Description
<b>BUS INTERFACE PINS</b>			
2	$\overline{\text{PRD}}$	O	<b>PORT READ:</b> Enables data from external latch on to local bus during a memory write cycle to local memory (remote write operation). This allows asynchronous transfer of data from the system memory to local memory.
3–6	RA0–RA3	I	<b>REGISTER ADDRESS:</b> These four pins are used to select a register to be read or written. The state of these inputs is ignored when the NIC is not in slave mode ( $\overline{\text{CS}}$ high).
7–17, 19, 22–25	AD0–AD15	I/O, Z	<b>MULTIPLEXED ADDRESS/DATA BUS:</b> <ul style="list-style-type: none"> <li>Register Access, with DMA inactive, <math>\overline{\text{CS}}</math> low and <math>\overline{\text{ACK}}</math> returned from SNIC, pins AD0–AD7 are used to read and write register data. AD8–AD15 float during I/O transfers, <math>\overline{\text{SRD}}</math>, <math>\overline{\text{SWR}}</math> pins are used to select direction of transfer.</li> <li>Bus Master with BACK input asserted.           <ul style="list-style-type: none"> <li>During t1 of memory cycle AD0–AD15 contain address.</li> <li>During t2, t3, t4 AD0–AD15 contain data (word transfer mode).</li> <li>During t2, t3, t4 AD0–AD7 contain data, AD8–AD15 contain address (byte transfer mode).</li> </ul> </li> </ul> Direction of transfer is indicated by SNIC on $\overline{\text{MWR}}$ , $\overline{\text{MRD}}$ lines.
26	ADS0	I/O, Z	<b>ADDRESS STROBE 0:</b> <ul style="list-style-type: none"> <li>Input: with DMA inactive and <math>\overline{\text{CS}}</math> low, latches RA0–RA3 inputs on falling edge. If high, data present on RA0–RA3 will flow through latch.</li> <li>Output: When Bus Master, latches address bits (A0–A15) to external memory during DMA transfers.</li> </ul>
27	$\overline{\text{CS}}$	O	<b>CHIP SELECT:</b> Chip Select places controller in slave mode for $\mu\text{P}$ access to internal registers. Must be valid through data portion of bus cycle. RA0–RA3 are used to select the internal register. $\overline{\text{SWR}}$ and $\overline{\text{SRD}}$ select direction of data transfer.
28	$\overline{\text{MWR}}$	O, Z	<b>MASTER WRITE STROBE:</b> (Strobe for DMA transfers) Active low during write cycles (t2, t3, tw) to buffer memory. Rising edge coincides with the presence of valid output data. TRI-STATE® until BACK asserted.
29	$\overline{\text{MRD}}$	O, Z	<b>MASTER READ STROBE:</b> (Strobe for DMA transfers) Active during read cycles (t2, t3, tw) to buffer memory. Input data must be valid on rising edge of $\overline{\text{MRD}}$ . TRI-STATE until BACK asserted.
30	$\overline{\text{SWR}}$	I	<b>SLAVE WRITE STROBE:</b> Strobe from CPU to write an internal register selected by RA0–RA3. Data is latched into the SNIC on the rising edge of this input.
31	$\overline{\text{SRD}}$	I	<b>SLAVE READ STROBE:</b> Strobe from CPU to read an internal register selected by RA0–RA3. The register data is output when $\overline{\text{SRD}}$ goes low.
32	$\overline{\text{ACK}}$	O	<b>ACKNOWLEDGE:</b> Active low when SNIC grants access to CPU. Used to insert WAIT states to CPU until SNIC is synchronized for a register read or write operation.
34	BCK	I	<b>BUS CLOCK:</b> This clock is used to establish the period of the DMA memory cycle. Four clock cycles (t1, t2, t3, t4) are used per DMA cycle. DMA transfers can be extended by one BCK increments using the READY input.
36	$\overline{\text{RACK}}$	I	<b>READ ACKNOWLEDGE:</b> Indicates that the system DMA or host CPU has read the data placed in the external latch by the SNIC. The SNIC will begin a read cycle to update the latch.
37	$\overline{\text{PWR}}$	O	<b>PORT WRITE:</b> Strobe used to latch data from the SNIC into external latch for transfer to host memory during Remote Read transfers. The rising edge of $\overline{\text{PWR}}$ coincides with the presence of valid data on the local bus.
38	READY	I	<b>READY:</b> This pin is set high to insert wait states during a DMA transfer. The SNIC will sample this signal at t3 during DMA transfers.

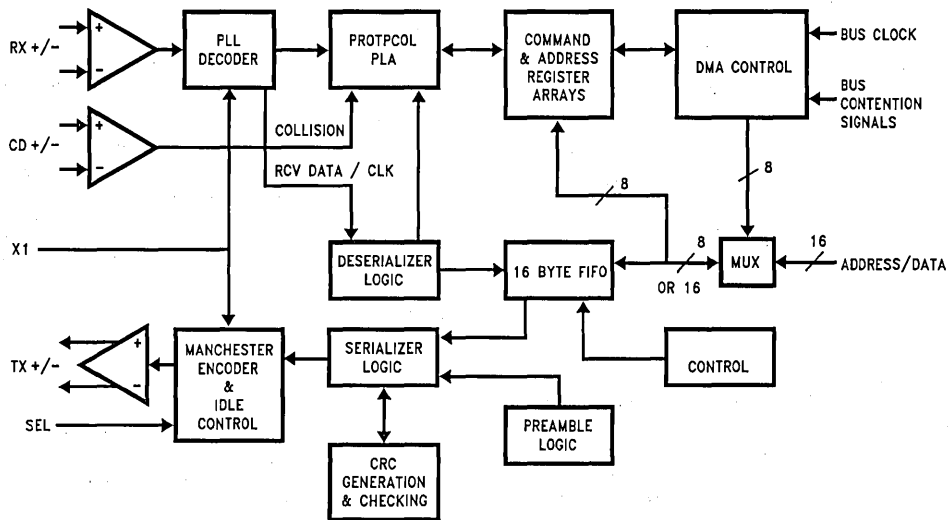

## Pin Description (Continued)

Pin No	Pin Name	I/O	Description
<b>BUS INTERFACE PINS (Continued)</b>			
39	PRQ/ADS1	O, Z	<p><b>PORT REQUEST/ADDRESS STROBE 1</b></p> <ul style="list-style-type: none"> <li>• <b>32-BIT MODE:</b> If LAS is set in the Data Configuration Register, this line is programmed as ADS1. It is used to strobe addresses A16–A31 into external latches. (A16–A31 are the fixed addresses stored in RSAR0, RSAR1). ADS1 will remain at TRI-STATE until BACK is received.</li> <li>• <b>16-BIT MODE:</b> If LAS is not set in the Data Configuration Register, this line is programmed as PRQ and is used for Remote DMA Transfers. The SNIC initiates a single remote DMA read or write operation by asserting this pin. In this mode PRQ will be a standard logic output.</li> </ul> <p><b>Note:</b> This line will power up as TRI-STATE until the Data Configuration Register is programmed.</p>
40	BACK	I	<p><b>BUS ACKNOWLEDGE:</b> Bus Acknowledge is an active high signal indicating that the CPU has granted the bus to the SNIC. If immediate bus access is desired, BREQ should be tied to BACK. <b>Tying BACK to V<sub>CC</sub> will result in a deadlock.</b></p>
41	BREQ	O	<p><b>BUS REQUEST:</b> Bus Request is an active high signal used to request the bus for DMA transfers. This signal is automatically generated when the FIFO needs servicing.</p>
65	RESET	I	<p><b>RESET:</b> Reset is active low and places the SNIC in a reset immediately, no packets are transmitted or received by the SNIC until STA bit is set. Affects Command Register, Interrupt Mask Register, Data Configuration Register and Transmit Configuration Register. The SNIC will execute reset within 10 BSCK cycles and TXC cycles.</p>
67	INT	O	<p><b>INTERRUPT:</b> Indicates that the SNIC requires CPU attention after reception transmission or completion of DMA transfers. The interrupt is cleared by writing to the ISR (Interrupt Service Register). All interrupts are maskable.</p>
68	WACK	I	<p><b>WRITE ACKNOWLEDGE:</b> Issued from system to SNIC to indicate that data has been written to the external latch. The SNIC will begin a write cycle to place the data in local memory.</p>
<b>NETWORK INTERFACE PINS</b>			
42, 43	TX– TX+	O	<p><b>TRANSMIT OUTPUT:</b> Differential driver which sends the encoded data to the transceiver. The outputs are source followers which require 270Ω pulldown resistors.</p>
46	TEST	I	<p><b>FACTORY TEST INPUT:</b> Used to check the chip's internal functions. Tied low during normal operation.</p>
47	SEL	I	<p><b>MODE SELECT:</b> When high, Transmit+ and Transmit– are the same voltage in the idle state. When low, Transmit+ is positive with respect to Transmit– in the idle state, at the transformer's primary.</p>
50	X1	I	<p><b>EXTERNAL OSCILLATOR INPUT</b></p>
51	GND/X2	O	<p><b>GROUND/X2:</b> This in should normally be connected to ground. It is possible to use a crystal oscillator using X1 and GND/X2 if certain precautions are taken. Contact National Semiconductor for more information.</p>
56	SNISEL	I	<p><b>FACTORY TEST INPUT:</b> For normal operation tied to V<sub>CC</sub>. When low enables the ENDEC module to be tested independently of the SNIC module.</p>
60, 61	RX– RX+	I	<p><b>RECEIVE INPUT:</b> Differential receive input pair from the transceiver.</p>
62, 63	CD– CD+	I	<p><b>COLLISION INPUT:</b> Differential collision pair input from the transceiver.</p>

## 4.0 Functional Description (Refer to Figure 1)

### ENCODER/DECODER (ENDEC) MODULE

The ENDEC consists of four main logical blocks:

- a) The Manchester encoder accepts NRZ data from the controller, encodes the data to Manchester, and transmits it differentially to the transceiver, through the differential transmit driver.
- b) The Manchester decoder receives Manchester data from the transceiver, converts it to NRZ data and clock pulses, and sends it to the controller.
- c) The collision translator indicates to the controller the presence of a valid 10 MHz collision signal to the PLL.

#### MANCHESTER ENCODER AND DIFFERENTIAL DRIVER

The differential transmit pair, on the secondary of the employed transformer, drives up to 50 meters of twisted pair AUI cable. These outputs are source followers which require two 270 $\Omega$  pull-down resistors to ground.

The DP83901A allows both half-step and full-step to be compatible with Ethernet and IEEE 802.3. With the SEL pin low (for Ethernet I), Transmit+ is positive with respect to Transmit- during idle; with SEL high (for IEEE 802.3), Transmit+ and Transmit- are equal in the idle state. This provides zero differential voltage to operate with transformer-coupled loads.

#### MANCHESTER DECODER

The decoder consists of a differential receiver and a PLL to separate a Manchester decoded data stream into internal clock signals and data. The differential input must be externally terminated with two 39 $\Omega$  resistors connected in series if the standard 78 $\Omega$  transceiver drop cable is used, in thin Ethernet applications, these resistors are optional. To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with levels less than -175 mV. Signals more negative than -300 mV and a duration greater than 30 ns are decoded. Data becomes valid typically within 5 bit times. The DP83901A may tolerate bit jitter up to 18 ns in the received data. The decoder detects the end of a frame when no more mid-bit transitions are detected.

#### COLLISION TRANSLATOR

When the Ethernet transceiver (DP8392 CTI) detects a collision, it generates a 10 MHz signal to the differential collision inputs (CD $\pm$ ) of the DP83901A. When these inputs are detected active, the DP83901A uses this signal to back off its current transmission and reschedule another one.

The collision differential inputs are terminated the same way as the differential receive inputs. The squelch circuitry is also similar, rejecting pulses with levels less than -175 mV.

### NIC (Media Access Control) MODULE

#### RECEIVE DESERIALIZER

The Receive Deserializer is activated when the input signal Carrier Sense is asserted to allow incoming bits to be shifted into the shift register by the receive clock. The serial receive data is also routed to the CRC generator/checker. The Receive Deserializer includes a synch detector which detects the SFD (Start of Frame Delimiter) to establish where byte boundaries within the serial bit stream are located. After every eight receive clocks, the byte wide data is transferred to the 16-byte FIFO and the Receive Byte Count is incremented. The first six bytes after the SFD are checked for valid comparison by the Address Recognition Logic. If the Address Recognition Logic does not recognize the packet, the FIFO is cleared.

#### CRC GENERATOR/CHECKER

During transmission, the CRC logic generates a local CRC field for the transmitted bit sequence. The CRC encodes all fields after the SFD. The CRC is shifted out MSB first following the last transmit byte. During reception the CRC logic generates a CRC field from the incoming packet. This local CRC is serially compared to the incoming CRC appended to the end of the packet by the transmitting node. If the local and received CRC match, a specific pattern will be generated and decoded to indicate no data errors. Transmission errors result in different pattern and are detected, resulting in rejection of a packet (if so programmed).

#### TRANSMIT SERIALIZER

The Transmit Serializer reads parallel data from the FIFO and serializes it for transmission. The serializer is clocked by the transmit clock generated internally. The serial data is also shifted into the CRC generator/checker. At the beginning of each transmission, the Preamble and Synch Generator append 62 bits of 1,0 preamble and a 1,1 synch pattern. After the last data byte of the packet has been serialized the 32-bit FCS field is shifted directly out of the CRC generator. In the event of a collision the Preamble and Synch generator is used to generate a 32-bit JAM pattern of all 1's.

#### ADDRESS RECOGNITION LOGIC

The address recognition logic compares the Destination Address Field (first 6 bytes of the received packet) to the Physical address registers stored in the Address Register Array. If any one of the six bytes does not match the pre-programmed physical address, the Protocol Control Logic rejects the packet. All multicast destination addresses are filtered using a hashing technique. (See register description.) If the multicast address indexes a bit that has been set in the filter bit array of the Multicast Address Register Array the packet is accepted, otherwise it is rejected by the Proto-

## 4.0 Functional Description (Continued)

col Control Logic. Each destination address is also checked for all 1's which is the reserved broadcast address.

### FIFO AND BUS OPERATIONS

#### Overview

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the SNIC contains a 16-byte FIFO for buffering data between the media. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO at different rates. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

FIFO underruns or overruns are caused by two conditions: (1) the bus latency is so long that the FIFO has filled (or emptied) from the network before the local DMA has serviced the FIFO and (2) the bus latency has slowed the throughput of the local DMA to point where it is slower than the network data rate (10 Mbit/sec). This second condition is also dependent upon DMA clock and word width (byte wide or word wide). The worst case condition ultimately limits the overall bus latency which the SNIC can tolerate.

#### Beginning of Receive

At the beginning or reception, the SNIC stores entire Address field of each incoming packet in the FIFO to determine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that BREQ is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu$ s. This operation affects the bus latencies at 2 and 4-byte thresholds during the first receive BREQ since the FIFO must be filled to 8 bytes (or 4 words) before issuing a BREQ.

#### End of Receive

When the end of a packet is detected by the ENDEC module, the SNIC enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet. The SNIC holds onto the bus for the entire sequence. The longest time BREQ may be extended occurs when a packet ends just as the SNIC performs its last FIFO burst. The SNIC, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completed by writing the header information to memory. The following steps occur during this sequence.

1. SNIC issues BREQ because the FIFO threshold has been reached.

2. During the burst, packet ends, resulting in BREQ extended.
3. SNIC flushes remaining bytes from FIFO.
4. SNIC performs internal processing to prepare for writing the header.
5. SNIC writes 4-byte (2-word) header.
6. SNIC de-asserts BREQ.

#### FIFO Threshold Detection

To assure that no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the  $n+1$  byte has entered the FIFO; thus, with an 8-byte threshold, the SNIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until the  $n+2$  bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to 8-byte threshold), BREQ is issued when the 10th byte has entered the FIFO.

#### Beginning of Transmit

Before transmitting, the SNIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next BREQ is not issued until after the SNIC actually begins transmitting data, i.e., after SFD.

#### Reading the FIFO

During normal operation, the FIFO must not be read. The SNIC will not issue an ACKnowledge back to the CPU if the FIFO is read. The FIFO should only be read during loopback diagnostics.

#### PROTOCOL PLA

The protocol PLA is responsible for implementing the IEEE 802.3 protocol, including collision recovery with random backoff. The Protocol PLA also formats packets during transmission and strips preamble and synch during reception.

#### DMA AND BUFFER CONTROL LOGIC

The DMA and Buffer Control Logic is used to control two 16-bit DMA channels. During reception, the local DMA stores packets in a receive buffer ring, located in buffer memory. During transmission the Local DMA uses programmed pointer and length registers to transfer a packet from local buffer memory to the FIFO. A second DMA channel is used as a slave DMA to transfer data between the local buffer memory and the host system. The Local DMA and Remote DMA are internally arbitrated, with the Local DMA channel having highest priority. Both DMA channels use a common external bus clock to generate all required bus timing. External arbitration is performed with a standard bus request, bus acknowledge handshake protocol.

## 5.0 Transmit/Receive Packet Encapsulation/Decapsulation

A standard IEEE 802.3 packet consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data, and Frame Check Sequence (FCS). The typical format is shown in *Figure 2*. The packets are Manchester encoded and decoded by the ENDEC module and transferred serially to the NIC module using NRZ data with a clock. All fields are of fixed length except for the data field. The SNIC generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

### PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted each packet contains 62 bits of alternating 1,0 preamble. Some of this preamble will be lost as the packet travels through the network. The preamble field is stripped by the NIC module. Byte alignment is performed with the Start of Frame Delimiter (SFD) pattern which consists of two consecutive 1's. The SNIC does not treat the SFD pattern as a byte, it detects only the two bit pattern. This allows any preceding preamble within the SFD to be used for phase locking.

### DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted packets from reaching a node. There are three types of address formats supported by the SNIC: physical, multicast and broadcast. The physical address is a unique address that corresponds only to a single node. All physical addresses have an MSB of "0". These addresses are compared to the internally stored physical address registers. Each bit in the destination address must match in order for the SNIC to accept the packet. Multicast addresses begin with an MSB

of "1". The SNIC filters multicast addresses using a standard hashing algorithm that maps all multicast addresses into a 6-bit value. This 6-bit value indexes a 64-bit array that filters the value. If the address consists of all 1's it is a broadcast address, indicating that the packet is intended for all nodes. A promiscuous mode allows reception of all packets: the destination address is not required to match any filters. Physical, broadcast, multicast, and promiscuous address modes can be selected.

### SOURCE ADDRESS

The source address is the physical address of the node that sent the packet. Source addresses cannot be multicast or broadcast addresses. This field is simply passed to buffer memory.

### LENGTH FIELD

The 2-byte length field indicates the number of bytes that are contained in the data field of the packet. This field is not interpreted by the SNIC.

### DATA FIELD

The data field consists of anywhere from 46 to 1500 bytes. Messages longer than 1500 bytes need to be broken into multiple packets. Messages shorter than 46 bytes will require appending a pad to bring the data field to the minimum length of 46 bytes. If the data field is padded, the number of valid data bytes is indicated in the length field. **The SNIC does not strip or append pad bytes for short packets, or check for oversize packets.**

### FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of errors when a packet is received. During reception, error free packets result in a specific pattern in the CRC generator. Packets with improper CRC will be rejected. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X^1 + 1$ ) polynomial is used for the CRC calculations.

FIGURE 2

TL/F/10469-5

## 6.0 Direct Memory Access Control (DMA)

The DMA capabilities of the SNIC greatly simplify the use of the DP83901A in typical configurations. The local DMA channel transfers data between the FIFO and memory. On transmission, the packet is DMA'd from memory to the FIFO in bursts. Should a collision occur (up to 15 times), the packet is retransmitted with no processor intervention. On reception, packets are DMAed from the FIFO to the receive buffer ring (as explained below).

A remote DMA channel is also provided on the SNIC to accomplish transfers between a buffer memory and system memory. The two DMA channels can alternatively be combined to form a single 32-bit address with 8- or 16-bit data.

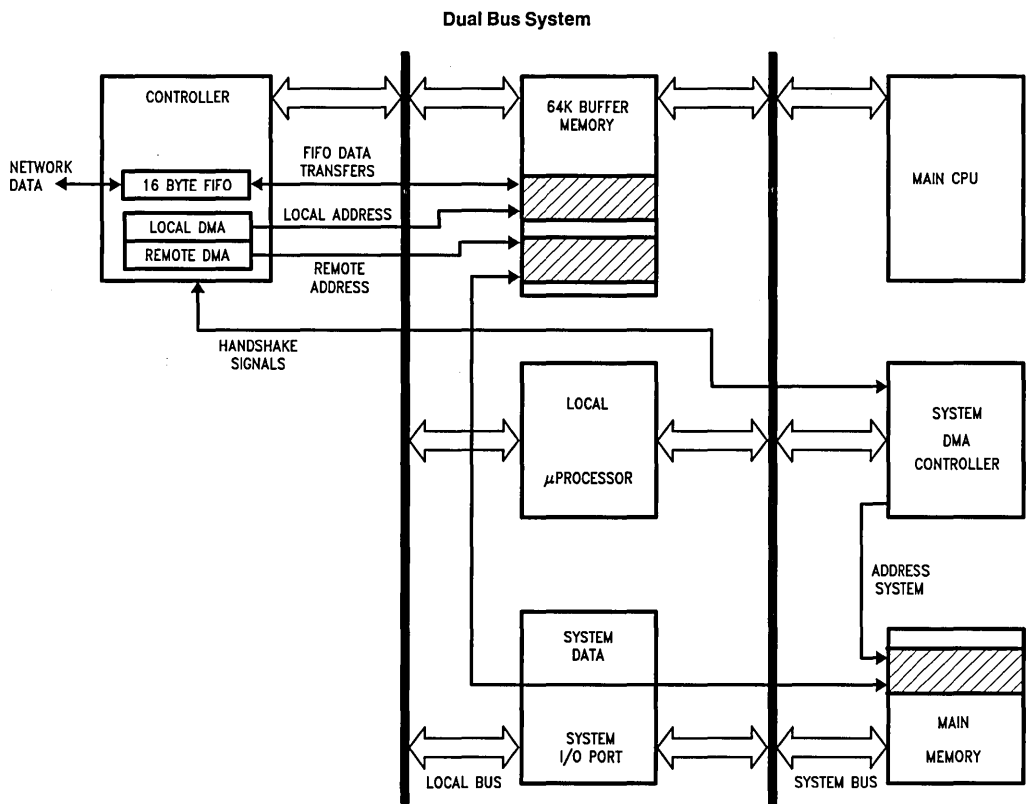

### DUAL DMA CONFIGURATION

An example configuration using both the local and remote DMA channels is shown below. Network activity is isolated

on a local bus, where the SNIC's local DMA channel performs burst transfers between the buffer memory and the SNIC's FIFO. The Remote DMA transfers data between the buffer memory and the host memory via a bidirectional I/O port. The Remote DMA provides local addressing capability and is used as a slave DMA by the host. Host side addressing must be provided by a host DMA or the CPU. The SNIC allows Local and Remote DMA operations to be interleaved.

### SINGLE CHANNEL DMA OPERATION

If desirable, the two DMA channels can be combined to provide a 32-bit DMA address. The upper 16 bits of the 32-bit address are static and are used to point to a 64 kbyte (or 32k word) page of memory where packets are to be received and transmitted.

TL/F/10469-6

## 7.0 Packet Reception

The Local DMA receive channel uses a Buffer Ring Structure comprised of a series of contiguous fixed length 256-byte (128 word) buffers for storage of received packets. The location of the Receive Buffer Ring is programmed in two registers, a Page Start and a Page Stop Register. Ethernet packets consist of a distribution of shorter link control packets and longer data packets, the 256-byte buffer length provides a good compromise between short packets and longer packets to most efficiently use memory. In addition these buffers provide memory resources for storage of back-to-back packets in loaded networks. The assignment of buffers for storing packets is controlled by Buffer Management Logic in the SNIC. The Buffer Management Logic

provides three basic functions: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of buffer pages that have been read by the host.

At initialization, a portion of the 64 kbyte (or 32k word) address space is reserved for the receive buffer ring. Two 8-bit registers, The Page Start Address Register (PSTART) and the Page Stop Address Register (PSTOP) define the physical boundaries of where the buffers reside. The SNIC treats the list of buffers as a logical ring; whenever the DMA address reaches the Page Stop Address, the DMA is reset to the Page Start Address.

TL/F/10469-7

## 7.0 Packet Reception (Continued)

### INITIALIZATION OF THE BUFFER RING

Two static registers and two working registers control the operation of the Buffer Ring. These are the Page Start Register, Page Stop Register (both described previously), the Current Page Register and the Boundary Pointer Register. The Current Page Register points to the first buffer used to store a packet and is used to restore the DMA for writing status to the Buffer Ring or for restoring the DMA address in the event of a Runt packet, a CRC, or Frame Alignment error. The Boundary Register points to the first packet in the Ring not yet read by the host. If the local DMA address ever reaches the Boundary, reception is aborted. The Boundary Pointer is also used to initialize the Remote DMA for removing a packet and is advanced when a packet is removed. A

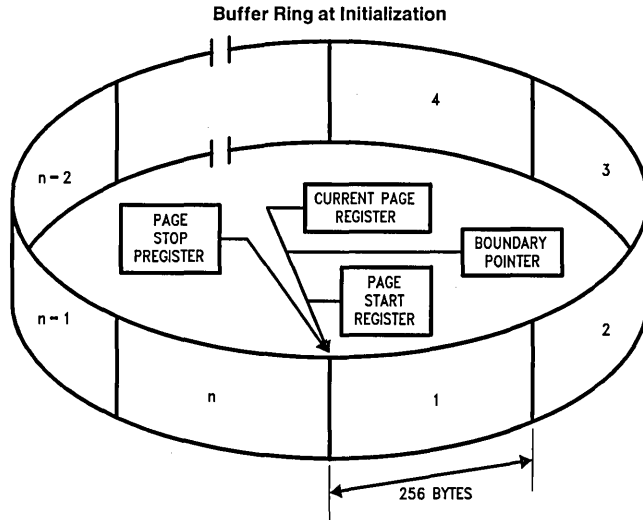

simple analogy to remember the function of these registers is that the Current Page Register acts as a Write Pointer and the Boundary Pointer acts as a Read Pointer.

**Note:** At initialization, the Page Start Register value should be loaded into both the Current Page Register and the Boundary Pointer Register.

**Note:** The Page Start Register must not be initialized to 00H.

### BEGINNING OF RECEPTION

When the first packet begins arriving the SNIC begins storing the packet at the location pointed to by the Current Page Register. An offset of 4 bytes is saved in this first buffer to allow room for storing receive status corresponding to this packet.

TL/F/10469-8

TL/F/10469-9

## 7.0 Packet Reception (Continued)

### LINKING RECEIVE BUFFER PAGES

If the length of the packet exhausts the first 256-byte buffer, the DMA performs a forward link to the next buffer to store the remainder of the packet. For a maximal length packet the buffer logic will link six buffers to store the entire packet. Buffers cannot be skipped when linking, a packet will always be stored in contiguous buffers. Before the next buffer can be linked, the Buffer Management Logic performs two comparisons. The first comparison tests for equality between the DMA address of the next buffer and the contents of the Page Stop Register. If the buffer address equals the Page Stop Register, the buffer management logic will restore the DMA to the first buffer in the Receive Buffer Ring value programmed in the Page Start Address Register. The second comparison tests for equality between the DMA ad-

dress of the next buffer address and the contents of the Boundary Pointer Register. If the two values are equal the reception is aborted. The Boundary Pointer Register can be used to protect against overwriting any area in the receive buffer ring that has not yet been read. When linking buffers, buffer management will never cross this pointer, effectively avoiding any overwrites. If the buffer address does not match either the Boundary Pointer or Page Stop Address, the link to the next buffer is performed.

### Linking Buffers

Before the DMA can enter the next contiguous 256-byte buffer, the address is checked for equality to PSTOP and to the Boundary Pointer. If neither are reached, the DMA is allowed to use the next buffer.

TL/F/10469-10

- 1) Check for = to PSTOP
- 2) Check for = to Boundary

## 7.0 Packet Reception (Continued)

### Buffer Ring Overflow

If the Buffer Ring has been filled and the DMA reaches the Boundary Pointer Address, reception of the incoming packet will be aborted by the SNIC. Thus, the packets previously received and still contained in the Ring will not be destroyed.

In heavily loaded network which cause overflows of the Receive Buffer Ring, the SNIC may disable the local DMA and suspend further receptions even if the Boundary register is advanced beyond the Current register. To guarantee this will not happen, a software reset must be issued during all Receive Buffer Ring overflows (indicated by the OVW bit in the Interrupt Status Register). The following procedure is required to recover from a Receiver Buffer Ring Overflow.

If this routine is not adhered to, the SNIC may act in an unpredictable manner. It should also be noted that it is not permissible to service an overflow interrupt by continuing to empty packets from the receive buffer without implementing the prescribed overflow routine. A flow chart of the SNIC's overflow routine can be found on the next page.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

1. Read and store the value of the TXP bit in the SNIC's Command Register.
2. Issue the STOP command to the SNIC. This is accomplished by setting the STP bit in the SNIC's Command Register. Writing 21H to the Command Register will stop the SNIC.
3. Wait for at least 1.6 ms. Since the SNIC will complete any transmission or reception that is in progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommended that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.
4. Clear the SNIC's Remote Byte Count registers (RBCR0 and RBCR1).
5. Read the stored value of the TXP bit from step 1, above. If this value is a 0, set the "Resend" variable to a 0 and jump to step 6. If this value is a 1, read the SNIC's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Trans-

mit Error bit (TXE) is set to a 1, set the "Resend" variable to a 0 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the SNIC's ISR is read to determine whether or not the packet was recognized by the SNIC. If neither the PTX nor TXE bit was set, then the packet will essentially be lost and re-transmitted only after a time-out takes place in the upper level software. By determining that the packet was lost at the driver level, a transmit command can be reissued to the SNIC once the overflow routine is completed (as in step 11). Also, it is possible for the SNIC to defer indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the SNIC to operate correctly.

6. Place the SNIC in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to "0,1" or "1,0", respectively.
7. Issue the START command to the SNIC. This can be accomplished by writing 22H to the Command Register. This is necessary to activate the SNIC's Remote DMA channel.
8. Remove one or more packets from the receive buffer ring.
9. Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.
10. Take the SNIC out of loopback. This is done by writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)
11. If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by writing a value of 26H to the Command Register. If the "Resend" variable is 0, nothing needs to be done.

**Note 1:** If Remote DMA is not being used, the SNIC does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7.

**Note 2:** When the SNIC is in STOP mode, the Missed Talley Counter is disabled.

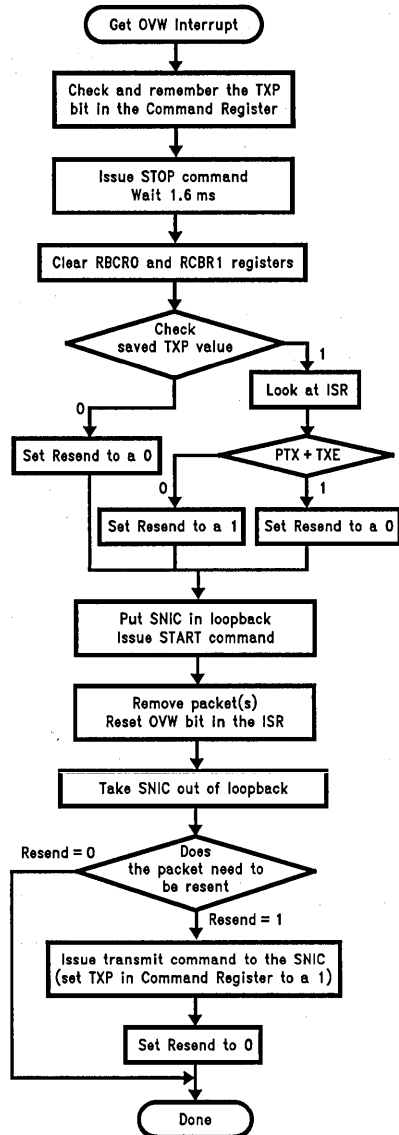

Received Packet Aborted If It Hits Boundary

## 7.0 Packet Reception (Continued)

Overflow Routine Flow Chart

TL/F/10469-52

## 7.0 Packet Reception (Continued)

### Enabling the SNIC On An Active Network

After the SNIC has been initialized the procedure for disabling and then re-enabling the SNIC on the network is similar to handling Receive Buffer Ring overflow as described previously.

1. Program Command Register for page 0 (Command Register = 21H)
2. Initialize Data Configuration Register (DCR)
3. Clear Remote Byte Count Registers (RBCR0, RBCR1)
4. Initialize Receive Configuration Register (RCR)
5. Place the SNIC in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
6. Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
7. Clear Interrupt Status Register (ISR) by writing 0FFH to it.
8. Initialize Interrupt Mask Register (IMR)
9. Program Command Register for page 1 (Command Register = 61H)
  - i) Initialize Physical Address Registers (PAR0-PAR5)
  - ii) Initialize Multicast Address Registers (MAR0-MAR7)
  - iii) Initialize CURRent pointer

- 10) Put SNIC in START mode (Command Register = 22H).  
The local receive DMA is still not active since the SNIC is in LOOPBACK.
- 11) Initialize the Transmit Configuration for the intended value. The SNIC is now ready for transmission and reception.

### END OF PACKET OPERATIONS

At the end of the packet the SNIC determines whether the received packet is to be accepted or rejected. It either branches to a routine to store the Buffer Header or to another routine that recovers the buffers used to store the packet.

### SUCCESSFUL RECEPTION

If the packet is successfully received, the DMA is restored to the first buffer used to store the packet (pointed to by the Current Page Register). The DMA then stores the Receive Status, a Pointer to where the next packet will be stored (Buffer 4) and the number of received bytes. Note that the remaining bytes in the last buffer are discarded and reception of the next packet begins on the next empty 256-byte buffer boundary. The Current Page Register is then initialized to the next available buffer in the Buffer Ring. (The location of the next buffer had been previously calculated and temporarily stored in an internal scratchpad register.)

Termination of Received Packet—Packet Accepted

TL/F/10469-12

## 7.0 Packet Reception (Continued)

### BUFFER RECOVERY FOR REJECTED PACKETS

If the packet is a runt packet or contains CRC or Frame Alignment errors, it is rejected. The buffer management logic resets the DMA back to the first buffer page used to store the packet (pointed to by CURR), recovering all buffers that had been used to store the rejected packet. This operation will not be performed if the SNIC is programmed to accept either runt packets or packets with CRC or Frame Alignment

errors. The received CRC is always stored in buffer memory after the last byte of received data for the packet.

### Error Recovery

If the packet is rejected as shown, the DMA is restored by the SNIC by reprogramming the DMA starting address pointed to by the Current Page Register.

TL/F/10469-13

## 7.0 Packet Reception (Continued)

### REMOVING PACKETS FROM THE RING

Packets are removed from the ring using the Remote DMA or an external device. When using the Remote DMA the Send Packet command can be used. This programs the Remote DMA to automatically remove the received packet pointed to by the Boundary Pointer. At the end of the transfer, the SNIC moves the Boundary Pointer, freeing additional buffers for reception. The Boundary Pointer can also be moved manually by programming the Boundary Register.

### STORAGE FORMAT FOR RECEIVED PACKETS

The following diagrams describe the format for how received packets are placed into memory by the local DMA channel. These modes are selected in the Data Configuration Register.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 1		Receive Byte Count 0	
Byte 2		Byte 1	

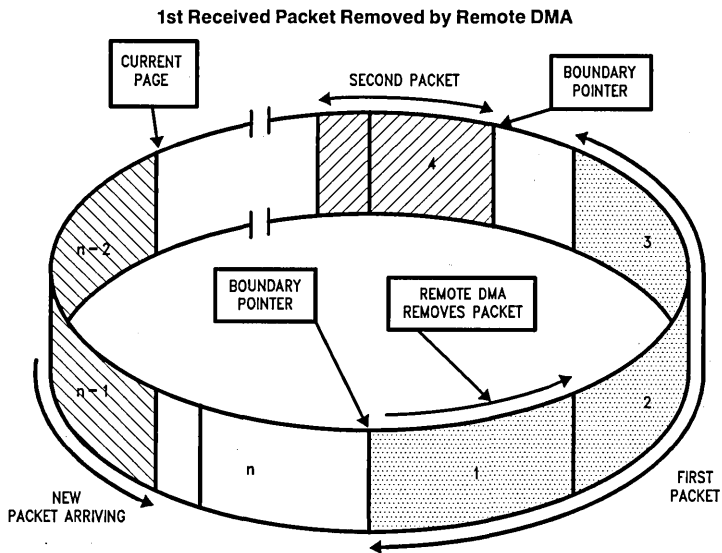

BOS = 0, WTS = 1 in Data Configuration Register. This format is used with Series 32xxx, or 808xx processors.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 0		Receive Byte Count 1	
Byte 1		Byte 2	

BOS = 1, WTS = 1 in Data Configuration Register. This format is used with 680x0 type processors. (Note: The Receive Count ordering remains the same for BOS = 0 or 1.)

Receive Status
Next Packet Pointer
Receive Byte Count 0
Receive Byte Count 1
Byte 0
Byte 1

BOS = 0, WTS = 0 in Data Configuration Register. This format is used with general 8-bit processors.

TL/F/10469-14

## 8.0 Packet Transmission

The Local DMA is also used during transmission of a packet. Three registers control the DMA transfer during transmission, a Transmit Page Start Address Register (TPSR) and the Transmit Byte Count Registers (TBCRO, 1). When the SNIC receives a command to transmit the packet pointed to by these registers, buffer memory data will be moved into the FIFO as required during transmission. The SNIC will generate and append the preamble, synch and CRC fields.

General Transmit Packet Format		
Transmit	Destination Address	6 Bytes
Byte	Source Address	6 Bytes
Count	Type/Length	2 Bytes
TBCRO, 1	Data	≥ 46 Bytes
	Pad (If Data < 46 Bytes)	

### TRANSMIT PACKET ASSEMBLY

The SNIC requires a contiguous assembled packet with the format shown. The transmit byte count includes the Destination Address, Source Address, Length Field and Data. It does not include preamble and CRC. When transmitting data smaller than 46 bytes, the packet must be padded to a minimum size of 64 bytes. The programmer is responsible for adding and stripping pad bytes.

### TRANSMISSION

Prior to transmission, the TPSR (Transmit Page Start Register) and TBCRO, TBCR1 (Transmit Byte Count Registers) must be initialized. To initiate transmission of the packet the TXP bit in the Command Register is set. The Transmit Status Register (TSR) is cleared and the SNIC begins to prefetch transmit data from memory (unless the SNIC is currently receiving). If the interframe gap has timed out the SNIC will begin transmission.

### CONDITIONS REQUIRED TO BEGIN TRANSMISSION

In order to transmit a packet, the following three conditions must be met:

1. The Interframe Gap Timer has timed out the first 6.4 μs of the Interframe Gap.
2. At least one byte has entered the FIFO. (This indicates that the burst transfer has been started.)
3. If a collision had been detected then before transmission the packet time must have timed out.

In typical systems the SNIC prefetches the first burst of bytes before the 6.4 μs timer expires. The time during which SNIC transmits preamble can also be used to load the FIFO.

**Note:** If carrier sense is asserted before a byte has been loaded into the FIFO, the SNIC will become a receiver.

### COLLISION RECOVERY

During transmission, the Buffer Management logic monitors the transmit circuitry to determine if a collision has occurred. If a collision is detected, the Buffer Management logic will reset the FIFO and restore the Transmit DMA pointers for retransmission of the packet. The COL bit will be set in the TSR and the NCR (Number of Collisions Register) will be incremented. If 15 retransmissions each result in a collision the transmission will be aborted and the ABT bit in the TSR will be set.

**Note:** NCR reads as zeroes if excessive collisions are encountered.

### TRANSMIT PACKET ASSEMBLY FORMAT

The following diagrams describe the format for how packets must be assembled prior to transmission for different byte ordering schemes. The various formats are selected in the Data Configuration Register.

D15	D8	D7	D0
Destination Address 1		Destination Address 0	
Destination Address 3		Destination Address 2	
Destination Address 5		Destination Address 4	
Source Address 1		Source Address 0	
Source Address 3		Source Address 2	
Source Address 5		Source Address 4	
Type/Length 1		Type/Length 0	
Data 1		Data 0	

BOS = 0, WTS = 1 in Data Configuration Register.

This format is used with Series 32xxx, or 808xx processors.

D15	D8	D7	D0
Destination Address 0		Destination Address 1	
Destination Address 2		Destination Address 3	
Destination Address 4		Destination Address 5	
Source Address 0		Source Address 1	
Source Address 2		Source Address 3	
Source Address 4		Source Address 5	
Type/Length 0		Type/Length 1	
Data 0		Data 1	

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with 680x0 type processors.

D1	D0
Destination Address 0	
Destination Address 1	
Destination Address 2	
Destination Address 3	
Destination Address 4	
Destination Address 5	
Source Address 0	
Source Address 1	
Source Address 2	
Source Address 3	
Source Address 4	
Source Address 5	

BOS = 0, WTS = 0 in Data Configuration Register.

This format is used with general 8-bit processors.

**Note:** All examples above will result in a transmission of a packet in order of DA0, DA1, DA3 ... bits within each byte will be transmitted least significant bit first.

DA = Destination Address.

### 9.0 Remote DMA

The Remote DMA channel is used to both assemble packets for transmission, and to remove received packets from the Receive Buffer Ring. It may also be used as a general purpose slave DMA channel for moving blocks of data or commands between host memory and local buffer memory. There are three modes of operation, Remote Write, Remote Read, or Send Packet.

Two register pairs are used to control the Remote DMA, a Remote Start Address (RSAR0, RSAR1) and a Remote Byte Count (RBCR0, RBCR1) register pair. The Start Address Register pair points to the beginning of the block to be moved while the Byte Count Register pair is used to indicate the number of bytes to be transferred. Full handshake logic is provided to move data between local buffer memory and a bidirectional I/O port.

#### REMOTE WRITE

A Remote Write transfer is used to move a block of data from the host into local buffer memory. The Remote DMA will read data from the I/O port and sequentially write it to local buffer memory beginning at the Remote Start Address. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches a count of zero.

#### REMOTE READ

A Remote Read transfer is used to move a block of data from local buffer memory to the host. The Remote DMA will

sequentially read data from the local buffer memory, beginning at the Remote Start Address, and write data to the I/O port. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

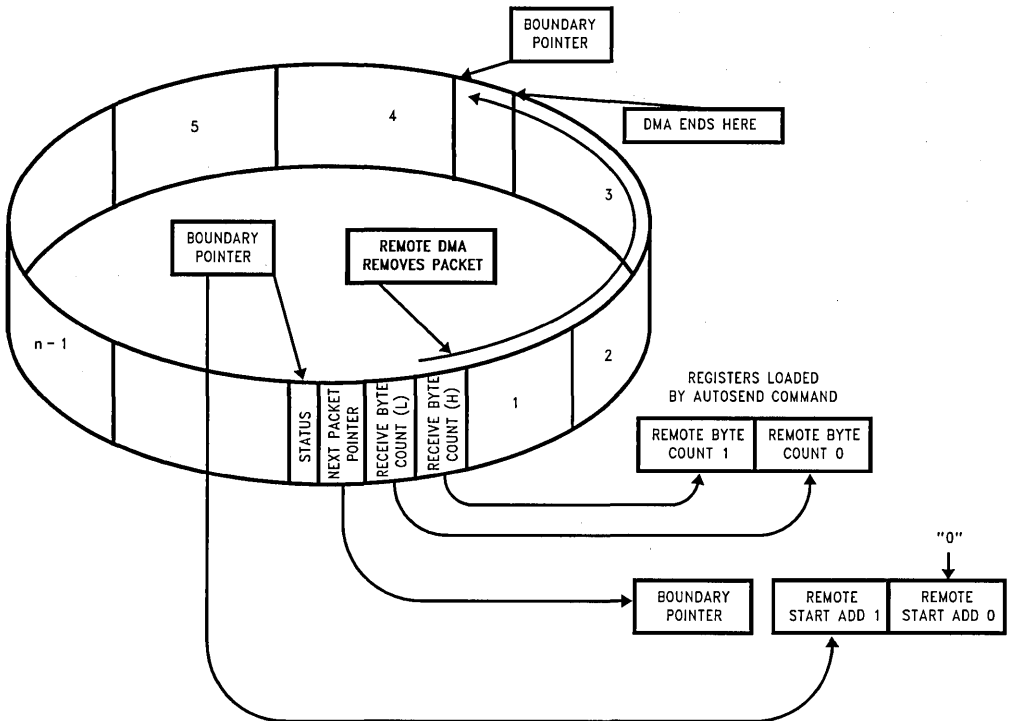

#### SEND PACKET COMMAND

The Remote DMA channel can be automatically initialized to transfer a single packet from the Receive Buffer Ring. The CPU begins this transfer by issuing a "Send Packet" Command. The DMA will be initialized to the value of the Boundary Pointer Register and the Remote Byte Count Register pair (RBCR0, RBCR1) will be initialized to the value of the Receive Byte Count fields found in the Buffer Header of each packet. After the data is transferred, the Boundary Pointer is advanced to allow the buffers to be used for new receive packets. The Remote Read will terminate when the Byte Count equals zero. The Remote DMA is then prepared to read the next packet from the Receive Buffer Ring. If the DMA pointer crosses the Page Stop Register, it is reset to the Page Start Address. This allows the Remote DMA to remove packets that have wrapped around to the top of the Receive Buffer Ring.

**Note 1:** In order for the SNIC to correctly execute the Send Packet Command, the upper Remote Byte Count Register (RBCR1) must first be loaded with 0FH.

**Note 2:** The Send Packet command cannot be used with 680x0 type processors.

Remote DMA Autoinitialization from Buffer Ring

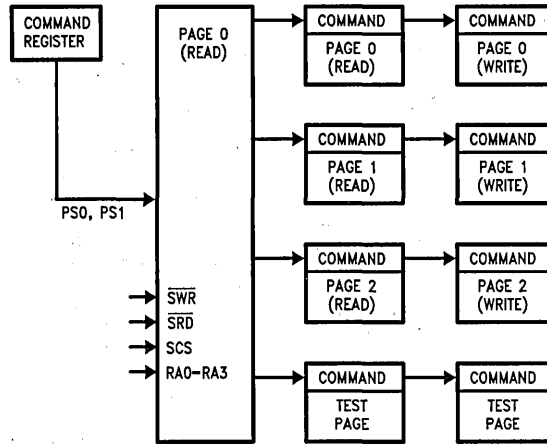

TL/F/10469-15

## 10.0 Internal Registers

All registers are 8-bit wide and mapped into four pages which are selected in the Command Register (PS0, PS1). Pins RA0-RA3 are used to address registers within each page. Page 0 registers are those registers which are com-

monly accessed during SNIC operation while page 1 registers are used primarily for initialization. The registers are partitioned to avoid having to perform two write/read cycles to access commonly used registers.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS

#### COMMAND REGISTER (CR) 00H (READ/WRITE)

The Command Register is used to initiate transmissions, enable or disable Remote DMA operations and to select register pages. To issue a command the microprocessor sets the corresponding bit(s) (RD2, RD1, RD0, TXP). Further commands may be overlapped, but with the following rules: (1) If a transmit command overlaps with a remote DMA operation, bits RD0, RD1, and RD2 must be maintained for the remote DMA command when setting the TXP bit. Note, if a remote DMA command is re-issued when giving the transmit command, the DMA will complete immediately if the remote byte count register has not been reinitialized. (2) If a remote DMA operation overlaps a transmission, RD0, RD1, and RD2 may be written with the desired values and a "0" written to the TXP bit. Writing a "0" to this bit has no effect. (3) A remote write DMA may not overlap remote read operation or visa versa. Either of these operations must either complete or be aborted before the other operation may start. Bits PS1, PS0, RD2, and STP may be set any time.

7	6	5	4	3	2	1	0
PS1	PS0	RD2	RD1	RD0	TXP	STA	STP

Bit	Symbol	Description																								
D0	STP	<p><b>Stop:</b> Software reset command, takes the controller offline, no packets will be received or transmitted. Any reception or transmission in progress will continue to completion before entering the reset state. To exit this state, the STP bit must be reset and the STA bit must be set high. To perform a software reset, this bit should be set high. The software reset has executed only when indicated by the RST bit in the ISR being set to 1. <b>STP powers up high.</b></p> <p><b>Note:</b> If the SNIC has previously been in start mode and the STP is set, both the STP and STA bits will remain set.</p>																								
D1	STA	<p><b>Start:</b> This bit is used to activate the SNIC after either power up, or when the SNIC has been placed in a reset mode by software command or error. <b>STA powers up low.</b></p>																								
D2	TXP	<p><b>Transmit Packet:</b> This bit must be set to initiate transmission of a packet. TXP is internally reset either after the transmission is completed or aborted. This bit should be set only after the Transmit Byte Count and Transmit Page Start registers have been programmed.</p>																								
D3, D4, and D5	RD0, RD1, and RD2	<p><b>Remote DMA Command:</b> These three encoded bits control operation of the Remote DMA channel. RD2 can be set to abort any Remote DMA command in progress. The Remote Byte Count Registers should be cleared when a Remote DMA has been aborted. The Remote Start Addresses are not restored to the starting address if the Remote DMA is aborted.</p> <table border="1"> <tr> <td>RD2</td> <td>RD1</td> <td>RD0</td> <td></td> </tr> <tr> <td>0</td> <td>0</td> <td>0</td> <td>Not Allowed</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>Remote Read</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>Remote Write (Note 2)</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>Send Packet</td> </tr> <tr> <td>1</td> <td>X</td> <td>X</td> <td>Abort/Complete Remote DMA (Note 1)</td> </tr> </table> <p><b>Note 1:</b> If a remote DMA operation is aborted and the remote byte count has not decremented to zero, PRQ will remain high. A read acknowledge (RACK) on a write acknowledge (WACK) will reset PRQ low.</p> <p><b>Note 2:</b> For proper operation of the Remote Write DMA, there are two steps which must be performed before using the Remote Write DMA. The steps are as follows:</p> <ol style="list-style-type: none"> <li>I) Write a non-zero value into RBCR0.</li> <li>II) Set bits RD2, RD1, and RD0 to 0, 0, and 1.</li> <li>III) Issue the Remote Write DMA Command (RD2, RD1, RD0 = 0, 1, 0).</li> </ol>	RD2	RD1	RD0		0	0	0	Not Allowed	0	0	1	Remote Read	0	1	0	Remote Write (Note 2)	0	1	1	Send Packet	1	X	X	Abort/Complete Remote DMA (Note 1)

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### INTERRUPT STATUS REGISTER (ISR) 07H (READ/WRITE)

This register is accessed by the host processor to determine the cause of an interrupt. Any interrupt can be masked in the Interrupt Mask Register (IMR). Individual interrupt bits are cleared by writing a "1" into the corresponding bit of the ISR. The INT signal is active as long as any unmasked signal is set, and will not go low until all unmasked bits in this register have been cleared. The ISR must be cleared after power up by writing it with all 1's.

Bit	Symbol	Description
D0	PRX	<b>Packet Received:</b> Indicates packet received with no errors.
D1	PTX	<b>Packet Transmitted:</b> Indicates packet transmitted with no errors.
D2	RXE	<b>Receive Error:</b> Indicates that a packet was received with one or more of the following errors: — CRC Error — Frame Alignment Error — FIFO Overrun — Missed Packet
D3	TXE	<b>Transmit Error:</b> Set when packet transmitted with one or more of the following errors: — Excessive Collisions — FIFO Underrun
D4	OVW	<b>Overwrite Warning:</b> Set when receive buffer ring storage resources have been exhausted. (Local DMA has reached Boundary Pointer)
D5	CNT	<b>Counter Overflow:</b> Set when MSB of one or more of the Network Tally Counters has been set.
D6	RDC	<b>Remote DMA Complete:</b> Set when Remote DMA operation has been completed.
D7	RST	<b>Reset Status:</b> Set when SNIC enters reset state and cleared when a Start Command is issued to the CR. This bit is also set when a Receive Buffer Ring overflow occurs and is cleared when one or more packets have been removed from the ring. Writing to this bit has no effect.  <b>Note:</b> This bit does not generate an interrupt, it is merely a status indicator.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### INTERRUPT MASK REGISTER (IMR) 0FH (WRITE)

The Interrupt Mask Register is used to mask interrupts. Each interrupt mask bit corresponds to a bit in the Interrupt Status Register (ISR). If an interrupt mask bit is set, an interrupt will be issued whenever the corresponding bit in the ISR is set. If any bit in the IMR is set low, an interrupt will not occur when the bit in the ISR is set. **The IMR powers up to all zeroes.**

Bit	Symbol	Description
D0	PRXE	<b>Packet Received Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received
D1	PTXE	<b>Packet Transmitted Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when packet is transmitted
D2	RXEE	<b>Receive Error Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received with error
D3	TXEE	<b>Transmit Error Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when packet transmission results in error
D4	OVWE	<b>Overwrite Warning Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when Buffer Management Logic lacks sufficient buffers to store incoming packet
D5	CNTE	<b>Counter Overflow Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when MSB of one or more of the Network Statistics counters has been set
D6	RDCE	<b>DMA Complete Interrupt Enable</b> 0: Interrupt Disabled 1: Enables Interrupt when Remote DMA transfer has been completed
D7	Reserved	Reserved

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### DATA CONFIGURATION REGISTER (DCR) 0EH (WRITE)

This Register is used to program the SNIC for 8- or 16-bit memory interface, select byte ordering in 16-bit applications and establish FIFO thresholds. **The DCR must be initialized prior to loading the Remote Byte Count Registers. LAS is set on power up.**

7	6	5	4	3	2	1	0

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### TRANSMIT STATUS REGISTER (TSR) 04H (READ)

This register records events that occur on the media during transmission of a packet. It is cleared when the next transmission is initiated by the host. All bits remain low unless the event that corresponds to a particular bit occurs during transmission. Each transmission should be followed by a read of this register. The contents of this register are not specified until after the first transmission.

7	6	5	4	3	2	1	0
OWC	CDH	FU	CRS	ABT	COL	—	PTX

Bit	Symbol	Description
D0	PTX	<b>Packet Transmitted:</b> Indicates transmission without error. (No excessive collisions or FIFO underrun) (ABT = "0", FU = "0")
D1	Reserved	Reserved
D2	COL	<b>Transmit Collided:</b> Indicates that the transmission collided at least once with another station on the network. The number of collisions is recorded in the Number of Collisions Registers (NCR).
D3	ABT	<b>Transmit Aborted:</b> Indicates the SNIC aborted transmission because of excessive collisions. (Total number of transmissions including original transmission attempt equals 16.)
D4	CRS	<b>Carrier Sense Lost:</b> This bit is set when carrier is lost during transmission of the packet. Transmission is not aborted on loss of carrier.
D5	FU	<b>FIFO Underrun:</b> If the SNIC cannot gain access of the bus before the FIFO empties, this bit is set. Transmission of the packet will be aborted.
D6	CDH	<b>CD Heartbeat:</b> Failure of the transceiver to transmit a collision signal after transmission of a packet will set this bit. The Collision Detect (CD) heartbeat signal must commence during the first 6.4 $\mu$ s of the Interframe Gap following a transmission. In certain collisions, the CD Heartbeat bit will be set even though the transceiver is not performing the CD heartbeat test.
D7	OWC	<b>Out of Window Collision:</b> Indicates that a collision occurred after a slot time (51.2 $\mu$ s). Transmissions rescheduled as in normal collisions.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### RECEIVE CONFIGURATION REGISTER (RCR) OCH (WRITE)

This register determines operation of the SNIC during reception of a packet and is used to program what types of packets to accept.

Bit	Symbol	Description
D0	SEP	<p><b>Save Errored Packets</b></p> <p>0: Packets with receive errors are rejected.                      1: Packets with receive errors are accepted. Receive errors are CRC and Frame Alignment errors.</p>
D1	AR	<p><b>Accept Runt Packets:</b> This bit allows the receiver to accept packets that are smaller than 64 bytes. The packet must be at least 8 bytes long to be accepted as a runt.</p> <p>0: Packets with fewer than 64 bytes rejected.                      1: Packets with fewer than 64 bytes accepted.</p>
D2	AB	<p><b>Accept Broadcast:</b> Enables the receiver to accept a packet with an all 1's destination address.</p> <p>0: Packets with broadcast destination address rejected.                      1: Packets with broadcast destination address accepted.</p>
D3	AM	<p><b>Accept Multicast:</b> Enables the receiver to accept a packet with a multicast address, all multicast addresses must pass the hashing array.</p> <p>0: Packets with multicast destination address not checked.                      1: Packets with multicast destination address checked.</p>
D4	PRO	<p><b>Promiscuous Physical:</b> Enables the receiver to accept all packets with a physical address.</p> <p>0: Physical address of node must match the station address programmed in PAR0–PAR5.                      1: All packets with physical addresses accepted.</p>
D5	MON	<p><b>Monitor Mode:</b> Enables the receiver to check addresses and CRC on incoming packets without buffering to memory. The Missed Packet Tally counter will be incremented for each recognized packet.</p> <p>0: Packets buffered to memory.                      1: Packets checked for address match, good CRC and Frame Alignment but not buffered to memory.</p>
D6	Reserved	Reserved
D7	Reserved	Reserved

**Note:** D2 and D3 are "OR'd" together, i.e., if D2 and D3 are set the SNIC will accept broadcast and multicast addresses as well as its own physical address. To establish full promiscuous mode, bits D2, D3, and D4 should be set. In addition the multicast hashing array must be set to all 1's in order to accept all multicast addresses.

## 10.0 Internal Registers (Continued)

### 10.3 REGISTER DESCRIPTIONS (Continued)

#### RECEIVE STATUS REGISTER (RSR) 0CH (READ)

This register records status of the received packet, including information on errors and the type of address match, either physical or multicast. The contents of this register are written to buffer memory by the DMA after reception of a good packet. If packets with errors are to be saved the receive status is written to memory at the head of the erroneous packet if an erroneous packet is received. If packets with errors are to be rejected the RSR will not be written to memory. The contents will be cleared when the next packet arrives. CRC errors, Frame Alignment errors and missed packets are counted internally by the SNIC which relinquishes the Host from reading the RSR in real time to record errors for Network Management Functions. The contents of this register are not specified until after the first reception.

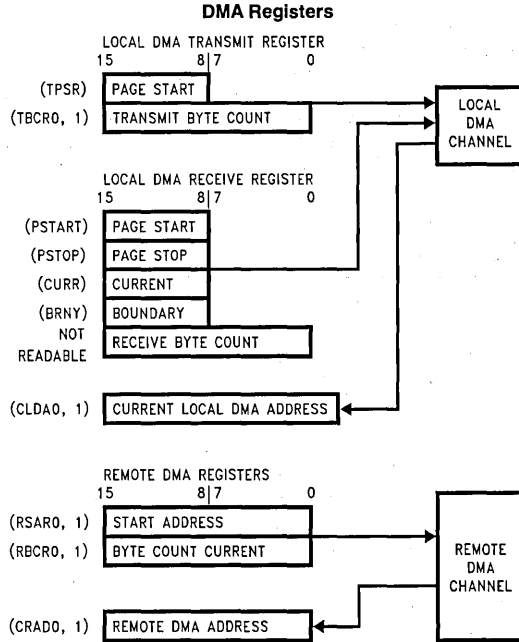

Bit	Symbol	Description
D0	PRX	<b>Packet Received Intact:</b> Indicates packet received without error. (Bits CRC, FAE, FO, and MPA are zero for the received packet.)
D1	CRC	<b>CRC Error:</b> Indicates packet received with CRC error. Increments Tally Counter (CNTR1). This bit will also be set for Frame Alignment errors.
D2	FAE	<b>Frame Alignment Error:</b> Indicates that the incoming packet did not end on a byte boundary and the CRC did not match at last byte boundary. Increments Tally Counter (CNTR0).
D3	FO	<b>FIFO Overrun:</b> This bit is set when the FIFO is not serviced causing overflow during reception. Reception of the packet will be aborted.
D4	MPA	<b>Missed Packet:</b> Set when a packet intended for node cannot be accepted by SNIC because of a lack of receive buffers or if the controller is in monitor mode and did not buffer the packet to memory. Increments Tally Counter (CNTR2).
D5	PHY	<b>Physical/Multicast Address:</b> Indicates whether received packet had a physical or multicast address type. 0: Physical Address Match 1: Multicast/Broadcast Address Match
D6	DIS	<b>Receiver Disabled:</b> Set when receiver disabled by entering Monitor mode. Reset when receiver is re-enabled when exiting Monitor mode.
D7	DFR	<b>Deferring:</b> Set when internal Carrier Sense or Collision signals are generated in the ENDEC module. If the transceiver has asserted the CD line as a result of the jabber, this bit will stay set indicating the jabber condition.

**Note:** Following coding applies to CRC and FAE bits.

FAE	CRC	Type of Error
0	0	No Error (Good CRC and <6 Dribble Bits)
0	1	CRC Error
1	0	Illegal, Will Not Occur
1	1	Frame Alignment Error and CRC Error

# 10.0 Internal Registers (Continued)

## 10.4 DMA REGISTERS

TL/F/10469-17

The DMA Registers are partitioned into groups; Transmit, Receive and Remote DMA Registers. The Transmit registers are used to initialize the Local DMA Channel for transmission of packets while the Receive Registers are used to initialize the Local DMA Channel for packet Reception. The Page Stop, Page Start, Current and Boundary Registers are used by the Buffer Management Logic to supervise the Receive Buffer Ring. The Remote DMA Registers are used to initialize the Remote DMA.

**Note:** In the figure above, registers are shown as 8 or 16 bits wide. Although some registers are 16-bit internal registers, all registers are accessed as 8-bit registers. Thus the 16-bit Transmit Byte Count Register is broken into two 8-bit registers, TBCR0, TBCR1. Also TPSR, PSTART, PSTOP, CURR and BNRY only check or control the upper 8 bits of address information on the bus. Thus, they are shifted to positions 15-8 in the diagram above.

### 10.5 TRANSMIT DMA REGISTERS

#### TRANSMIT PAGE START REGISTER (TPSR)

This register points to the assembled packet to be transmitted. Only the eight higher order addresses are specified since all transmit packets are assembled on 256-byte page boundaries. The bit assignment is shown below. The values placed in bits D7-D0 will be used to initialize the higher order address (A8-A15) of the Local DMA for transmission. The lower order bits (A7-A0) are initialized to zero.

Bit Assignment

	7	6	5	4	3	2	1	0
TPSR	A15	A14	A13	A12	A11	A10	A9	A8

(A7-A0 Initialized to Zero)

#### TRANSMIT BYTE COUNT REGISTER 0, 1 (TBCR0, TBCR1)

These two registers indicate the length of the packet to be transmitted in bytes. The count must include the number of bytes in the source, destination, length and data fields. The maximum number of transmit bytes allowed is 64 Kbytes. The SNIC will not truncate transmissions longer than 1500 bytes. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
TBCR1	L15	L14	L13	L12	L11	L10	L9	L8

	7	6	5	4	3	2	1	0
TBCR0	L7	L6	L5	L4	L3	L2	L1	L0

## 10.0 Internal Registers (Continued)

### 10.6 LOCAL DMA RECEIVE REGISTERS

#### PAGE START AND STOP REGISTERS (PSTART, PSTOP)

The Page Start and Page Stop Registers program the starting and stopping address of the Receive Buffer Ring. Since the SNIC uses fixed 256-byte buffers aligned on page boundaries only the upper 8 bits of the start and stop address are specified.

#### PSTART, PSTOP Bit Assignment

	7	6	5	4	3	2	1	0
PSTART,	A15	A14	A13	A12	A11	A10	A9	A8
PSTOP								

#### BOUNDARY (BNRY) REGISTER

This register is used to prevent overflow of the Receive Buffer Ring. Buffer management compares the contents of this register to the next buffer address when linking buffers together. If the contents of this register match the next buffer address the Local DMA operation is aborted.

	7	6	5	4	3	2	1	0
BNRY	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT PAGE REGISTER (CURR)

This register is used internally by the Buffer Management Logic as a backup register for reception. CURR contains the address of the first buffer to be used for a packet reception and is used to restore DMA pointers in the event of receive errors. This register is initialized to the same value as PSTART and should not be written to again unless the controller is Reset.

	7	6	5	4	3	2	1	0
CURR	A15	A14	A13	A12	A11	A10	A9	A8

#### CURRENT LOCAL DMA REGISTER 0,1 (CLDA0, 1)

These two registers can be accessed to determine the current local DMA address.

	7	6	5	4	3	2	1	0
CLDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CLDA0	A7	A6	A5	A4	A3	A2	A1	A0

### 10.7 REMOTE DMA REGISTERS

#### REMOTE START ADDRESS REGISTERS (RSAR0, 1)

Remote DMA operations are programmed via the Remote Start Address (RSAR0, 1) and Remote Byte Count (RBCR0, 1) registers. The Remote Start Address is used to point to the start of the block of data to be transferred and the Remote Byte Count is used to indicate the length of the block (in bytes).

	7	6	5	4	3	2	1	0
RSAR1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
RSAR0	A7	A6	A5	A4	A3	A2	A1	A0

#### REMOTE BYTE COUNT REGISTERS (RBCR0, 1)

	7	6	5	4	3	2	1	0
RBCR1	BC15	BC14	BC13	BC12	BC11	BC10	BC9	BC8

	7	6	5	4	3	2	1	0
RBCR0	BC7	BC6	BC5	BC4	BC3	BC2	BC1	BC0

Note: RSAR0 programs the start address bits A0-A7.

RSAR1 programs the start address bits A8-A15.

Address incremented by two for word transfers, and by one for byte transfers. Byte Count decremented by two for word transfers and by one for byte transfers.

RBCR0 programs LSB byte count.

RBCR1 programs MSB byte count.

#### CURRENT REMOTE DMA ADDRESS (CRDA0, CRDA1)

The Current Remote DMA Registers contain the current address of the Remote DMA. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
CRDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CRDA0	A7	A6	A5	A4	A3	A2	A1	A0

### 10.8 PHYSICAL ADDRESS REGISTERS (PAR0-PAR5)

The physical address registers are used to compare the destination address of incoming packets for rejecting or accepting packets. Comparisons are performed on a byte-wide basis. The bit assignment shown below relates the sequence in PAR0-PAR5 to the bit sequence of the received packet.

	D7	D6	D5	D4	D3	D2	D1	D0
PAR0	DA7	DA6	DA5	DA4	DA3	DA2	DA1	DA0
PAR1	DA15	DA14	DA13	DA12	DA11	DA10	DA9	DA8
PAR2	DA23	DA22	DA21	DA20	DA19	DA18	DA17	DA16
PAR3	DA31	DA30	DA29	DA28	DA27	DA26	DA25	DA24
PAR4	DA39	DA38	DA37	DA36	DA35	DA34	DA33	DA32
PAR5	DA47	DA46	DA45	DA44	DA43	DA42	DA41	DA40

#### Destination Address Source

P/S	DA0	DA1	DA2	DA3	...	DA46	DA47	SA0	...
-----	-----	-----	-----	-----	-----	------	------	-----	-----

Note: P/S = Preamble, Synch

DA0 = Physical/Multicast Bit

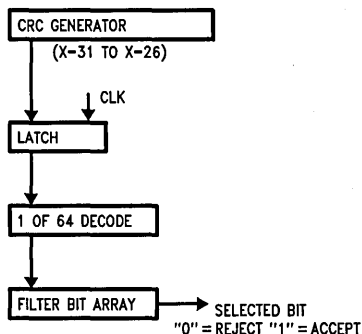

### 10.9 MULTICAST ADDRESS REGISTERS (MAR0-MAR7)

The multicast address registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 most signifi-

## 10.0 Internal Registers (Continued)

cant bits of the CRC generator are latched. These 6 bits are then decoded by a 1 of 64 decode to index a unique filter bit (FB0–63) in the multicast address registers. If the filter bit selected is set, the multicast packet is accepted. The system designer would use a program to determine which filter bits to set in the multicast registers. All multicast filter bits that correspond to multicast address accepted by the node are then set to one. To accept all multicast packets all of the registers are set to all ones.

**Note:** Although the hashing algorithm does not guarantee perfect filtering of multicast address, it will perfectly filter up to 64 multicast addresses if these addresses are chosen to map into unique locations in the multicast filter.

TL/F/10469-18

	D7	D6	D5	D4	D3	D2	D1	D0
MAR0	FB7	FB6	FB5	FB4	FB3	FB2	FB1	FB0
MAR1	FB15	FB14	FB13	FB12	FB11	FB10	FB9	FB8
MAR2	FB23	FB22	FB21	FB20	FB19	FB18	FB17	FB16
MAR3	FB31	FB30	FB29	FB28	FB27	FB26	FB25	FB24
MAR4	FB39	FB38	FB37	FB36	FB35	FB34	FB33	FB32
MAR5	FB47	FB46	FB45	FB44	FB43	FB42	FB41	FB40
MAR6	FB55	FB54	FB53	FB52	FB51	FB50	FB49	FB48
MAR7	FB63	FB62	FB61	FB60	FB59	FB58	FB57	FB56

If address Y is found to hash to the value 32 (20H), then FB32 in MAR4 should be initialized to "1". This will cause the SNIC to accept any multicast packet with the address Y.

## 10.10 NETWORK TALLY COUNTERS

Three 8-bit counters are provided for monitoring the number of CRC errors, Frame Alignment Errors and Missed Packets. The maximum count reached by any counter is 192 (COH). These registers will be cleared when read by the CPU. The count is recorded in binary in CT0–CT7 of each Tally Register.

### Frame Alignment Error Tally (CNTR0)

This counter increments every time a packet is received with a Frame Alignment Error. The packet must have been recognized by the address recognition logic. The counter is cleared after it is read by the processor.

### CRC Error Tally (CNTR1)

This counter is incremented every time a packet is received with a CRC error. The packet must first be recognized by the address recognition logic. The counter is cleared after it is read by the processor.

### Frames Lost Tally Register (CNTR2)

This counter is incremented if a packet cannot be received due to lack of buffer resources. In monitor mode, this counter will count the number of packets that pass the address recognition logic.

### FIFO

This is an 8-bit register that allows the CPU to examine the contents of the FIFO after loopback. The FIFO will contain the last 8 data bytes transmitted in the loopback packet. Sequential reads from the FIFO will advance a pointer in the FIFO and allow reading of all 8 bytes.

**Note:** The FIFO should only be read when the SNIC has been programmed in loopback mode.

### NUMBER OF COLLISIONS (NCR)

This register contains the number of collisions a node experiences when attempting to transmit a packet. If no collisions are experienced during a transmission attempt, the COL bit of the TSR will not be set and the contents of NCR will be zero. If there are excessive collisions, the ABT bit in the TSR will be set and the contents of NCR will be zero. The NCR is cleared after the TXP bit in the CR is set.

## 11.0 Initialization Procedures

The SNIC must be initialized prior to transmission or reception of packets from the network. Power on reset is applied to the SNIC's reset pin. This clears/sets the following bits:

Register	Reset Bits	Set Bits
Command Register (CR)	TXP, STA	RD2, STP
Interrupt Status (ISR)		RST
Interrupt Mask (IMR)	All Bits	
Data Control (DCR)		LAS
Transmit Config. (TCR)	LB1, LB0	

The SNIC remains in its reset state until a Start Command is issued. This guarantees that no packets are transmitted or received and that the SNIC remains a bus slave until all appropriate internal registers have been programmed. After initialization the STP bit of the command register is reset and packets may be received and transmitted.

### Initialization Sequence

The following initialization procedure is mandatory.

1. Program Command Register for Page 0 (Command Register = 21H)
2. Initialize Data Configuration Register (DCR)
3. Clear Remote Byte Count Registers (RBCR0, RBCR1)
4. Initialize Receive Configuration Register (RCR)
5. Place the SNIC in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
6. Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
7. Clear Interrupt Status Register (ISR) by writing 0FFH to it.
8. Initialize Interrupt Mask Register (IMR)
9. Program Command Register for page 1 (Command Register = 61H)
  - I) Initialize Physical Address Registers (PAR0-PAR5)
  - II) Initialize Multicast Address Registers (MAR0-MAR5)
  - III) Initialize CURRent pointer
10. Put SNIC in START mode (Command Register = 22H).
11. Initialize the Transmit Configuration for the intended value. The SNIC is now ready for transmission and reception.

Before receiving packets, the user must specify the location of the Receive Buffer Ring. This is programmed in the Page Start and Page Stop Registers. In addition, the Boundary and Current Page Register must be initialized to the value of the Page Start Register. These registers will be modified during reception of packets.

## 12.0 Loopback Diagnostics

Three forms of local loopback are provided on the SNIC. The user has the ability to loopback through the deserializer on the controller, through the ENDEC module or the Coax Transceiver on the DP83901A SNIC. **Because of the half duplex architecture of the SNIC, loopback testing is a special mode of operation with the following restrictions:**

### Restrictions During Loopback

The FIFO is split into two halves, one used for transmission the other for reception. Only 8-bit fields can be fetched from memory so two tests are required for 16-bit systems to verify integrity of the entire data path. During loopback the maximum latency from the assertion of BREQ to BACK is 2.0  $\mu$ s. Systems that wish to use the loopback test yet do not meet this latency can limit the loopback to 7 bytes without experiencing underflow. Only the last 8 bytes of the loopback packet are retained in the FIFO. The last 8 bytes can be read through the FIFO register which will advance through the FIFO to allow reading the receive packet sequentially.

Destination Address	= (6 Bytes) Station Physical Address
Source Address	
Length	2 Bytes
Data	= 46 to 1500 Bytes
CRC	Appended by SNIC if CRC = "0" in TCR

When in word-wide mode with Byte Order Select set, the loopback packet must be assembled in the even byte location as shown below. (The loopback only operated with byte wide transfers.)

TL/F/10469-50

When in word-wide mode with Byte Order Select low, the following format must be used for the loopback packet.

TL/F/10469-51

**Note:** When using loopback in word mode 2n bytes must be programmed in TBCR0, 1. Where n = actual number of bytes assembled in even or odd location.

## 12.0 Loopback Diagnostics (Continued)

To initiate a loopback the user first assembles the loopback packet then selects the type of loopback using the Transmit Configuration register bits LB0, LB1. The transmit configuration register must also be set to enable or disable CRC generation during transmission. The user then issues a normal transmit command to send the packet. During loopback the receiver checks for an address match and if CRC bit in the TCR is set, the receiver will also check the CRC. The last 8 bytes of the loopback packet are buffered and can read out of the FIFO using FIFO read port.

### Loopback Modes

**MODE 1:** Loopback through the NIC Module (LB1 = 0, LB0 = 1): If this loopback is used, the NIC Modules's serial-izer is connected to the deserial-izer.

**MODE 2:** Loopback through the ENDEC Module (LB1 = 1, LB0 = 0): If the loopback is to be performed through the SNI, the SNIC provides a control (LPBK) that forces the ENDEC module to loopback all signals.

**MODE 3:** Loopback to Coax (LB1 = 1, LB0 = 1). Packets can be transmitted to the coax in loopback mode to check all of the transmit and receive paths and the coax itself.

**Note:** Collision and Carrier Sense can be generated by the ENDEC module and are masked by the NIC module. It is not possible to go directly between the loopback modes, it is necessary to return to normal operation (00H) when changing modes.

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the SNIC to malfunction.

### Reading the Loopback Packet

The last 8 bytes of a received packet can be examined by 8 consecutive reads of the FIFO register. The FIFO pointer is incremented after the rising edge of the CPU's read strobe by internally synchronizing and advancing the pointer. This may take up to four bus clock cycles, if the pointer has not been incremented by the time the CPU reads the FIFO register again, the SNIC will insert wait states.

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the SNIC to malfunction.

### Alignment of the Received Packet in the FIFO

Reception of the packet in the FIFO begins at location zero, after the FIFO pointer reaches the last location in the FIFO, the pointer wraps to the top of the FIFO overwriting the previously received data. This process continued until the last byte is received. The SNIC then appends the received byte count in the next two locations of the FIFO. The contents of the Upper Byte Count are also copied to the next FIFO location. The number of bytes used in the loopback packet determined the alignment of the packet in the FIFO.

The alignment for a 64-byte packet is shown below.

FIFO Location	FIFO Contents	
0	Lower Byte Count	First Byte Read
1	Upper Byte Count	Second Byte Read
2	Upper Byte Count	•
3	Last Byte	•
4	CRC1	•
5	CRC2	•
6	CRC3	•
7	CRC4	Last Byte Read

For the following alignment in the FIFO the packet length should be  $(N \times 8) + 5$  Bytes. Note that if the CRC bit in the TCR is set, CRC will not be appended by the transmitter. If the CRC is appended by the transmitter, the 1st four bytes, bytes N-3 to N, correspond to the CRC.

FIFO Location	FIFO Contents	
0	Byte N-4	First Byte Read
1	Byte N-3 (CRC1)	Second Byte Read
2	Byte N-2 (CRC2)	•
3	Byte N-1 (CRC3)	•
4	Byte N (CRC4)	•
5	Lower Byte Count	•
6	Upper Byte Count	Last Byte Read
7	Upper Byte Count	

### LOOPBACK TESTS

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the DP83901A SNIC prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

1. Verify integrity of data path. Received data is checked against transmitted data.
2. Verify CRC logic's capability to generate good CRC on transmit, verify CRC on receive (good or bad CRC).

## 12.0 Loopback Diagnostics (Continued)

3. Verify that the Address Recognition Logic can

- a) Recognize address match packets
- b) Reject packets that fail to match an address

### LOOPBACK OPERATION IN THE SNIC

Loopback is a modified form of transmission using only half of the FIFO. This places certain restrictions on the use of loopback testing. When loopback mode is selected in the TCR, the FIFO is split. A packet should be assembled in memory with programming of TPSR and TBCR0, TBCR1 registers. When the transmit command is issued the following operations occur:

#### Transmitter Actions

1. Data is transferred from memory by the DMA until the FIFO is filled. For each transfer TBCR0 and TBCR1 are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
2. The SNIC generates 56 bits of preamble followed by an 8-bit synch pattern.
3. Data transferred from FIFO to serializer.
4. If CRC = 1 in TCR, no CRC calculated by SNIC, the last byte transmitted is the last byte from the FIFO (Allows software CRC to be appended). If CRC = 0, SNIC calculates and appends four bytes of CRC.
5. At end of Transmission PTX bit set in ISR.

#### Receiver Actions

1. Wait for synch, all preamble stripped.
2. Store packet in FIFO, increment receive byte count for each incoming byte.
3. If CRC = 1 in TRC, receiver checks incoming packet for CRC errors. If CRC = 0 in TCR, receiver does not check CRC errors, CRC error bit always set in RSR (for address matching packets).
4. At end of receive, receive byte count written into FIFO, receive status register is updated. The PRX bit is typically set in the RSR even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the RSR to be set.

#### EXAMPLES

The following examples show what results can be expected from a properly operating SNIC during loopback. The restrictions and results of each type of loopback are listed for reference. The loopback tests are divided into two sets of tests. One to verify the data path, CRC generation and byte count through all three paths. The second set of tests uses internal loopback to verify the receiver's CRC checking and address recognition. For all of the tests the DCR was programmed to 40H.

Path	TCR	RCR	TSR	RSR	ISR
SNIC Internal	02	1F	53 (Note 1)	02 (Note 2)	02 (Note 3)

**Note 1:** Since carrier sense and collision detect are generated in the EN-DEC module. They are blocked during NIC loopback, carrier and CD heartbeat are not seen and the CRS and CDH bits are set.

**Note 2:** CRC errors are always indicated by receiver if CRC is appended by the transmitter.

**Note 3:** Only the PTX bit in the ISR is set, the PRX bit is only set if status is written to memory. In loopback this action does not occur and the PRX bit remains 0 for all loopback modes.

**Note 4:** All values are hex.

Path	TCR	RCR	TSR	RSR	ISR
SNIC Internal	04	1F	43 (Note 1)	02	02

**Note 1:** CDH is set, CRS is not set since it is generated by the external encoder/decoder.

Path	TCR	RCR	TSR	RSR	ISR
SNIC External	06	1F	03 (Note 1)	02	02 (Note 2)

**Note 1:** CDH and CRS should not be set. The TSR however, could also contain 01H, 03H, 07H and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** Will contain 08H if packet is not transmittable.

**Note 3:** During external loopback the SNIC is now exposed to network traffic, it is therefore possible for the contents of both the Receive portion of the FIFO and the RSR to be corrupted by any other packet on the network. Thus in a live network the contents of the FIFO and RSR should not be depended on. The SNIC will still abide by the standard CSMA/CD protocol in external loopback mode. (i.e., The network will not be disturbed by the loopback packet.)

**Note 4:** All values are hex.

### CRC AND ADDRESS RECOGNITION

The next three tests exercise the address recognition logic and CRC. These tests should be performed using internal loopback only so that the SNIC is isolated from interference from the network. These tests also require the capability to generate CRC in software.

The address recognition logic cannot be directly tested. The CRC and FAE bits in the RSR are only set if the address in the packet matches the address filters. If errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch. The following sequence of packets will test the address recognition logic. The DCR should be set to 40H, the TCR should be set to 03H with a software generated CRC.

Packet Contents			Results
Test	Address	CRC	RSR
Test A	Matching	Good	01 (Note 1)
Test B	Matching	Bad	02 (Note 2)
Test C	Non-Matching	Bad	01

**Note 1:** Status will read 21H if multicast address used.

**Note 2:** Status will read 22H if multicast address used.

**Note 3:** In test A, the RSR is set up. In test B the address is found to match since the CRC is flagged as bad. Test C proves that the address recognition logic can distinguish a bad address and does not notify the RSR of the bad CRC. The receiving CRC is proven to work in test A and test B.

**Note 4:** All values are hex.

### NETWORK MANAGEMENT FUNCTIONS

Network management capabilities are required for maintenance and planning of a local area network. The SNIC supports the minimum requirement for network management in hardware, the remaining requirements can be met with software counts. There are three events that software alone can not track during reception of packets: CRC errors, Frame Alignment errors, and missed packets.

## 12.0 Loopback Diagnostics (Continued)

Since errored packets can be rejected, the status associated with these packets is lost unless the CPU can access the Receive Status Register before the next packet arrives. In situations where another packet arrives very quickly, the CPU may have no opportunity to do this. The SNIC counts the number of packets with CRC errors and Frame Alignment errors. 8-Bit counters have been selected to reduce overhead. The counters will generate interrupts whenever their MSBs are set so that a software routine can accumulate the network statistics and reset the counter before overflow occurs. The counters are sticky so that when they reach a count of 192 (C0H) counting is halted. An additional counter is provided to count the number of packets the SNIC misses due to buffer overflow or being offline.

The structure of the counters is shown below:

TL/F/10469-19

Additional information required for network management is available in the Receive and Transmit Status Registers. Transmit status is available after each transmission for information regarding events during transmission.

Typically, the following statistics might be gathered in software:

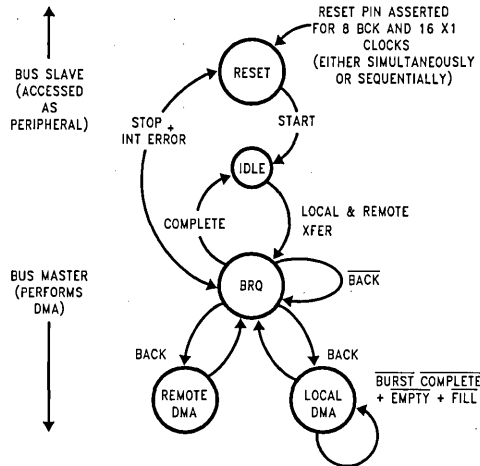

Traffic: Frames Sent OK  
 Frames Received OK  
 Multicast Frames Received  
 Packets Lost Due to Lack of Resources  
 Retries/Packet

Errors: CRC Errors  
 Alignment Errors  
 Excessive Collisions  
 Packet with Length Errors  
 Heartbeat Failure

### 13.0 Bus Arbitration and Timing

The SNIC operates in three possible modes:

- BUS MASTER (WHILE PERFORMING DMA)
- BUS SLAVE (WHILE BEING ACCESSED BY CPU)
- IDLE

TL/F/10469-20

Upon power-up the SNIC is in an indeterminate state. After receiving a hardware reset the SNIC is a bus slave in the Reset State, the receiver and transmitter are both disabled in this state. The reset state can be re-entered under three conditions, soft reset (Stop Command), hard reset (RESET input) or an error that shuts down the receiver of transmitter (FIFO underflow or overflow). After initialization of registers, the SNIC is issued a Start command and the SNIC enters Idle state. The idle state is exited by a request from the FIFO on the case of receiver or transmit, or from the Remote DMA in the case of Remote DMA operation. After acquiring

the bus in a BREQ/BACK handshake the Remote or Local DMA transfer is completed and the SNIC re-enters the idle state.

#### DMA TRANSFERS TIMING

The DMA can be programmed for the following types of transfers:

- 16-Bit Address, 8-bit Data Transfer
- 16-Bit Address, 16-bit Data Transfer
- 32-Bit Address, 8-bit Data Transfer
- 32-Bit Address, 16-bit Data Transfer

All DMA transfers use BSCK for timing. 16-Bit Address modes require 4 BSCK cycles as shown below:

TL/F/10469-21

### 13.0 Bus Arbitration and Timing (Continued)

16-Bit Address, 16-Bit Data

TL/F/10469-22

32-Bit Address, 8-Bit Data

TL/F/10469-23

32-Bit Address, 16-Bit Data

TL/F/10469-24

**Note:** In 32-bit address mode, ADS1 is at TRI-STATE after the first T1-T4 states; thus, a 4.7k pull-down resistor is required for 32-bit address.

### 13.0 Bus Arbitration and Timing (Continued)

When in 32-bit mode four additional BSCK cycles are required per burst. The first bus cycle (T1'-T4') of each burst is used to output the upper 16-bit addresses. This 16-bit address is programmed in RSAR0 and RSAR1 and points to a 64k page of system memory. All transmitted or received packets are constrained to reside within this 64k page.

#### FIFO BURST CONTROL

All Local DMA transfers are burst transfers, once the DMA requests the bus and the bus is acknowledged, the DMA will transfer an exact burst of bytes programmed in the Data Configuration Register (DCR) then relinquish the bus. If there are remaining bytes in the FIFO the next burst will not be initiated until the FIFO threshold is exceeded. If BACK is removed during the transfer, the burst transfer will be aborted. **(DROPPING BACK DURING A DMA CYCLE IS NOT RECOMMENDED.)**

TL/F/10469-25

where N = 1, 2, 4, or 6 Words or N = 2, 4, 8, or 12 Bytes when in byte mode.

#### INTERLEAVED LOCAL OPERATION

If a remote DMA transfer is initiated or in progress when a packet is being received or transmitted, the Remote DMA transfer will be interrupted for higher priority Local DMA

transfers. When the Local DMA transfer is completed the Remote DMA will re-arbitrate for the bus and continue its transfers. This is illustrated below:

TL/F/10469-26

Note that if the FIFO requires service while a remote DMA is in progress, BREQ is not dropped and the Local DMA burst is appended to the Remote Transfer. When switching from a local transfer to a remote transfer, however, BREQ is dropped and raised again. This allows the CPU or other devices to fairly contend for the bus.

#### FIFO AND BUS OPERATIONS

##### Overview

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the SNIC contains a 16-byte FIFO for buffering data between the bus and the media. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO at different rates. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

To understand FIFO underruns or overruns, there are two causes which produce this condition—

1. the bus latency is so long that the FIFO has filled (or emptied) from the network before the local DMA has serviced the FIFO.
2. the bus latency or bus data rate has slowed the throughput of the local DMA to a point where it is slower than the network data rate (10 Mb/s). This second condition is also dependent upon DMA clock and word width (byte wide or word wide).

The worst case condition ultimately limits the overall bus latency which the SNIC can tolerate.

##### FIFO Underrun and Transmit Enable

During transmission, if a FIFO underrun occurs, the Transmit enable (TXE) output may remain high (active). Generally, this will cause a very large packet to be transmitted onto the network. The jabber feature of the transceiver will terminate the transmission, and reset TXE.

To prevent this problem, a properly designed system will not allow FIFO underruns by giving the SNIC a bus acknowledge within time shown in the maximum bus latency curves shown and described later.

### 13.0 Bus Arbitration and Timing (Continued)

#### FIFO AT THE BEGINNING OF RECEIVE

At the beginning of reception, the SNIC stores entire Address field of each incoming packet in the FIFO to determine whether the packet matches its Physical Address Register or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that BREQ is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu\text{s}$ . This operation affects the bus latencies at 2 byte and 4 byte thresholds during the first receive BREQ since the FIFO must be filled to 8 bytes (or 4 words) before issuing a BREQ.

#### FIFO Operation at the End of Receive

When Carrier Sense goes low, the SNIC enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet, *Figure 5*. The SNIC holds onto the bus for the entire sequence. The longest time BREQ may be extended occurs when a packet ends just as the SNIC performs its last FIFO burst. The SNIC, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completes by writing the header information to memory. The following steps occur during this sequence.

1. SNIC issues BREQ because the FIFO threshold has been reached
2. During the burst, packet ends, resulting in BREQ extended.
3. SNIC flushes remaining bytes from FIFO
4. SNIC performs internal processing to prepare for writing the header.
5. SNIC writes 4-byte (2-word) header
6. SNIC deasserts BREQ

End of Packet Processing

TL/F/10469-53

End of Packet Processing (EOPP) times for 10 MHz and 20 MHz have been tabulated below.

End of Packet Processing Times for Various FIFO Thresholds, Bus Clocks and Transfer Modes

Mode	Threshold	Bus Clock	EOPP
Byte	2 bytes	10 MHz	7.0 $\mu\text{s}$
	4 bytes		8.6 $\mu\text{s}$
	8 bytes		11.0 $\mu\text{s}$
Byte	2 bytes	20 MHz	3.6 $\mu\text{s}$
	4 bytes		4.2 $\mu\text{s}$
	8 bytes		5.0 $\mu\text{s}$
Word	2 bytes	10 MHz	5.4 $\mu\text{s}$
	4 bytes		6.2 $\mu\text{s}$
	8 bytes		7.4 $\mu\text{s}$
Word	2 bytes	20 MHz	3.0 $\mu\text{s}$
	4 bytes		3.2 $\mu\text{s}$
	8 bytes		3.6 $\mu\text{s}$

Maximum Bus Latency for Byte Mode

TL/F/10469-54

Maximum Bus Latency for Word Mode

TL/F/10469-55

### 13.0 Bus Arbitration and Timing (Continued)

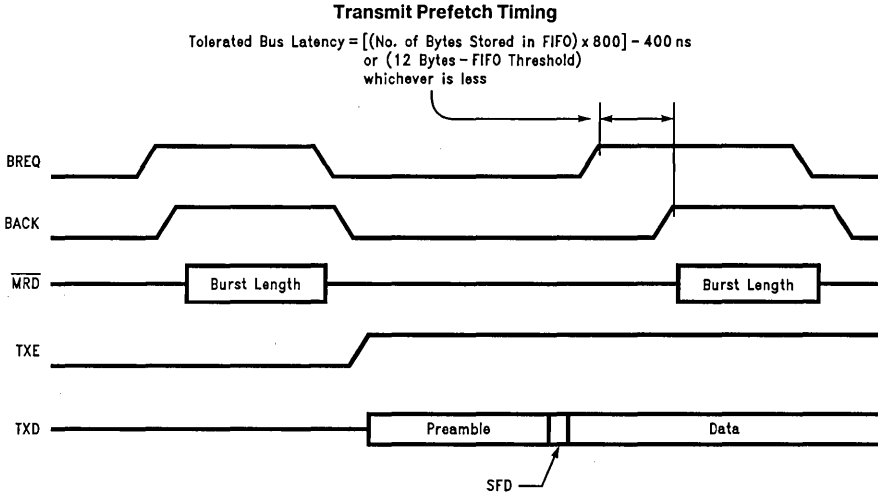

#### Threshold Detection (Bus Latency)

To assure that no overwriting of data in the FIFO occurs, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the n+1 byte has entered the FIFO; thus, with an 8 byte threshold, the SNIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until the n+2 bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to 8 byte threshold), BREQ is issued when the 10th byte has entered the FIFO. The two graphs indicate the maximum allowable bus latency for Word or Byte transfer modes.

hold), BREQ is issued when the 10th byte has entered the FIFO. The two graphs indicate the maximum allowable bus latency for Word or Byte transfer modes.

#### The FIFO at the Beginning of Transmit

Before transmitting, the SNIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next BREQ is not issued until after the SNIC actually begins transmitting data, i.e., after SFD. The Transmit Prefetch Timing diagram illustrates this process.

TL/F/10469-56

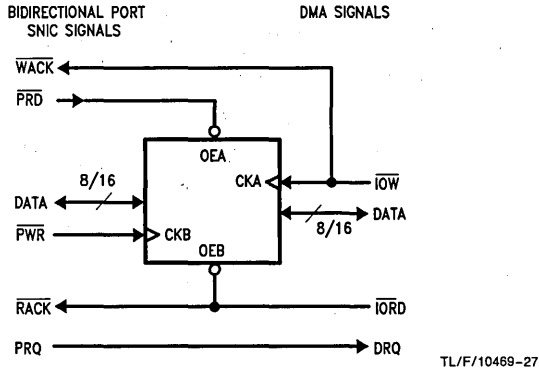

### 13.0 Bus Arbitration and Timing (Continued)

#### REMOTE DMA-BIDIRECTIONAL PORT CONTROL

The Remote DMA transfers data between the local buffer memory and a bidirectional port (memory to I/O transfer). This transfer is arbitrated on a byte by byte basis versus the burst transfer used for Local DMA transfers. This bidirec-

tional port is also read/written by the host. All transfers through this port are asynchronous. At any one time transfers are limited to one direction, either from the port to local buffer memory (Remote Write) or from local buffer memory to the port (Remote Read).

#### Bus Handshake Signals for Remote DMA Transfers

#### REMOTE READ TIMING

1. The DMA reads byte/word from local buffer memory and writes byte/word into latch, increments the DMA address and decrements the byte count (RBCR0, 1).
2. A Request Line (PRQ) is asserted to inform the system that a byte is available.
3. The system reads the port, the read strobe ( $\overline{RACK}$ ) is used as an acknowledge by the Remote DMA and it goes back to step 1.

Steps 1-3 are repeated until the remote DMA is complete. Note that in order for the Remote DMA to transfer a byte from memory to the latch, it must arbitrate access to the local bus via a BREQ, BACK handshake. After each byte or word is transferred to the latch, BREQ is dropped. If a Local DMA is in progress, the Remote DMA is held off until the local DMA is complete.

## 13.0 Bus Arbitration and Timing (Continued)

### REMOTE WRITE TIMING

A Remote Write operation transfers data from the I/O port to the local buffer RAM. The SNIC initiates a transfer by requesting a byte/word via the PRQ. The system transfers a byte/word to the latch via  $\overline{IOW}$ , this write strobe is detected by the SNIC and PRQ is removed. By removing the PRQ, the Remote DMA holds off further transfers into the latch until the current byte/word has been transferred from the latch, PRQ is reasserted and the next transfer can begin.

1. SNIC asserts PRQ. System writes byte/word into latch. SNIC removes PRQ.
2. Remote DMA reads contents of port and writes byte/word to local buffer memory, increments address and decrements byte count (RBCRO, 1).
3. Go back to step 1.

Steps 1–3 are repeated until the remote DMA is complete.

TL/F/10469-29

### REMOTE DMA WRITE

#### Setting PRQ Using the Remote Read

Under certain conditions the SNIC's bus state machine may issue  $\overline{MWR}$  and  $\overline{PRD}$  before PRQ for the first DMA transfer of a Remote Write Command. If this occurs this could cause data corruption, or cause the remote DMA count to be different from the main CPU count causing the system to "lock up."

To prevent this condition when implementing a Remote DMA Write, the Remote DMA Write command should first be preceded by a Remote DMA Read command to insure that the PRQ signal is asserted before the SNIC starts its port read cycle. The reason for this is that the state machine that asserts PRQ runs independently of the state machine that controls the DMA signals. The DMA machine assumes that PRQ is asserted, but actually may not be. To remedy this situation, a single Remote Read cycle should be inserted before the actual DMA Write Command is given. This will ensure that PRQ is asserted when the Remote DMA

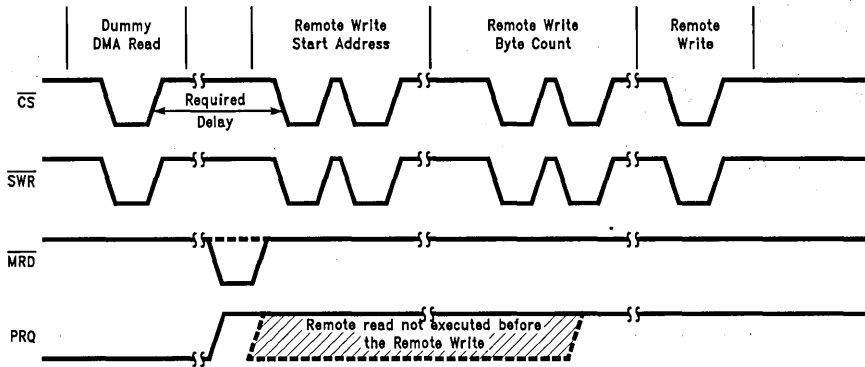

Write is subsequently executed. This single Remote Read cycle is called a "dummy Remote Read." In order for the dummy Remote Read cycle to operate correctly, the Start Address should be programmed to a known, safe location in the buffer memory space, and the Remote Byte Count should be programmed to a value greater than 1. This will ensure that the master read cycle is performed safely, eliminating the possibility of data corruption.

#### Remote Write with High Speed Buses

When implementing the Remote DMA Write solution with high speed buses and CPU's, timing problems may cause the system to hang. Therefore additional considerations are required.

The problem occurs when the system can execute the dummy Remote Read and then start the Remote Write before the SNIC has had a chance to execute the Remote Read. If this happens the PRQ signal will not get set, and the Remote Byte Count and Remote Start Address for the Remote

## 13.0 Bus Arbitration and Timing (Continued)

TL/F/10469-57

Note: The dashed lines indicate incorrect timing as described in the text.

**FIGURE 9. Timing Diagram for Dummy Remote Read**

Write operation could be corrupted. This is shown by the hatched waveforms in the timing diagram of *Figure 9*. The execution of the Remote Read can be delayed by the local DMA operations (particularly during end-of-packet processing).

To ensure the dummy Remote Read does execute, a delay must be inserted between writing the Remote Read Command, and starting to write the Remote Write State Address. (This time is designated in *Figure 9* by the delay arrows.) The recommended method to avoid this problem is after the Remote Read command is given, to poll both bytes of the Current Remote DMA Address Registers. When the address has incremented PRQ has been set. Software should recognize this and then start the Remote Write.

An additional caution for high speed systems is that the polling must follow guidelines specified in Time Between Chip Select section. That is, there must be at least 4 bus clocks between chip selects (for example when BSK = 20 MHz, then this time should be 200 ns).

The general flow for executing a Remote Write is:

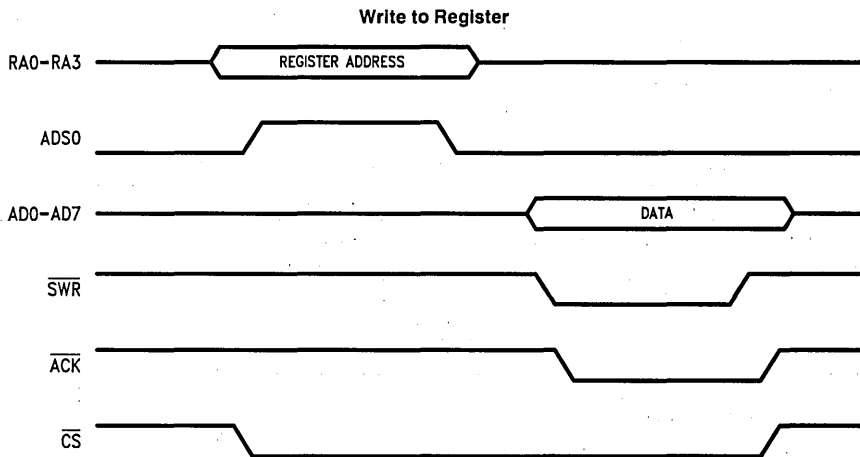

1. Set Remote Byte Count to a value  $> 1$  and Remote Start Address to unused RAM (one location before the transmit start address is usually a safe location).
2. Issue the "dummy" Remote Read command.
3. Read the Current Remote DMA Address (CRDA) (both bytes).
4. Compare to previous CRDA value if different go to 6.
5. Delay and jump to 3.
6. Set up for the Remote Write command, by setting the Remote Byte Count and the Remote Start Address (note that if Remote Byte count in step 1 can be set to the transmit byte count plus one, and the Remote Start Address to one less, these will now be incremented to the correct values.)
7. Issue the Remote Write command.

### 13.0 Bus Arbitration and Timing (Continued)

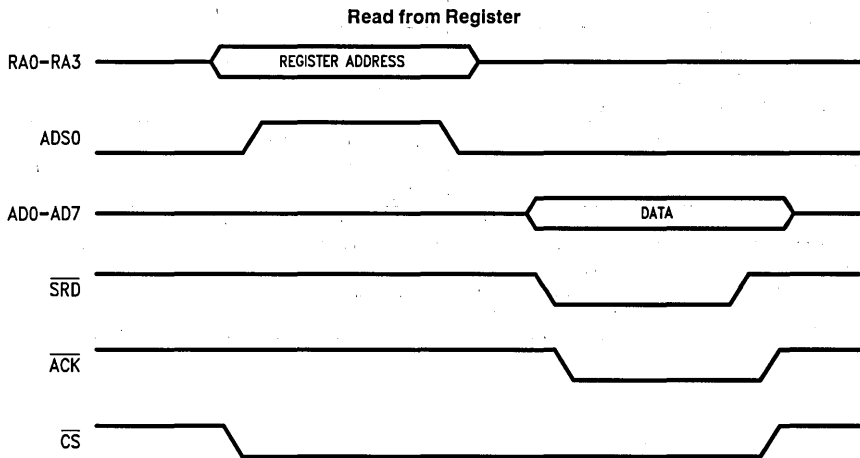

#### SLAVE MODE TIMING

When  $\overline{CS}$  is low, the SNIC becomes a bus slave. The CPU can then read or write any internal registers. All register access is byte wide. The timing for register access is shown below. The host CPU accesses internal registers with four address lines, RA0-RA3, SRD and SWR strobes.

ADS0 is used to latch the address when interfacing to a multiplexed, address data bus. Since the SNIC may be a local bus master when the host CPU attempts to read or write to the controller, an  $\overline{ACK}$  line is used to hold off the CPU until the SNIC leaves master mode. Some number of BSKC cycles is also required to allow the SNIC to synchronize to the read or write cycles.

TL/F/10469-30

TL/F/10469-31

#### TIME BETWEEN CHIP SELECTS

The SNIC requires that successive chip selects be no closer than 4 bus clocks (BSKC) together. If the condition is violated, the SNIC may glitch  $\overline{ACK}$ . CPUs that operate from pipelined instructions (i.e., 386) or have a cache (i.e., 486) can

execute consecutive I/O cycles very quickly. The solution is to delay the execution of consecutive I/O cycles by either breaking the pipeline or forcing the CPU to access outside its cache.

TL/F/10469-58

## 14.0 Preliminary Electrical Characteristics

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to +7.0V
DC Input Voltage ( $V_{IN}$ )	-0.5V to $V_{CC} + 0.5V$
DC Output Voltage ( $V_{OUT}$ )	-0.5V to $V_{CC} + 0.5V$
Storage Temperature Range ( $T_{STG}$ )	-65°C to +150°C
Power Dissipation (PD)	800 mW
Lead Temp. (TL) (Soldering, 10 sec.)	260°C
ESD Rating ( $R_{ZAP} = 1.5k, C_{ZAP} = 120 pF$ )	1.5 kV

Note: Absolute Maximum ratings are those values beyond which the safety of the device cannot be guaranteed. They are not meant to imply that the device should be operated at these limits.

Note: All specifications in this datasheet are valid only if the mandatory isolation is employed and all differential signals are taken to exist at the AUI side of the isolation.

### Preliminary DC Specifications $T_A = 0^\circ\text{C}$ to $70^\circ\text{C}$ , $V_{CC} = 5V \pm 5\%$ , unless otherwise specified.

Symbol	Parameter	Conditions	Min	Max	Units
$V_{OH}$	Minimum High Level Output Voltage (Notes 1, 4)	$I_{OH} = -20 \mu\text{A}$	$V_{CC} - 0.1$		V
		$I_{OH} = -2.0 \text{ mA}$	3.5		V
$V_{OL}$	Minimum Low Level Output Voltage (Notes 1, 4)	$I_{OL} = 20 \mu\text{A}$		0.1	V
		$I_{OL} = 2.0 \text{ mA}$		0.4	V
$V_{IH}$	Minimum High Level Input Voltage (Note 2)		2.0		V
$V_{IH2}$	Minimum High Level Input Voltage For RACK WACK (Note 2)		2.7		V
$V_{IL}$	Minimum Low Level Input Voltage (Note 2)			0.8	V
$V_{IL2}$	Minimum Low Level Input Voltage For RACK, WACK (Note 2)			0.6	V
$I_{IN}$	Input Current	$V_I = V_{CC}$ or GND	-1.0	+1.0	$\mu\text{A}$
$I_{OZ}$	Minimum TRI-STATE Output Leakage Current (Note 5)	$V_{OUT} = V_{CC}$ or GND	-10	+10	$\mu\text{A}$
$I_{CC}$	Average Supply Current (Note 3)	X1 = 20 MHz Clock $I_{OUT} = 0 \mu\text{A}$ $V_{IN} = V_{CC}$ or GND		110	mA

**Note 1:** These levels are tested dynamically using a limited amount of functional test patterns, please refer to AC test load.

**Note 2:** Limited functional test patterns are performed at these input levels. The majority of functional tests are performed at levels of 0V and 3V.

**Note 3:** This is measured with a 0.1  $\mu\text{F}$  bypass capacitor between  $V_{CC}$  and GND.

**Note 4:** The low drive CMOS compatible  $V_{OH}$  and  $V_{OL}$  limits are not tested directly. Detailed device characterization validates that this specification can be guaranteed by testing the high drive TTL compatible  $V_{OL}$  and  $V_{OH}$  specification.

**Note 5:** RA0-RA3, PRD, WACK, BREQ and INT pins are used as outputs in test mode and as a result are tested as if they are TRI-STATE input/outputs. For these pins the input leakage specification is  $I_{OZ}$ .

## 14.0 Preliminary Electrical Characteristics (Continued)

### Preliminary DC Specifications $T_A = 0^\circ\text{C}$ to $70^\circ\text{C}$ , $V = 5\text{V} \pm 5\%$ , unless otherwise specified.

I <sub>OSC</sub>	X1 Input Current	GND/X2 is Grounded V <sub>IN</sub> = V <sub>CC</sub> or GND		+3	mA

Note 1: This parameter is guaranteed by the isolation and is not tested.

# 15.0 Switching Characteristics AC Specs DP83901A Note: All Timing is Preliminary

Register Read (Latched Using ADS0)

TL/F/10469-32

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	13		ns
aswi	Address Strobe Width In	15		ns
ackdv	Acknowledge Low to Data Valid		55	ns
rdz	Read Strobe to Data TRI-STATE (Note 3)	15	70	ns
rackl	Read Strobe to $\overline{ACK}$ Low (Notes 1, 2)		$n \cdot \text{bcyc} + 30$	ns
rackh	Read Strobe to $\overline{ACK}$ High		30	ns
rsrsl	Register Select to Slave Read Low, Latched RS0-3	10		ns

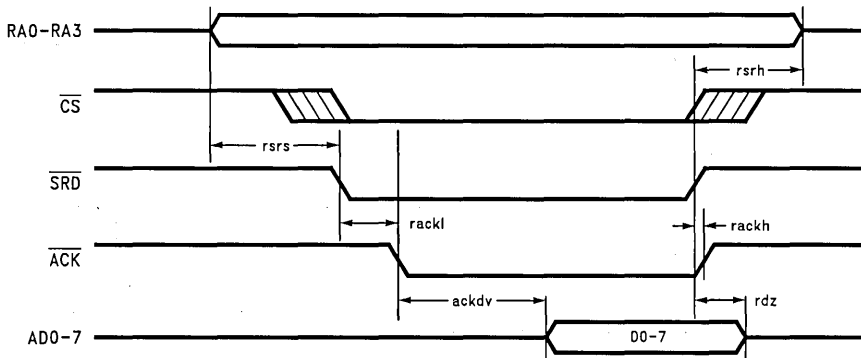

**Note 1:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SRD}$  are low and the SNIC has synchronized to the register access. The SNIC will insert an integral number of Bus Clock cycles until it is synchronized. In Dual Bus systems additional cycles will be used for a local or remote DMA to complete. Wait states must be issued to the CPU until  $\overline{ACK}$  is asserted low.

**Note 2:**  $\overline{CS}$  may be asserted before or after  $\overline{SRD}$ . If  $\overline{CS}$  is asserted after  $\overline{SRD}$ , rackl is referenced from falling edge of  $\overline{CS}$ .  $\overline{CS}$  can be de-asserted concurrently with  $\overline{SRD}$  or after  $\overline{SRD}$  is de-asserted.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns, enabling other devices to drive these lines with no contention.

### 15.0 Switching Characteristics AC Specs DP83901A Note: All Timing is Preliminary (Continued)

Register Read (Non-Latched, ADS0 = 1)

TL/F/10469-33

Symbol	Parameter	Min	Max	Units
rsrc	Register Select to Read Setup (Notes 1, 3)	10		ns
rsrh	Register Select Hold from Read	0		ns
ackdv	$\overline{\text{ACK}}$ Low to Valid Data		55	ns
rdz	Read Strobe to Data TRI-STATE (Note 2)	15	70	ns
rackl	Read Strobe to $\overline{\text{ACK}}$ Low (Note 3)		$n \cdot \text{bcyc} + 30$	ns
rackh	Read Strobe to $\overline{\text{ACK}}$ High		30	ns

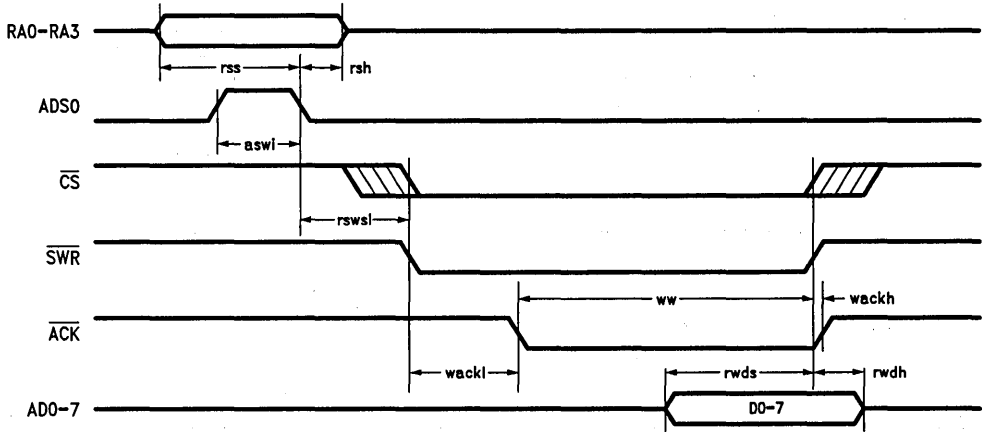

**Note 1:** rsrc includes flow-through time of latch.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns enabling other devices to drive these lines with no contention.

**Note 3:**  $\overline{\text{CS}}$  may be asserted before or after RA0-3, and  $\overline{\text{SRD}}$ , since address decode begins when  $\overline{\text{ACK}}$  is asserted. If  $\overline{\text{CS}}$  is asserted after RA0-3, and  $\overline{\text{SRD}}$ , rackl is referenced from falling edge of  $\overline{\text{CS}}$ .

**15.0 Switching Characteristics** AC Specs DP83901A Note: All Timing is Preliminary (Continued)

**Register Write (Latched Using ADS0)**

TL/F/10469-34

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	17		ns
aswi	Address Strobe Width In	15		ns
rwds	Register Write Data Setup	20		ns
rwdh	Register Write Data Hold	21		ns
ww	Write Strobe Width from $\overline{ACK}$	50		ns
wackh	Write Strobe High to $\overline{ACK}$ High		30	ns
wackl	Write Low to $\overline{ACK}$ Low (Notes 1, 2)		$n \cdot \text{bcyc} + 30$	ns
rswsl	Register Select to Write Strobe Low	10		ns

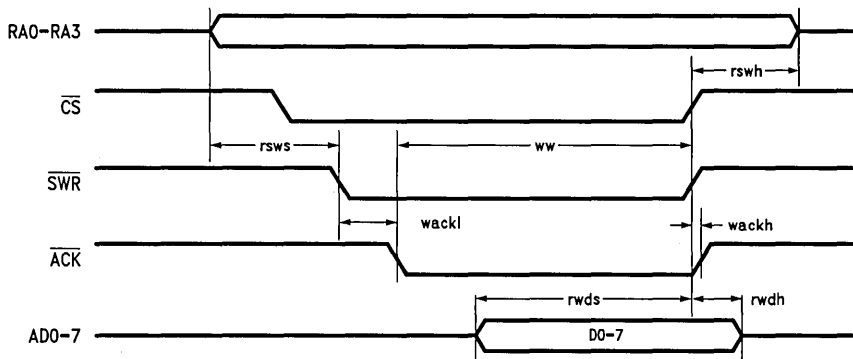

**Note 1:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SWR}$  are low and the SNIC has synchronized to the register access. In Dual Bus Systems additional cycles will be used for a local DMA or Remote DMA to complete.

**Note 2:**  $\overline{CS}$  may be asserted before or after  $\overline{SWR}$ . If  $\overline{CS}$  is asserted after  $\overline{SWR}$ , wackl is referenced from falling edge of  $\overline{CS}$ .

**15.0 Switching Characteristics** AC Specs DP83901A **Note:** All Timing is Preliminary (Continued)

**Register Write (Non-Latched, ADS0 = 1)**

TL/F/10469-35

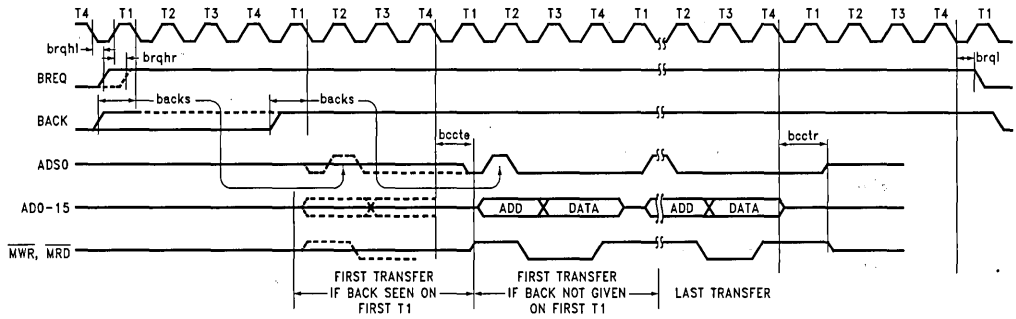

Symbol	Parameter	Min	Max	Units
rsws	Register Select to Write Setup (Note 1)	15		ns
rswh	Register Select Hold from Write	0		ns
rwds	Register Write Data Setup	20		ns
rwdh	Register Write Data Hold	21		ns
wackl	Write Low to $\overline{ACK}$ Low (Note 2)		$n \cdot bcyc + 30$	ns
wackh	Write High to $\overline{ACK}$ High		30	ns
ww	Write Width from $\overline{ACK}$	50		ns

**Note 1:** Assumes ADS0 is high when RA0-3 changing.

**Note 2:** ACK is not generated until CS and SWR are low and the SNIC has synchronized to the register access. In Dual Bus systems additional cycles will be used for a local DMA or remote DMA to complete.

wdh	Data Hold from $\overline{WR}$ Low	$\text{bch} + 7$		ns
waz	Write Strobe to Address TRI-STATE (Notes 1, 2)		$\text{bch} + 40$	ns
asds	Address Strobe to Data Strobe		$\text{bcl} + 10$	ns
aswd	Address Strobe to Write Data Valid		$\text{bcl} + 30$	ns

**Note 1:** When using byte mode transfers A8-A15 are only TRI-STATE on the last transfer, waz timing is only valid for last transfer in a burst.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within  $\text{bch} + 15$  ns, enabling other devices to drive these lines with no contention.

# 15.0 Switching Characteristics AC Specs DP83901A Note: All Timing is Preliminary (Continued)

Wait State Insertion

TL/F/10469-40

Symbol	Parameter	Min	Max	Units
ews	External Wait Setup to T3 0Clock (Note 1)	10		ns
ewr	External Wait Release Time (Note 1)	15		ns

**Note 1:** The addition of wait states affects the count of deserialized bytes and is limited to a number of bus clock cycles depending on the bus clock and network rates. The allowable wait states are found in the table below. (Assumes 10 Mbit/sec data rate.)

BSCCK (MHz)	Max # of Wait States	
	Byte Transfer	Word Transfer
8	0	1
10	0	1
12	1	2
14	1	2
16	1	3
18	2	3
20	2	4

Table assumes 10 MHz network clock.

The number of allowable wait states in byte mode can be calculated using:

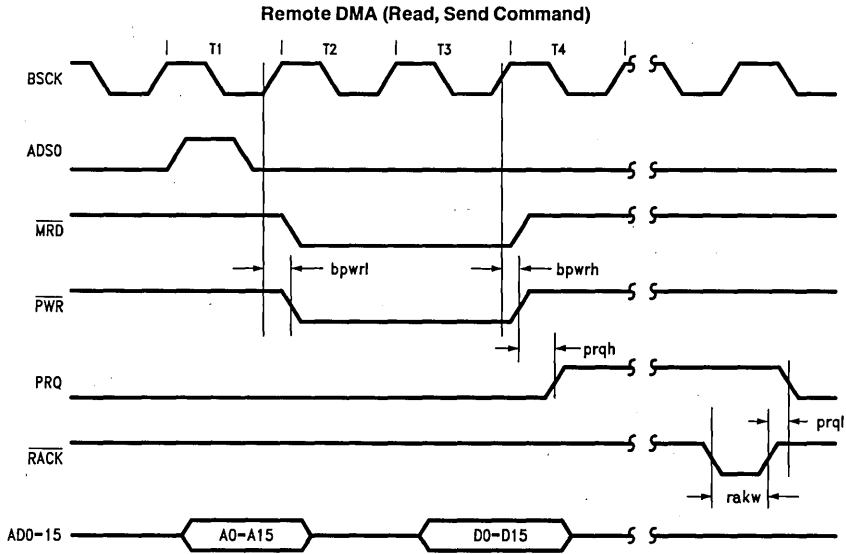

$$\#W_{(\text{byte mode})} = \left( \frac{8 \text{ tnw}}{4.5 \text{ tbsck}} - 1 \right)$$

- #W = Number of Wait States
- tnw = Network Clock Period
- tbsck = BSCCK Period

The number of allowable wait states in word mode can be calculated using:

$$\#W_{(\text{word mode})} = \left( \frac{5 \text{ tnw}}{2 \text{ tbsck}} - 1 \right)$$

wprq	Remote Write Port Request to Port Request Time (Notes 3, 4, 5)	12		BSCK

**Note 1:** The first port request is issued in response to the remote write command. It is subsequently issued on T1 clock cycles following completion of remote DMA cycles.

**Note 2:** The start of the remote DMA write following WACK is dependent on where WACK is issued relative to BSCK and whether a local DMA is pending.

**Note 3:** Assuming wackw < 1 BSCK, and no local DMA interleave, no CS, immediate BACK, and WACK goes high before T4.

**Note 4:** WACK must be high for a minimum of 7 BSCK.

**Note 5:** This is not a measured value but guaranteed by design.

## 15.0 Switching Characteristics AC Specs DP83901A Note: All Timing is Preliminary (Continued)

Transmit Timing (End of Packet)

TL/F/10469-47

TRANSMIT SPECIFICATIONS (End of Packet)

Symbol	Parameter	Min	Max	Units
$t_{TOH}$	Transmit Output High before Idle (Half Step)	200		ns
$t_{TOI}$	Transmit Output Idle Time to $\pm 40$ mV(Half Step)		8000	ns

Reset Timing

TL/F/10469-45

Symbol	Parameter	Min	Max	Units
rstw	Reset Pulse Width (Note 1)	8		BSKC Cycles or TXC Cycles (Note 2)

**Note 1:** The RESET pulse requires the BSKC and TXC be stable. On power up, RESET should not be raised until BSKC and TXC have become stable. Several registers are affected by RESET. Consult the register descriptions for details.

**Note 2:** The slower of BSKC or TXC clocks will determine the minimum time for the RESET signal to be low. TXC is X1 divided by 2.

If BSKC < TXC then RESET = 8 x BSKC  
 If TXC < BSKC then RESET = 8 x TXC

## 16.0 AC Timing Test Conditions

All specifications are valid only if the mandatory isolation is employed and all differential signals are taken to be at the AUI side of the pulse transformer.

- Input Pulse Levels (TTL/CMOS) GND to 3.0V
- Input Rise and Fall Times (TTL/CMOS) 5 ns
- Input and Output Reference Levels (TTL/CMOS) 1.3V
- Input Pulse Levels (Diff.) -350 mV to -1315 mV
- Input and Output Reference Levels (Diff.) 50% Point of the Differential
- TRI-STATE Reference Levels Float ( $\Delta V$ )  $\pm 0.5V$
- Output Load (See Figure Below)

TL/F/10469-48

**Note 1:** 50 pF, includes scope and jig capacitance

**Note 2:** S1 = Open for timing tests for push pull outputs.

S1 = VCC for VOL test.

S1 = GND for VOH test.

S1 = VCC for High Impedance to active low and active low to High Impedance measurements.

S1 = GND for High Impedance to active high and active high to High Impedance measurements.

**Pin Capacitance**  $T_A = 25^\circ\text{C}$ ,  $f = 1\text{ MHz}$ 

Symbol	Parameter	Typ	Units
$C_{IN}$	Input Capacitance	7	pF
$C_{OUT}$	Output Capacitance	7	pF

**DERATING FACTOR**

Output timings are measured with a purely capacitive load for 50 pF. The following correction factor can be used for other loads:  $C_L \geq 50\text{ pF} + 0.3\text{ ns/pF}$ .

TL/F/10469-49

**Note:** In the above diagram, the TX+ and TX- signals are taken from the AUI side of the isolation (pulse transformer). The pulse transformer used for all testing is the Pulse Engineering PE64103.

# DP8390D/NS32490D NIC Network Interface Controller

## General Description

The DP8390D/NS32490D Network Interface Controller (NIC) is a microCMOS VLSI device designed to ease interfacing with CSMA/CD type local area networks including Ethernet, Thin Ethernet (Cheapernet) and StarLAN. The NIC implements all Media Access Control (MAC) layer functions for transmission and reception of packets in accordance with the IEEE 802.3 Standard. Unique dual DMA channels and an internal FIFO provide a simple yet efficient packet management design. To minimize system parts count and cost, all bus arbitration and memory support logic are integrated into the NIC.

The NIC is the heart of a three chip set that implements the complete IEEE 802.3 protocol and node electronics as shown below. The others include the DP8391 Serial Network Interface (SNI) and the DP8392 Coaxial Transceiver Interface (CTI).

## Features

- Compatible with IEEE 802.3/Ethernet II/Thin Ethernet/StarLAN
- Interfaces with 8-, 16- and 32-bit microprocessor systems
- Implements simple, versatile buffer management
- Requires single 5V supply
- Utilizes low power microCMOS process
- Includes
  - Two 16-bit DMA channels
  - 16-byte internal FIFO with programmable threshold
  - Network statistics storage
- Supports physical, multicast, and broadcast address filtering
- Provides 3 levels of loopback
- Utilizes independent system and network clocks

TL/F/8582-1

## 2.0 Block Diagram

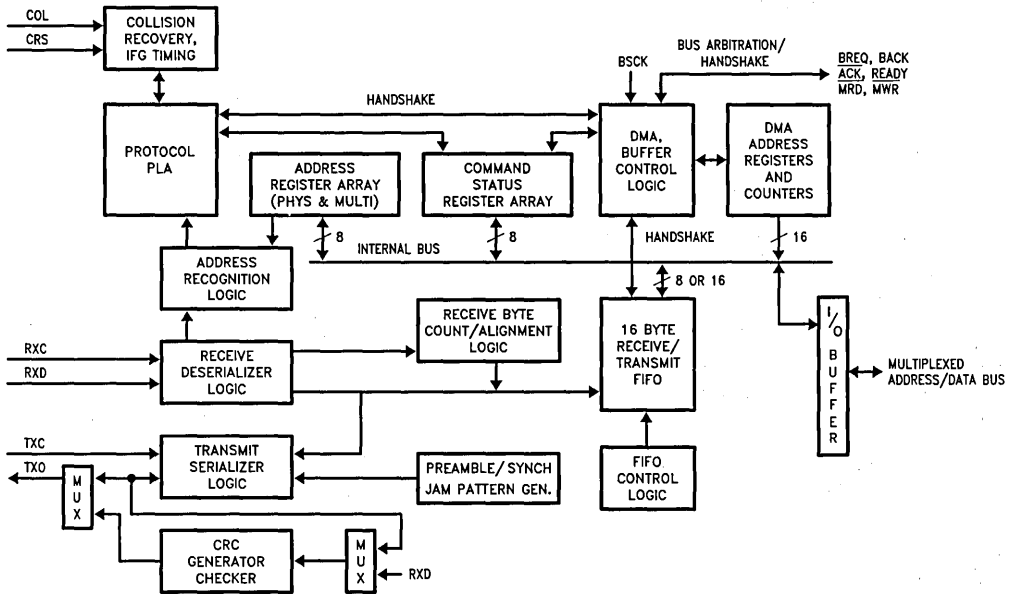

FIGURE 1

TL/F/8592-2

## 3.0 Functional Description

(Refer to Figure 1)

### RECEIVE DESERIALIZER

The Receive Deserializer is activated when the input signal Carrier Sense is asserted to allow incoming bits to be shifted into the shift register by the receive clock. The serial receive data is also routed to the CRC generator/checker. The Receive Deserializer includes a synch detector which detects the SFD (Start of Frame Delimiter) to establish where byte boundaries within the serial bit stream are located. After every eight receive clocks, the byte wide data is transferred to the 16-byte FIFO and the Receive Byte Count is incremented. The first six bytes after the SFD are checked for valid comparison by the Address Recognition Logic. If the Address Recognition Logic does not recognize the packet, the FIFO is cleared.

### CRC GENERATOR/CHECKER

During transmission, the CRC logic generates a local CRC field for the transmitted bit sequence. The CRC encodes all fields after the synch byte. The CRC is shifted out MSB first following the last transmit byte. During reception the CRC logic generates a CRC field from the incoming packet. This local CRC is serially compared to the incoming CRC appended to the end of the packet by the transmitting node. If the local and received CRC match, a specific pattern will be generated and decoded to indicate no data errors. Transmission errors result in a different pattern and are detected, resulting in rejection of a packet.

### TRANSMIT SERIALIZER

The Transmit Serializer reads parallel data from the FIFO and serializes it for transmission. The serializer is clocked by

the transmit clock generated by the Serial Network Interface (DP8391). The serial data is also shifted into the CRC generator/checker. At the beginning of each transmission, the Preamble and Synch Generator append 62 bits of 1,0 preamble and a 1,1 synch pattern. After the last data byte of the packet has been serialized the 32-bit FCS field is shifted directly out of the CRC generator. In the event of a collision the Preamble and Synch generator is used to generate a 32-bit JAM pattern of all 1's

### ADDRESS RECOGNITION LOGIC

The address recognition logic compares the Destination Address Field (first 6 bytes of the received packet) to the Physical address registers stored in the Address Register Array. If any one of the six bytes does not match the pre-programmed physical address, the Protocol Control Logic rejects the packet. All multicast destination addresses are filtered using a hashing technique. (See register description.) If the multicast address indexes a bit that has been set in the filter bit array of the Multicast Address Register Array the packet is accepted, otherwise it is rejected by the Protocol Control Logic. Each destination address is also checked for all 1's which is the reserved broadcast address.

### FIFO AND FIFO CONTROL LOGIC

The NIC features a 16-byte FIFO. During transmission the DMA writes data into the FIFO and the Transmit Serializer reads data from the FIFO and transmits it. During reception the Receive Deserializer writes data into the FIFO and the DMA reads data from the FIFO. The FIFO control logic is used to count the number of bytes in the FIFO so that after a preset level, the DMA can begin a bus access and write/read data to/from the FIFO before a FIFO underflow/overflow occurs.

### 3.0 Functional Description (Continued)

Because the NIC must buffer the Address field of each incoming packet to determine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers, the first local DMA transfer does not occur until 8 bytes have accumulated in the FIFO.

To assure that there is no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO; this effectively shortens the FIFO to 13 bytes. In addition, the FIFO logic operates differently in Byte Mode than in Word Mode. In Byte Mode, a threshold is indicated when the  $n + 1$  byte has entered the FIFO; thus, with an 8-byte threshold, the NIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until the  $n + 2$  bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to an 8-byte threshold), BREQ is issued when the 10th byte has entered the FIFO.

#### PROTOCOL PLA

The protocol PLA is responsible for implementing the IEEE 802.3 protocol, including collision recovery with random backoff. The Protocol PLA also formats packets during transmission and strips preamble and synch during reception.

#### DMA AND BUFFER CONTROL LOGIC

The DMA and Buffer Control Logic is used to control two 16-bit DMA channels. During reception, the Local DMA stores packets in a receive buffer ring, located in buffer memory. During transmission the Local DMA uses programmed pointer and length registers to transfer a packet from local buffer memory to the FIFO. A second DMA channel is used as a slave DMA to transfer data between the local buffer memory and the host system. The Local DMA and Remote DMA are internally arbitrated, with the Local DMA channel having highest priority. Both DMA channels use a common external bus clock to generate all required bus timing. External arbitration is performed with a standard bus request, bus acknowledge handshake protocol.

### 4.0 Transmit/Receive Packet Encapsulation/Decapsulation

A standard IEEE 802.3 packet consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data, and Frame Check Sequence (FCS). The typical format is shown in *Figure 2*. The packets are Manchester encoded and decoded by the DP8391 SNI and transferred serially to the NIC using NRZ data with a clock. All fields are of fixed length except for the data field. The NIC generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

#### PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the SNI (DP8391) to acquire bit synchronization with an incoming packet. When transmitted each packet contains 62 bits of alternating 1,0 preamble. Some of this preamble will be lost as the packet travels through the network. The preamble field is stripped by the NIC. Byte alignment is performed with the Start of Frame Delimiter (SFD) pattern which consists of two consecutive 1's. The NIC does not treat the SFD pattern as a byte, it detects only the

two bit pattern. This allows any preceding preamble within the SFD to be used for phase locking.

#### DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted packets from reaching a node. There are three types of address formats supported by the NIC: physical, multicast, and broadcast. The physical address is a unique address that corresponds only to a single node. All physical addresses have an MSB of "0". These addresses are compared to the internally stored physical address registers. Each bit in the destination address must match in order for the NIC to accept the packet. Multicast addresses begin with an MSB of "1". The DP8390D filters multicast addresses using a standard hashing algorithm that maps all multicast addresses into a 6-bit value. This 6-bit value indexes a 64-bit array that filters the value. If the address consists of all 1's it is a broadcast address, indicating that the packet is intended for all nodes. A promiscuous mode allows reception of all packets: the destination address is not required to match any filters. Physical, broadcast, multicast, and promiscuous address modes can be selected.

#### SOURCE ADDRESS

The source address is the physical address of the node that sent the packet. Source addresses cannot be multicast or broadcast addresses. This field is simply passed to buffer memory.

#### LENGTH FIELD

The 2-byte length field indicates the number of bytes that are contained in the data field of the packet. This field is not interpreted by the NIC.

#### DATA FIELD

The data field consists of anywhere from 46 to 1500 bytes. Messages longer than 1500 bytes need to be broken into multiple packets. Messages shorter than 46 bytes will require appending a pad to bring the data field to the minimum length of 46 bytes. If the data field is padded, the number of valid data bytes is indicated in the length field. **The NIC does not strip or append pad bytes for short packets, or check for oversize packets.**

#### FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of errors when a packet is received. During reception, error free packets result in a specific pattern in the CRC generator. Packets with improper CRC will be rejected. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X + 1$ ) polynomial is used for the CRC calculations.

## 5.0 Pin Descriptions (Continued)

### BUS INTERFACE PINS (Continued)

Symbol	DIP Pin No	Function	Description
$\overline{CS}$	19	I	<b>CHIP SELECT:</b> Chip Select places controller in slave mode for $\mu P$ access to internal registers. Must be valid through data portion of bus cycle. RA0–RA3 are used to select the internal register. SWR and SRD select direction of data transfer.
$\overline{MWR}$	20	O,Z	<b>MASTER WRITE STROBE:</b> Strobe for DMA transfers, active low during write cycles (t2, t3, tw) to buffer memory. Rising edge coincides with the presence of valid output data. TRI-STATE® until BACK asserted.
$\overline{MRD}$	21	O,Z	<b>MASTER READ STROBE:</b> Strobe for DMA transfers, active during read cycles (t2, t3, tw) to buffer memory. Input data must be valid on rising edge of $\overline{MRD}$ . TRI-STATE until BACK asserted.
$\overline{SWR}$	22	I	<b>SLAVE WRITE STROBE:</b> Strobe from CPU to write an internal register selected by RA0–RA3.
$\overline{SRD}$	23	I	<b>SLAVE READ STROBE:</b> Strobe from CPU to read an internal register selected by RA0–RA3.
$\overline{ACK}$	24	O	<b>ACKNOWLEDGE:</b> Active low when NIC grants access to CPU. Used to insert WAIT states to CPU until NIC is synchronized for a register read or write operation.
RA0–RA3	45–48	I	<b>REGISTER ADDRESS:</b> These four pins are used to select a register to be read or written. The state of these inputs is ignored when the NIC is not in slave mode ( $\overline{CS}$ high).
$\overline{PRD}$	44	O	<b>PORT READ:</b> Enables data from external latch onto local bus during a memory write cycle to local memory (remote write operation). This allows asynchronous transfer of data from the system memory to local memory.
$\overline{WACK}$	43	I	<b>WRITE ACKNOWLEDGE:</b> Issued from system to NIC to indicate that data has been written to the external latch. The NIC will begin a write cycle to place the data in local memory.
INT	42	O	<b>INTERRUPT:</b> Indicates that the NIC requires CPU attention after reception transmission or completion of DMA transfers. The interrupt is cleared by writing to the ISR. All interrupts are maskable.
$\overline{RESET}$	41	I	<b>RESET:</b> Reset is active low and places the NIC in a reset mode immediately, no packets are transmitted or received by the NIC until STA bit is set. Affects Command Register, Interrupt Mask Register, Data Configuration Register and Transmit Configuration Register. The NIC will execute reset within 10 BUSK cycles.
BREQ	31	O	<b>BUS REQUEST:</b> Bus Request is an active high signal used to request the bus for DMA transfers. This signal is automatically generated when the FIFO needs servicing.
BACK	30	I	<b>BUS ACKNOWLEDGE:</b> Bus Acknowledge is an active high signal indicating that the CPU has granted the bus to the NIC. If immediate bus access is desired, BREQ should be tied to BACK. <b>Tying BACK to <math>V_{CC}</math> will result in a deadlock.</b>
PRQ, ADS1	29	O,Z	<b>PORT REQUEST/ADDRESS STROBE 1</b> <ul style="list-style-type: none"> <li>• <b>32-BIT MODE:</b> If LAS is set in the Data Configuration Register, this line is programmed as ADS1. It is used to strobe addresses A16–A31 into external latches. (A16–A31 are the fixed addresses stored in RSAR0, RSAR1.) ADS1 will remain at TRI-STATE until BACK is received.</li> <li>• <b>16-BIT MODE:</b> If LAS is not set in the Data Configuration Register, this line is programmed as PRQ and is used for Remote DMA Transfers. In this mode PRQ will be a standard logic output.</li> </ul> <b>NOTE: This line will power up as TRI-STATE until the Data Configuration Register is programmed.</b>
READY	28	I	<b>READY:</b> This pin is set high to insert wait states during a DMA transfer. The NIC will sample this signal at t3 during DMA transfers.

## 5.0 Pin Descriptions (Continued)

### BUS INTERFACE PINS (Continued)

Symbol	DIP Pin No	Function	Description
$\overline{PWR}$	27	O	<b>PORT WRITE:</b> Strobe used to latch data from the NIC into external latch for transfer to host memory during Remote Read transfers. The rising edge of $\overline{PWR}$ coincides with the presence of valid data on the local bus.
$\overline{RACK}$	26	I	<b>READ ACKNOWLEDGE:</b> Indicates that the system DMA or host CPU has read the data placed in the external latch by the NIC. The NIC will begin a read cycle to update the latch.
BSCK	25	I	This clock is used to establish the period of the DMA memory cycle. Four clock cycles (t1, t2, t3, t4) are used per DMA cycle. DMA transfers can be extended by one BSCK increments using the $\overline{READY}$ input.

### NETWORK INTERFACE PINS

COL	40	I	<b>COLLISION DETECT:</b> This line becomes active when a collision has been detected on the coaxial cable. During transmission this line is monitored after preamble and synch have been transmitted. At the end of each transmission this line is monitored for CD heartbeat.
RXD	39	I	<b>RECEIVE DATA:</b> Serial NRZ data received from the ENDEC, clocked into the NIC on the rising edge of RXC.
CRS	38	I	<b>CARRIER SENSE:</b> This signal is provided by the ENDEC and indicates that carrier is present. This signal is active high.
RXC	37	I	<b>RECEIVE CLOCK:</b> Re-synchronized clock from the ENDEC used to clock data from the ENDEC into the NIC.
LBK	35	O	<b>LOOPBACK:</b> This output is set high when the NIC is programmed to perform a loopback through the StarLAN ENDEC.
TXD	34	O	<b>TRANSMIT DATA:</b> Serial NRZ Data output to the ENDEC. The data is valid on the rising edge of TXC.
TXC	33	I	<b>TRANSMIT CLOCK:</b> This clock is used to provide timing for internal operation and to shift bits out of the transmit serializer. TXC is nominally a 1 MHz clock provided by the ENDEC.
TXE	32	O	<b>TRANSMIT ENABLE:</b> This output becomes active when the first bit of the packet is valid on TXD and goes low after the last bit of the packet is clocked out of TXD. This signal connects directly to the ENDEC. This signal is active high.

### POWER

$V_{CC}$	36		+ 5V DC is required. It is suggested that a decoupling capacitor be connected between these pins. It is essential to provide a path to ground for the GND pin with the lowest possible impedance.
GND	13		

## 6.0 Direct Memory Access Control (DMA)

The DMA capabilities of the NIC greatly simplify use of the DP8390D in typical configurations. The local DMA channel transfers data between the FIFO and memory. On transmission, the packet is DMA'd from memory to the FIFO in bursts. Should a collision occur (up to 15 times), the packet is retransmitted with no processor intervention. On reception, packets are DMAed from the FIFO to the receive buffer ring (as explained below).

A remote DMA channel is also provided on the NIC to accomplish transfers between a buffer memory and system memory. The two DMA channels can alternatively be combined to form a single 32-bit address with 8- or 16-bit data.

### DUAL DMA CONFIGURATION

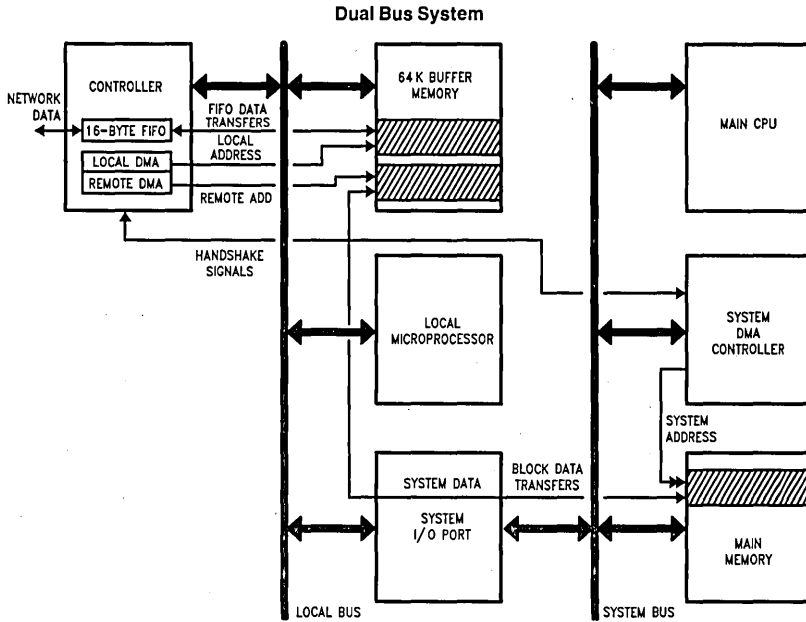

An example configuration using both the local and remote DMA channels is shown below. Network activity is isolated

on a local bus, where the NIC's local DMA channel performs burst transfers between the buffer memory and the NIC's FIFO. The Remote DMA transfers data between the buffer memory and the host memory via a bidirectional I/O port. The Remote DMA provides local addressing capability and is used as a slave DMA by the host. Host side addressing must be provided by a host DMA or the CPU. The NIC allows Local and Remote DMA operations to be interleaved.

### SINGLE CHANNEL DMA OPERATION

If desirable, the two DMA channels can be combined to provide a 32-bit DMA address. The upper 16 bits of the 32-bit address are static and are used to point to a 64k byte (or 32k word) page of memory where packets are to be received and transmitted.

## 6.0 Direct Memory Access Control (DMA) (Continued)

TL/F/8582-55

### 32-Bit DMA Operation

TL/F/8582-6

## 7.0 Packet Reception

The Local DMA receive channel uses a Buffer Ring Structure comprised of a series of contiguous fixed length 256 byte (128 word) buffers for storage of received packets. The location of the Receive Buffer Ring is programmed in two registers, a Page Start and a Page Stop Register. Ethernet packets consist of a distribution of shorter link control packets and longer data packets, the 256 byte buffer length provides a good compromise between short packets and longer packets to most efficiently use memory. In addition these buffers provide memory resources for storage of back-to-back packets in loaded networks. The assignment of buffers

### NIC Receive Buffer Ring

TL/F/8582-7

## 7.0 Packet Reception (Continued)

for storing packets is controlled by Buffer Management Logic in the NIC. The Buffer Management Logic provides three basic functions: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of buffer pages that have been read by the host.

At initialization, a portion of the 64k byte (or 32k word) address space is reserved for the receive buffer ring. Two eight bit registers, the Page Start Address Register (PSTART) and the Page Stop Address Register (PSTOP) define the physical boundaries of where the buffers reside. The NIC treats the list of buffers as a logical ring; whenever the DMA address reaches the Page Stop Address, the DMA is reset to the Page Start Address.

### INITIALIZATION OF THE BUFFER RING

Two static registers and two working registers control the operation of the Buffer Ring. These are the Page Start Register, Page Stop Register (both described previously), the Current Page Register and the Boundary Pointer Register. The Current Page Register points to the first buffer used to store a packet and is used to restore the DMA for writing status to the Buffer Ring or for restoring the DMA address in the event of a Runt packet, a CRC, or Frame Alignment error. The Boundary Register points to the first packet in the Ring not yet read by the host. If the local DMA address ever reaches the Boundary, reception is aborted. The Boundary Pointer is also used to initialize the Remote DMA for removing a packet and is advanced when a packet is removed. A simple analogy to remember the function of these registers is that the Current Page Register acts as a Write Pointer and the Boundary Pointer acts as a Read Pointer.

**Note 1:** At initialization, the Page Start Register value should be loaded into both the Current Page Register and the Boundary Pointer Register.

**Note 2:** The Page Start Register must not be initialized to 00H.

Receive Buffer Ring At Initialization

TL/F/8582-30

### BEGINNING OF RECEPTION

When the first packet begins arriving the NIC begins storing the packet at the location pointed to by the Current Page

Linking Receive Buffer Pages

- 1) Check for = to PSTOP
- 2) Check for = to Boundary

TL/F/8582-32

Register. An offset of 4 bytes is saved in this first buffer to allow room for storing receive status corresponding to this packet.

Received Packet Enters Buffer Pages

TL/F/8582-31

### LINKING RECEIVE BUFFER PAGES

If the length of the packet exhausts the first 256 byte buffer, the DMA performs a forward link to the next buffer to store the remainder of the packet. For a maximal length packet the buffer logic will link six buffers to store the entire packet. Buffers cannot be skipped when linking, a packet will always be stored in contiguous buffers. Before the next buffer can be linked, the Buffer Management Logic performs two comparisons. The first comparison tests for equality between the DMA address of the next buffer and the contents of the Page Stop Register. If the buffer address equals the Page Stop Register, the buffer management logic will restore the DMA to the first buffer in the Receive Buffer Ring value programmed in the Page Start Address Register. The second comparison tests for equality between the DMA address of the next buffer address and the contents of the Boundary Pointer Register. If the two values are equal the reception is aborted. The Boundary Pointer Register can be used to protect against overwriting any area in the receive buffer ring that has not yet been read. When linking buffers, buffer management will never cross this pointer, effectively avoiding any overwrites. If the buffer address does not match either the Boundary Pointer or Page Stop Address, the link to the next buffer is performed.

### Linking Buffers

Before the DMA can enter the next contiguous 256 byte buffer, the address is checked for equality to PSTOP and to the Boundary Pointer. If neither are reached, the DMA is allowed to use the next buffer.

## 7.0 Packet Reception (Continued)

### Received Packet Aborted if It Hits Boundary Pointer

TL/F/8582-8

### Buffer Ring Overflow

If the Buffer Ring has been filled and the DMA reaches the Boundary Pointer Address, reception of the incoming packet will be aborted by the NIC. Thus, the packets previously received and still contained in the Ring will not be destroyed.

In a heavily loaded network environment the local DMA may be disabled, preventing the NIC from buffering packets from the network. To guarantee this will not happen, a software reset must be issued during all Receive Buffer Ring overflows (indicated by the OVW bit in the Interrupt Status Register). **The following procedure is required to recover from a Receiver Buffer Ring Overflow.**

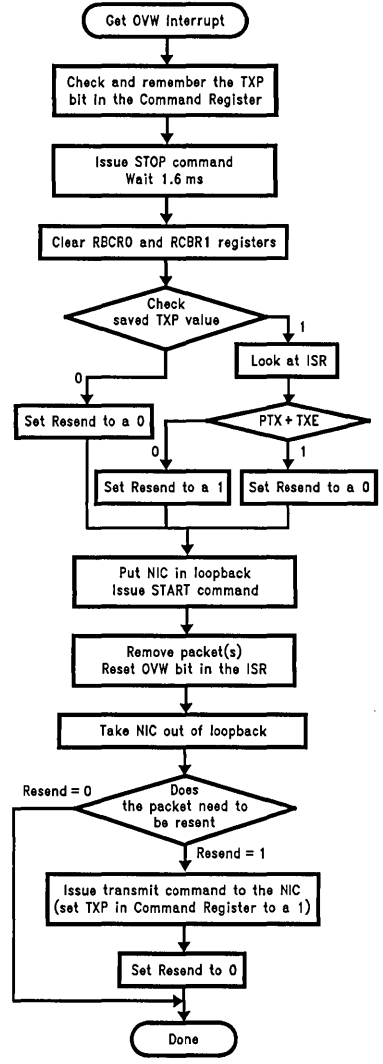

If this routine is not adhered to, the NIC may act in an unpredictable manner. It should also be noted that it is not permissible to service an overflow interrupt by continuing to empty packets from the receive buffer without implementing the prescribed overflow routine. A flow chart of the NIC's overflow routine can be found at the right.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

1. Read and store the value of the TXP bit in the NIC's Command Register.
2. Issue the STOP command to the NIC. This is accomplished by setting the STP bit in the NIC's Command Register. Writing 21H to the Command Register will stop the NIC.

**Note:** If the STP is set when a transmission is in progress, the RST bit may not be set. In this case, the NIC is guaranteed to be reset after the longest packet time (1500 bytes = 1.2 ms). For the DP8390D (but not for the DP8390B), the NIC will be reset within 2 microseconds after the STP bit is set and Loopback mode 1 is programmed.

3. Wait for at least 1.6 ms. Since the NIC will complete any transmission or reception that is in progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommended that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.
4. Clear the NIC's Remote Byte Count registers (RBCR0 and RBCR1).

TL/F/8582-95

Overflow Routine Flow Chart

5. Read the stored value of the TXP bit from step 1, above. If this value is a 0, set the "Resend" variable to a 0 and jump to step 6. If this value is a 1, read the NIC's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 0 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6. This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the NIC's ISR is read to determine whether or not the packet was recognized by the NIC. If neither the PTX nor TXE bit was set,

## 7.0 Packet Reception (Continued)

then the packet will essentially be lost and re-transmitted only after a time-out takes place in the upper level software. By determining that the packet was lost at the driver level, a transmit command can be reissued to the NIC once the overflow routine is completed (as in step 11). Also, it is possible for the NIC to defer indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the NIC to operate correctly.

6. Place the NIC in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to "0,1" or "1,0", respectively.
7. Issue the START command to the NIC. This can be accomplished by writing 22H to the Command Register. This is necessary to activate the NIC's Remote DMA channel.
8. Remove one or more packets from the receive buffer ring.
9. Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.
10. Take the NIC out of loopback. This is done by writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)
11. If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by writing a value of 26H to the Command Register. If the "Resend" variable is 0, nothing needs to be done.

**Note:** If Remote DMA is not being used, the NIC does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7.

### END OF PACKET OPERATIONS

At the end of the packet the NIC determines whether the received packet is to be accepted or rejected. It either branches to a routine to store the Buffer Header or to another routine that recovers the buffers used to store the packet.

### SUCCESSFUL RECEPTION

If the packet is successfully received as shown, the DMA is restored to the first buffer used to store the packet (pointed

#### Termination of Received Packet—Packet Accepted

TL/F/8582-10

to by the Current Page Register). The DMA then stores the Receive Status, a Pointer to where the next packet will be stored (Buffer 4) and the number of received bytes. Note that the remaining bytes in the last buffer are discarded and reception of the next packet begins on the next empty 256-byte buffer boundary. The Current Page Register is then initialized to the next available buffer in the Buffer Ring. (The location of the next buffer had been previously calculated and temporarily stored in an internal scratchpad register.)

### BUFFER RECOVERY FOR REJECTED PACKETS

If the packet is a runt packet or contains CRC or Frame Alignment errors, it is rejected. The buffer management logic resets the DMA back to the first buffer page used to store the packet (pointed to by CURR), recovering all buffers that had been used to store the rejected packet. This operation will not be performed if the NIC is programmed to accept either runt packets or packets with CRC or Frame Alignment errors. The received CRC is always stored in buffer memory after the last byte of received data for the packet.

#### Termination of Received Packet—Packet Rejected

TL/F/8582-13

### Error Recovery

If the packet is rejected as shown, the DMA is restored by the NIC by reprogramming the DMA starting address pointed to by the Current Page Register.

### REMOVING PACKETS FROM THE RING

Packets are removed from the ring using the Remote DMA or an external device. When using the Remote DMA the Send Packet command can be used. This programs the Remote DMA to automatically remove the received packet pointed to by the Boundary Pointer. At the end of the transfer, the NIC moves the Boundary Pointer, freeing additional buffers for reception. The Boundary Pointer can also be moved manually by programming the Boundary Register. Care should be taken to keep the Boundary Pointer at least one buffer behind the Current Page Pointer.

The following is a suggested method for maintaining the Receive Buffer Ring pointers.

1. At initialization, set up a software variable (next\_pkt) to indicate where the next packet will be read. At the beginning of each Remote Read DMA operation, the value of next\_pkt will be loaded into RSAR0 and RSAR1.
2. When initializing the NIC set:
  - BNDRY = PSTART
  - CURR = PSTART + 1
  - next\_pkt = PSTART + 1

## 7.0 Packet Reception (Continued)

3. After a packet is DMAed from the Receive Buffer Ring, the Next Page Pointer (second byte in NIC buffer header) is used to update BNDRY and next\_pkt.

next\_pkt = Next Page Pointer

BNDRY = Next Page Pointer - 1

If BNDRY < PSTART then BNDRY = PSTOP - 1

Note the size of the Receive Buffer Ring is reduced by one 256-byte buffer; this will not, however, impede the operation of the NIC.

In StarLAN applications using bus clock frequencies greater than 4 MHz, the NIC does not update the buffer header information properly because of the disparity between the network and bus clock speeds. The lower byte count is copied twice into the third and fourth locations of the buffer header and the upper byte count is not written. The upper byte count, however, can be calculated from the current next page pointer (second byte in the buffer header) and the previous next page pointer (stored in memory by the CPU). The following routine calculates the upper byte count and allows StarLAN applications to be insensitive to bus clock speeds. Next\_pkt is defined similarly as above.

### 1st Received Packet Removed By Remote DMA

TL/F/8582-57

upper byte count = next page pointer - next\_pkt - 1

if (upper byte count) < 0 then

upper byte count = (PSTOP - next\_pkt) +

(next page pointer - PSTART) - 1

if (lower byte count) > 0 fch then

upper byte count = upper byte count + 1

### STORAGE FORMAT FOR RECEIVED PACKETS

The following diagrams describe the format for how received packets are placed into memory by the local DMA channel. These modes are selected in the Data Configuration Register.

#### Storage Format

AD15	AD8	AD7	AD0
Next Packet Pointer	Receive Status		
Receive Byte Count 1	Receive Byte Count 0		
Byte 2	Byte 1		

BOS = 0, WTS = 1 in Data Configuration Register.

This format used with Series 32000 808X type processors.

AD15	AD8	AD7	AD0
Next Packet Pointer		Receive Status	
Receive Byte Count 0		Receive Byte Count 1	
Byte 1		Byte 2	

BOS = 1, WTS = 1 in Data Configuration Register.

This format used with 68000 type processors.

Note: The Receive Byte Count ordering remains the same for BOS=0 or 1.

AD7	AD0
Receive Status	
Next Packet Pointer	
Receive Byte Count 0	
Receive Byte Count 1	
Byte 0	
Byte 1	

BOS = 0, WTS = 0 in Data Configuration Register.

This format used with general 8-bit CPUs.

## 8.0 Packet Transmission

The Local DMA is also used during transmission of a packet. Three registers control the DMA transfer during transmission, a Transmit Page Start Address Register (TPSR) and the Transmit Byte Count Registers (TBCR0,1). When the NIC receives a command to transmit the packet pointed to by these registers, buffer memory data will be moved into the FIFO as required during transmission. The NIC will generate and append the preamble, synch and CRC fields.

### TRANSMIT PACKET ASSEMBLY

The NIC requires a contiguous assembled packet with the format shown. The transmit byte count includes the Destination Address, Source Address, Length Field and Data. It does not include preamble and CRC. When transmitting data smaller than 46 bytes, the packet must be padded to a minimum size of 64 bytes. The programmer is responsible for adding and stripping pad bytes.

#### General Transmit Packet Format

TL/F/8582-58

## 8.0 Packet Transmission (Continued)

### TRANSMISSION

Prior to transmission, the TPSR (Transmit Page Start Register) and TBCR0, TBCR1 (Transmit Byte Count Registers) must be initialized. To initiate transmission of the packet the TXP bit in the Command Register is set. The Transmit Status Register (TSR) is cleared and the NIC begins to pre-fetch transmit data from memory (unless the NIC is currently receiving). If the interframe gap has timed out the NIC will begin transmission.

### CONDITIONS REQUIRED TO BEGIN TRANSMISSION

In order to transmit a packet, the following three conditions must be met:

1. The Interframe Gap Timer has timed out the first 6.4  $\mu$ s of the Interframe Gap (See appendix for Interframe Gap Flowchart)
2. At least one byte has entered the FIFO. (This indicates that the burst transfer has been started)
3. If the NIC had collided, the backoff timer has expired.

In typical systems the NIC has already prefetched the first burst of bytes before the 6.4  $\mu$ s timer expires. The time during which NIC transmits preamble can also be used to load the FIFO.

**Note:** If carrier sense is asserted before a byte has been loaded into the FIFO, the NIC will become a receiver.

### COLLISION RECOVERY

During transmission, the Buffer Management logic monitors the transmit circuitry to determine if a collision has occurred. If a collision is detected, the Buffer Management logic will reset the FIFO and restore the Transmit DMA pointers for retransmission of the packet. The COL bit will be set in the TSR and the NCR (Number of Collisions Register) will be incremented. If 15 retransmissions each result in a collision the transmission will be aborted and the ABT bit in the TSR will be set.

**Note:** NCR reads as zeroes if excessive collisions are encountered.

### TRANSMIT PACKET ASSEMBLY FORMAT

The following diagrams describe the format for how packets must be assembled prior to transmission for different byte ordering schemes. The various formats are selected in the Data Configuration Register.

D15	D8 D7	D0
DA1		DA0
DA3		DA2
DA5		DA4
SA1		DA0
SA3		DA2
SA5		DA4
T/L1		T/L0
DATA 1		DATA 0

BOS = 0, WTS = 1 in Data Configuration Register.

This format is used with Series 32000, 808X type processors.

D15	D8 D7	D0
DA0		DA1
DA2		DA3
DA4		DA5
SA0		SA1
SA2		SA3
SA4		SA5
T/L0		T/L1
DATA 0		DATA 1

BOS = 1, WTS = 1 in Data Configuration Register.

This format is used with 68000 type processors.

D7	D0
	DA0
	DA1
	DA2
	DA3
	DA4
	DA5
	SA0
	SA1
	SA2
	SA3

BOS = 0, WTS = 0 in Data Configuration Register.

This format is used with general 8-bit CPUs.

**Note:** All examples above will result in a transmission of a packet in order of DA0, DA1, DA2, DA3 . . . bits within each byte will be transmitted least significant bit first.

DA = Destination Address

SA = Source Address

T/L = Type/Length Field

## 9.0 Remote DMA

The Remote DMA channel is used to both assemble packets for transmission, and to remove received packets from the Receive Buffer Ring. It may also be used as a general purpose slave DMA channel for moving blocks of data or commands between host memory and local buffer memory. There are three modes of operation, Remote Write, Remote Read, or Send Packet.

Two register pairs are used to control the Remote DMA, a Remote Start Address (RSAR0, RSAR1) and a Remote Byte Count (RBCR0, RBCR1) register pair. The Start Address Register pair points to the beginning of the block to be moved while the Byte Count Register pair is used to indicate the number of bytes to be transferred. Full handshake logic is provided to move data between local buffer memory and a bidirectional I/O port.

## 9.0 Remote DMA (Continued)

### REMOTE WRITE

A Remote Write transfer is used to move a block of data from the host into local buffer memory. The Remote DMA will read data from the I/O port and sequentially write it to local buffer memory beginning at the Remote Start Address. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches a count of zero.

### REMOTE READ

A Remote Read transfer is used to move a block of data from local buffer memory to the host. The Remote DMA will sequentially read data from the local buffer memory, beginning at the Remote Start Address, and write data to the I/O port. The DMA Address will be incremented and the Byte Counter will be decremented after each transfer. The DMA is terminated when the Remote Byte Count Register reaches zero.

### REMOTE DMA WRITE

#### Setting PRQ Using the Remote Read

Under certain conditions the NIC's bus state machine may issue /MWR and /PRD before PRQ for the first DMA transfer of a Remote Write Command. If this occurs this could cause data corruption, or cause the remote DMA count to be different from the main CPU count causing the system to "lock up".

To prevent this condition when implementing a Remote DMA Write, the Remote DMA Write command should first be preceded by a Remote DMA Read command to insure that the PRQ signal is asserted before the NIC starts its port read cycle. The reason for this is that the state machine that asserts PRQ runs independently of the state machine that controls the DMA signals. The DMA machine assumes that PRQ is asserted, but actually may not be. To remedy this situation, a single Remote Read cycle should be inserted before the actual DMA Write Command is given. This will ensure that PRQ is asserted when the Remote DMA Write is subsequently executed. This single Remote Read cycle is

called a "dummy Remote Read." In order for the dummy Remote Read cycle to operate correctly, the Start Address should be programmed to a known, safe location in the buffer memory space, and the Remote Byte Count should be programmed to a value greater than 1. This will ensure that the master read cycle is performed safely, eliminating the possibility of data corruption.

#### Remote Write with High Speed Buses

When implementing the Remote DMA Write solution in previous section with high speed buses and CPU's, timing problems may cause the system to hang. Therefore additional considerations are required.

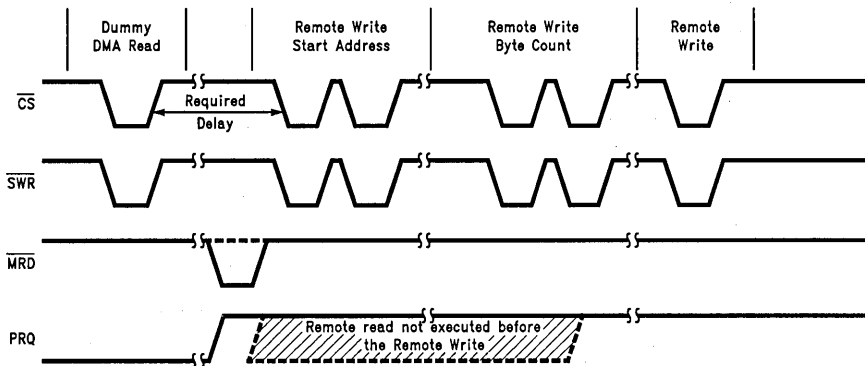

The problem occurs when the system can execute the dummy Remote Read and then start the Remote Write before the NIC has had a chance to execute the Remote Read. If this happens the PRQ signal will not get set, and the Remote Byte Count and Remote Start Address for the Remote Write operation could be corrupted. This is shown by the hatched waveforms in the timing diagram below. The execution of the Remote Read can be delayed by the local DMA operations (particularly during end-of-packet processing).

To ensure the dummy Remote Read does execute, a delay must be inserted between writing the Remote Read Command, and starting to write the Remote Write Start Address. (This time is designated in figure below by the delay arrows.) The recommended method to avoid this problem is, after the Remote Read command is given, to poll both bytes of the Current Remote DMA Address Registers. When the address has incremented, PRQ has been set. Software should recognize this and then start the Remote Write.

An additional caution for high speed systems is that the polling must follow guidelines specified at the end of Section 13. That is, there must be at least 4 bus clocks between chip selects. (For example, when BSCK = 20 MHz, then this time should be 200 ns.)

The general flow for executing a Remote Write is:

1. Set Remote Byte Count to a value > 1 and Remote Start Address to unused RAM (one location before the transmit start address is usually a safe location).

Timing Diagram for Dummy Remote Read

TL/F/8582-98

Note: The dashed lines indicate incorrect timing.

## 9.0 Remote DMA (Continued)

2. Issue the "dummy" Remote Read command.
3. Read the Current Remote DMA Address (CRDA) (both bytes).
4. Compare to previous CRDA value if different go to 6.
5. Delay and jump to 3.
6. Set up for the Remote Write command, by setting the Remote Byte Count and the Remote Start Address (note that if the Remote Byte Count in step 1 can be set to the transmit byte count plus one, and the Remote Start Address to one less, these will now be incremented to the correct values.)
7. Issue the Remote Write command.

### FIFO AND BUS OPERATIONS

#### Overview

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the NIC contains a 16-byte FIFO for buffering data between the bus and the media. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO at different rates. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes (or words) into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time; otherwise a FIFO underrun (or overrun) occurs.

To understand FIFO underruns or overruns, there are two causes which produce this condition—

- 1) the bus latency is so long that the FIFO has filled (or emptied) from the network before the local DMA has serviced the FIFO.
- 2) the bus latency or bus data rate has slowed the throughput of the local DMA to point where it is slower than the network data rate (10 Mb/s). This second condition is also dependent upon DMA clock and word width (byte wide or word wide).

The worst case condition ultimately limits the overall bus latency which the NIC can tolerate.

#### FIFO Underrun and Transmit Enable

During transmission, if a FIFO underrun occurs, the Transmit enable (TXE) output may remain high (active). Generally, this will cause a very large packet to be transmitted onto the network. The jabber feature of the transceiver will terminate the transmission, and reset TXE.

To prevent this problem, a properly designed system will not allow FIFO underruns by giving the NIC a bus acknowledge within time shown in the maximum bus latency curves shown and described later.

#### FIFO at the Beginning of Receive

At the beginning of reception, the NIC stores entire Address field of each incoming packet in the FIFO to determine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. This causes the FIFO to accumulate 8 bytes. Furthermore, there are some synchronization delays in the DMA PLA. Thus, the actual time that BREQ is asserted from the time the Start of Frame Delimiter (SFD) is detected is 7.8  $\mu$ s. This operation affects the bus latencies at 2 and 4 byte thresholds during the first receive BREQ since the FIFO must be filled to 8 bytes (4 words) before issuing a BREQ.

#### FIFO Operation at the End of Receive

When Carrier Sense goes low, the NIC enters its end of packet processing sequence, emptying its FIFO and writing the status information at the beginning of the packet, figure below. This NIC holds onto the bus for the entire sequence. The longest time BREQ may be extended occurs when a packet ends just as the NIC performs its last FIFO burst. The NIC, in this case, performs a programmed burst transfer followed by flushing the remaining bytes in the FIFO, and completes by writing the header information to memory. The following steps occur during this sequence.

- 1) NIC issues BREQ because the FIFO threshold has been reached.
- 2) During the burst, packet ends, resulting in BREQ extended.
- 3) NIC flushes remaining bytes from FIFO.
- 4) NIC performs internal processing to prepare for writing the header.
- 5) NIC writes 4-byte (2-word) header.
- 6) NIC deasserts BREQ.

#### End of Packet Processing

End of Packet Processing (EOPP) times for 10 MHz and 20 MHz have been tabulated in the table below.

**End of Packet Processing Times for Various FIFO Thresholds, Bus Clocks and Transfer Modes**

Mode	Threshold	Bus Clock	EOPP
Byte	2 bytes	10 MHz	7.0 $\mu$ s
	4 bytes		8.6 $\mu$ s
	8 bytes		11.0 $\mu$ s
Byte	2 bytes	20 MHz	3.6 $\mu$ s
	4 bytes		4.2 $\mu$ s
	8 bytes		5.0 $\mu$ s
Word	2 bytes	10 MHz	5.4 $\mu$ s
	4 bytes		6.2 $\mu$ s
	8 bytes		7.4 $\mu$ s
Word	2 bytes	20 MHz	3.0 $\mu$ s
	4 bytes		3.2 $\mu$ s
	8 bytes		3.6 $\mu$ s

#### Threshold Detection (Bus Latency)

To assure that no overwriting of data in the FIFO, the FIFO logic flags a FIFO overrun as the 13th byte is written into the FIFO, effectively shortening the FIFO to 13 bytes. The FIFO logic also operates differently in Byte Mode and in Word Mode. In Byte Mode, a threshold is indicated when the n + 1

## 9.0 Remote DMA (Continued)

Maximum Bus Latency for Byte Mode

TL/F/8582-98

Maximum Bus Latency for Word Mode

TL/F/8582-99

byte has entered the FIFO; thus, with an 8 byte threshold, the NIC issues Bus Request (BREQ) when the 9th byte has entered the FIFO. For Word Mode, BREQ is not generated until the  $n + 2$  bytes have entered the FIFO. Thus, with a 4 word threshold (equivalent to 8 byte threshold), BREQ is issued when the 10th byte has entered the FIFO. The two graphs, the figures above, indicate the maximum allowable bus latency for Word and Byte transfer modes.

### The FIFO at the Beginning of Transmit

Before transmitting, the NIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold. The next BREQ is not issued until after the NIC actually begins transmitting data, i.e., after SFD. The Transmit Prefetch diagram illustrates this process.

### SEND PACKET COMMAND

The Remote DMA channel can be automatically initialized to transfer a single packet from the Receive Buffer Ring.

The CPU begins this transfer by issuing a "Send Packet" Command. The DMA will be initialized to the value of the Boundary Pointer Register and the Remote Byte Count Register pair (RBCR0, RBCR1) will be initialized to the value of the Receive Byte Count fields found in the Buffer Header of each packet. After the data is transferred, the Boundary Pointer is advanced to allow the buffers to be used for new receive packets. The Remote Read will terminate when the Byte Count equals zero. The Remote DMA is then prepared to read the next packet from the Receive Buffer Ring. If the DMA pointer crosses the Page Stop Register, it is reset to the Page Start Address. This allows the Remote DMA to remove packets that have wrapped around to the top of the Receive Buffer Ring.

**Note 1:** In order for the NIC to correctly execute the Send Packet Command, the upper Remote Byte Count Register (RBCR1) must first be loaded with 0FH.

**Note 2:** The Send Packet command cannot be used with 68000 type processors.

### Transmit Prefetch Timing

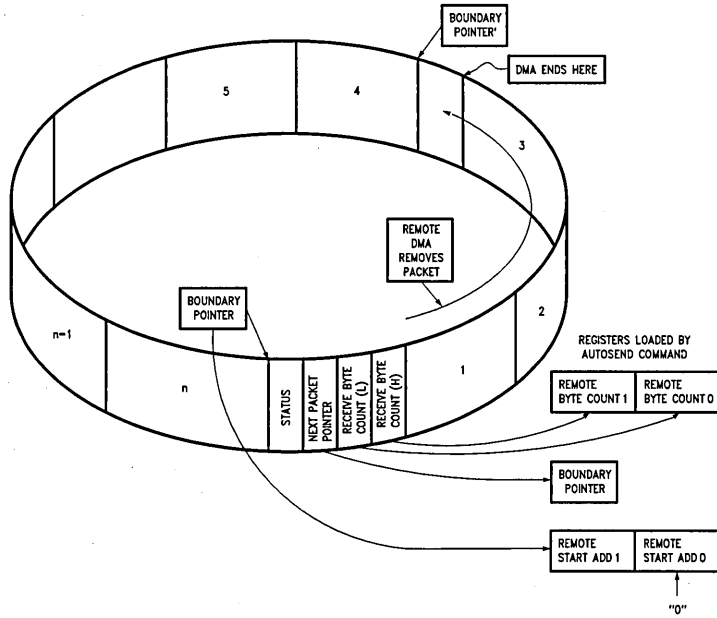

$$\text{Tolerated Bus Latency} = \left[ \left( \text{No. of Bytes Stored in FIFO} \times 800 \right) - 400 \text{ ns} \right] \text{ or } \left( 12 \text{ Bytes} - \text{FIFO Threshold} \right) \text{ whichever is less}$$

### Remote DMA Autoinitialization from Buffer Ring

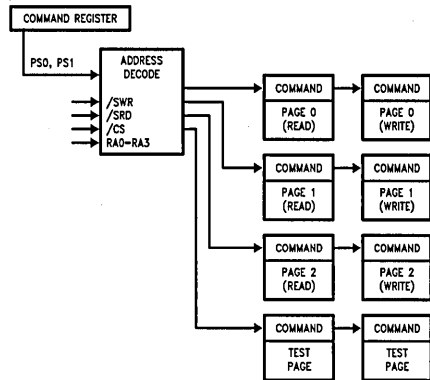

TL/F/8582-59

## 10.0 Internal Registers

All registers are 8-bit wide and mapped into two pages which are selected in the Command Register (PS0, PS1). Pins RA0-RA3 are used to address registers within each page. Page 0 registers are those registers which are commonly accessed during NIC operation while page 1 registers are used primarily for initialization. The registers are partitioned to avoid having to perform two write/read cycles to access commonly used registers.

### 10.3 Register Descriptions

#### COMMAND REGISTER (CR) 00H (READ/WRITE)

The Command Register is used to initiate transmissions, enable or disable Remote DMA operations and to select register pages. To issue a command the microprocessor sets the corresponding bit(s) (RD2, RD1, RD0, TXP). Further commands may be overlapped, but with the following rules: (1) If a transmit command overlaps with a remote DMA operation, bits RD0, RD1, and RD2 must be maintained for the remote DMA command when setting the TXP bit. Note, if a remote DMA command is re-issued when giving the transmit command, the DMA will complete immediately if the remote byte count register have not been re-initialized. (2) If a remote DMA operation overlaps a transmission, RD0, RD1, and RD2 may be written with the desired values and a "0" written to the TXP bit. Writing a "0" to this bit has no effect. (3) A remote write DMA may not overlap remote read operation or visa versa. Either of these operations must either complete or be aborted before the other operation may start. Bits PS1, PS0, RD2, and STP may be set any time.

7	6	5	4	3	2	1	0
PS1	PS0	RD2	RD1	RD0	TXP	STA	STP

Bit	Symbol	Description																								
D0	STP	<p><b>STOP:</b> Software reset command, takes the controller offline, no packets will be received or transmitted. Any reception or transmission in progress will continue to completion before entering the reset state. To exit this state, the STP bit must be reset and the STA bit must be set high. To perform a software reset, this bit should be set high. The software reset has executed only when indicated by the RST bit in the ISR being set to a 1. <b>STP powers up high.</b></p> <p><b>Note:</b> If the NIC has previously been in start mode and the STP is set, both the STP and STA bits will remain set.</p>																								
D1	STA	<p><b>START:</b> This bit is used to activate the NIC after either power up, or when the NIC has been placed in a reset mode by software command or error. <b>STA powers up low.</b></p>																								
D2	TXP	<p><b>TRANSMIT PACKET:</b> This bit must be set to initiate transmission of a packet. TXP is internally reset either after the transmission is completed or aborted. This bit should be set only after the Transmit Byte Count and Transmit Page Start registers have been programmed.</p> <p><b>Note:</b> Before the transmit command is given, the STA bit must be set and the STP bit reset.</p>																								
D3, D4, D5	RD0, RD1, RD2	<p><b>REMOTE DMA COMMAND:</b> These three encoded bits control operation of the Remote DMA channel. RD2 can be set to abort any Remote DMA command in progress. The Remote Byte Count Registers should be cleared when a Remote DMA has been aborted. The Remote Start Addresses are not restored to the starting address if the Remote DMA is aborted.</p> <table style="width: 100%; border-collapse: collapse;"> <tr> <td style="text-align: left;">RD2</td> <td style="text-align: left;">RD1</td> <td style="text-align: left;">RD0</td> <td></td> </tr> <tr> <td>0</td> <td>0</td> <td>0</td> <td>Not Allowed</td> </tr> <tr> <td>0</td> <td>0</td> <td>1</td> <td>Remote Read</td> </tr> <tr> <td>0</td> <td>1</td> <td>0</td> <td>Remote Write (Note 2)</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> <td>Send Packet</td> </tr> <tr> <td>1</td> <td>X</td> <td>X</td> <td>Abort/Complete Remote DMA (Note 1)</td> </tr> </table> <p><b>Note 1:</b> If a remote DMA operation is aborted and the remote byte count has not decremented to zero, PRQ (pin 29, DIP) will remain high. A read acknowledge (RACK) on a write acknowledge (WACK) will reset PRQ low.</p> <p><b>Note 2:</b> For proper operation of the Remote Write DMA, there are two steps which must be performed before using the Remote Write DMA. The steps are as follows:</p> <ol style="list-style-type: none"> <li>i) Write a non-zero value into RBCR0.</li> <li>ii) Set bits RD2, RD1, RD0 to 0, 0, 1.</li> <li>iii) Set RBCR0, 1 and RSAR0, 1</li> <li>iv) Issue the Remote Write DMA Command (RD2, RD1, RD0 = 0, 1, 0)</li> </ol>	RD2	RD1	RD0		0	0	0	Not Allowed	0	0	1	Remote Read	0	1	0	Remote Write (Note 2)	0	1	1	Send Packet	1	X	X	Abort/Complete Remote DMA (Note 1)

### 10.3 Register Descriptions (Continued)

#### INTERRUPT STATUS REGISTER (ISR) 07H (READ/WRITE)

This register is accessed by the host processor to determine the cause of an interrupt. Any interrupt can be masked in the Interrupt Mask Register (IMR). Individual interrupt bits are cleared by writing a "1" into the corresponding bit of the ISR. The INT signal is active as long as any unmasked signal is set, and will not go low until all unmasked bits in this register have been cleared. The ISR must be cleared after power up by writing it with all 1's.

7	6	5	4	3	2	1	0
RST	RDC	CNT	OVW	TXE	RXE	PTX	PRX

Bit	Symbol	Description
D0	PRX	<b>PACKET RECEIVED:</b> Indicates packet received with no errors.
D1	PTX	<b>PACKET TRANSMITTED:</b> Indicates packet transmitted with no errors.
D2	RXE	<b>RECEIVE ERROR:</b> Indicates that a packet was received with one or more of the following errors: —CRC Error —Frame Alignment Error —FIFO Overrun —Missed Packet
D3	TXE	<b>TRANSMIT ERROR:</b> Set when packet transmitted with one or more of the following errors: —Excessive Collisions —FIFO Underrun
D4	OVW	<b>OVERWRITE WARNING:</b> Set when receive buffer ring storage resources have been exhausted. (Local DMA has reached Boundary Pointer).
D5	CNT	<b>COUNTER OVERFLOW:</b> Set when MSB of one or more of the Network Tally Counters has been set.
D6	RDC	<b>REMOTE DMA COMPLETE:</b> Set when Remote DMA operation has been completed.
D7	RST	<b>RESET STATUS:</b> Set when NIC enters reset state and cleared when a Start Command is issued to the CR. This bit is also set when a Receive Buffer Ring overflow occurs and is cleared when one or more packets have been removed from the ring. Writing to this bit has no effect. <b>NOTE:</b> This bit does not generate an interrupt, it is merely a status indicator.

## 10.0 Internal Registers (Continued)

### 10.3 Register Descriptions (Continued)

#### INTERRUPT MASK REGISTER (IMR) 0FH (WRITE)

The Interrupt Mask Register is used to mask interrupts. Each interrupt mask bit corresponds to a bit in the Interrupt Status Register (ISR). If an interrupt mask bit is set an interrupt will be issued whenever the corresponding bit in the ISR is set. If any bit in the IMR is set low, an interrupt will not occur when the bit in the ISR is set. **The IMR powers up all zeroes.**

Bit	Symbol	Description
D0	PRXE	<b>PACKET RECEIVED INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received.
D1	PTXE	<b>PACKET TRANSMITTED INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet is transmitted.
D2	RXEE	<b>RECEIVE ERROR INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet received with error.
D3	TXEE	<b>TRANSMIT ERROR INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when packet transmission results in error.
D4	OVWE	<b>OVERWRITE WARNING INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when Buffer Management Logic lacks sufficient buffers to store incoming packet.
D5	CNTE	<b>COUNTER OVERFLOW INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when MSB of one or more of the Network Statistics counters has been set.
D6	RDCE	<b>DMA COMPLETE INTERRUPT ENABLE</b> 0: Interrupt Disabled 1: Enables Interrupt when Remote DMA transfer has been completed.
D7	reserved	reserved

## 10.0 Internal Registers (Continued)

### 10.3 Register Descriptions (Continued)

#### DATA CONFIGURATION REGISTER (DCR) 0EH (WRITE)

This Register is used to program the NIC for 8- or 16-bit memory interface, select byte ordering in 16-bit applications and establish FIFO thresholds. **The DCR must be initialized prior to loading the Remote Byte Count Registers. LAS is set on power up.**

7	6	5	4	3	2	1	0

### 10.3 Register Descriptions (Continued)

#### TRANSMIT STATUS REGISTER (TSR) 04H (READ)

This register records events that occur on the media during transmission of a packet. It is cleared when the next transmission is initiated by the host. All bits remain low unless the event that corresponds to a particular bit occurs during transmission. Each transmission should be followed by a read of this register. The contents of this register are not specified until after the first transmission.

D0	PTX	<b>PACKET TRANSMITTED:</b> Indicates transmission without error. (No excessive collisions or FIFO underrun) (ABT = "0", FU = "0").
D1	reserved	reserved
D2	COL	<b>TRANSMIT COLLIDED:</b> Indicates that the transmission collided at least once with another station on the network. The number of collisions is recorded in the Number of Collisions Registers (NCR).
D3	ABT	<b>TRANSMIT ABORTED:</b> Indicates the NIC aborted transmission because of excessive collisions. (Total number of transmissions including original transmission attempt equals 16).
D4	CRS	<b>CARRIER SENSE LOST:</b> This bit is set when carrier is lost during transmission of the packet. Carrier Sense is monitored from the end of Preamble/Synch until TXEN is dropped. Transmission is not aborted on loss of carrier.
D5	FU	<b>FIFO UNDERRUN:</b> If the NIC cannot gain access of the bus before the FIFO empties, this bit is set. Transmission of the packet will be aborted.
D6	CDH	<b>CD HEARTBEAT:</b> Failure of the transceiver to transmit a collision signal after transmission of a packet will set this bit. The Collision Detect (CD) heartbeat signal must commence during the first 6.4 $\mu$ s of the Interframe Gap following a transmission. In certain collisions, the CD Heartbeat bit will be set even though the transceiver is not performing the CD heartbeat test.
D7	OWC	<b>OUT OF WINDOW COLLISION:</b> Indicates that a collision occurred after a slot time (51.2 $\mu$ s). Transmissions rescheduled as in normal collisions.

## 10.0 Internal Registers (Continued)

### 10.3 Register Descriptions (Continued)

#### RECEIVE CONFIGURATION REGISTER (RCR) OCH (WRITE)

This register determines operation of the NIC during reception of a packet and is used to program what types of packets to accept.

7	6	5	4	3	2	1	0
—	—	MON	PRO	AM	AB	AR	SEP

Bit	Symbol	Description
D0	SEP	<p><b>SAVE ERRORED PACKETS</b>                      0: Packets with receive errors are rejected.                      1: Packets with receive errors are accepted. Receive errors are CRC and Frame Alignment errors.</p>
D1	AR	<p><b>ACCEPT RUNT PACKETS:</b> This bit allows the receiver to accept packets that are smaller than 64 bytes. The packet must be at least 8 bytes long to be accepted as a runt.                      0: Packets with fewer than 64 bytes rejected.                      1: Packets with fewer than 64 bytes accepted.</p>
D2	AB	<p><b>ACCEPT BROADCAST:</b> Enables the receiver to accept a packet with an all 1's destination address.                      0: Packets with broadcast destination address rejected.                      1: Packets with broadcast destination address accepted.</p>
D3	AM	<p><b>ACCEPT MULTICAST:</b> Enables the receiver to accept a packet with a multicast address, all multicast addresses must pass the hashing array.                      0: Packets with multicast destination address not checked.                      1: Packets with multicast destination address checked.</p>
D4	PRO	<p><b>PROMISCUOUS PHYSICAL:</b> Enables the receiver to accept all packets with a physical address.                      0: Physical address of node must match the station address programmed in PAR0–PAR5.                      1: All packets with physical addresses accepted.</p>
D5	MON	<p><b>MONITOR MODE:</b> Enables the receiver to check addresses and CRC on incoming packets without buffering to memory. The Missed Packet Tally counter will be incremented for each recognized packet.                      0: Packets buffered to memory.                      1: Packets checked for address match, good CRC and Frame Alignment but not buffered to memory.</p>
D6	reserved	reserved
D7	reserved	reserved

**Note:** D2 and D3 are "OR'd" together, i.e., if D2 and D3 are set the NIC will accept broadcast and multicast addresses as well as its own physical address. To establish full promiscuous mode, bits D2, D3, and D4 should be set. In addition the multicast hashing array must be set to all 1's in order to accept all multicast addresses.

## 10.0 Internal Registers (Continued)

### 10.3 Register Descriptions (Continued)

#### RECEIVE STATUS REGISTER (RSR) OCH (READ)

This register records status of the received packet, including information on errors and the type of address match, either physical or multicast. The contents of this register are written to buffer memory by the DMA after reception of a good packet. If packets with errors are to be saved the receive status is written to memory at the head of the erroneous packet if an erroneous packet is received. If packets with errors are to be rejected the RSR will not be written to memory. The contents will be cleared when the next packet arrives. CRC errors, Frame Alignment errors and missed packets are counted internally by the NIC which relinquishes the Host from reading the RSR in real time to record errors for Network Management Functions. The contents of this register are not specified until after the first reception.

7	6	5	4	3	2	1	0
DFR	DIS	PHY	MPA	FO	FAE	CRC	PRX

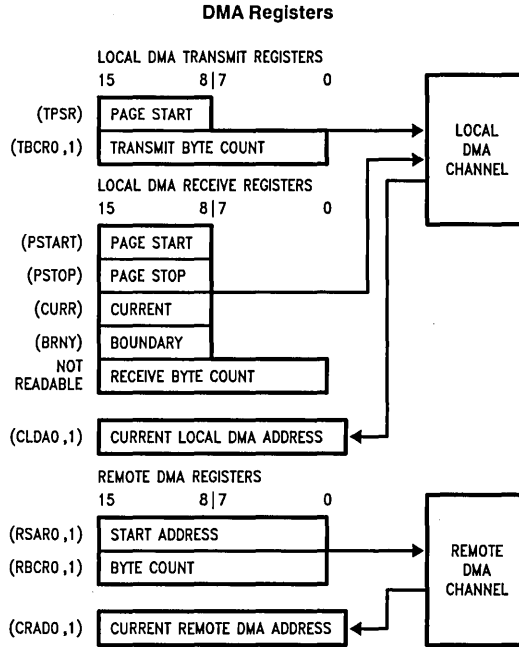

Bit	Symbol	Description
D0	PRX	<b>PACKET RECEIVED INTACT:</b> Indicates packet received without error. (Bits CRC, FAE, FO, and MPA are zero for the received packet.)
D1	CRC	<b>CRC ERROR:</b> Indicates packet received with CRC error. Increments Tally Counter (CNTR1). This bit will also be set for Frame Alignment errors.
D2	FAE	<b>FRAME ALIGNMENT ERROR:</b> Indicates that the incoming packet did not end on a byte boundary and the CRC did not match at last byte boundary. Increments Tally Counter (CNTR0).
D3	FO	<b>FIFO OVERRUN:</b> This bit is set when the FIFO is not serviced causing overflow during reception. Reception of the packet will be aborted.
D4	MPA	<b>MISSED PACKET:</b> Set when packet intended for node cannot be accepted by NIC because of a lack of receive buffers or if the controller is in monitor mode and did not buffer the packet to memory. Increments Tally Counter (CNTR2).
D5	PHY	<b>PHYSICAL/MULTICAST ADDRESS:</b> Indicates whether received packet had a physical or multicast address type. 0: Physical Address Match 1: Multicast/Broadcast Address Match
D6	DIS	<b>RECEIVER DISABLED:</b> Set when receiver disabled by entering Monitor mode. Reset when receiver is re-enabled when exiting Monitor mode.
D7	DFR	<b>DEFERRING:</b> Set when CRS or COL inputs are active. If the transceiver has asserted the CD line as a result of the jabber, this bit will stay set indicating the jabber condition.

**Note:** Following coding applies to CRC and FAE bits

FAE/CRC	Type of Error
0 0	No Error (Good CRC and <6 Dribble Bits)
0 1	CRC Error
1 0	Illegal, will not occur
1 1	Frame Alignment Error and CRC Error

# 10.0 Internal Registers (Continued)

## 10.4 DMA REGISTERS

TL/F/8582-61

The DMA Registers are partitioned into three groups; Transmit, Receive and Remote DMA Registers. The Transmit registers are used to initialize the Local DMA Channel for transmission of packets while the Receive Registers are used to initialize the Local DMA Channel for packet Reception. The Page Stop, Page Start, Current and Boundary Registers are used by the Buffer Management Logic to supervise the Receive Buffer Ring. The Remote DMA Registers are used to initialize the Remote DMA.

**Note:** In the figure above, registers are shown as 8 or 16 bits wide. Although some registers are 16-bit internal registers, all registers are accessed as 8-bit registers. Thus the 16-bit Transmit Byte Count Register is broken into two 8-bit registers, TBCR0 and TBCR1. Also TPSR, PSTART, PSTOP, CURR and BRNY only check or control the upper 8 bits of address information on the bus. Thus they are shifted to positions 15-8 in the diagram above.

### 10.5 TRANSMIT DMA REGISTERS

#### TRANSMIT PAGE START REGISTER (TPSR)

This register points to the assembled packet to be transmitted. Only the eight higher order addresses are specified since all transmit packets are assembled on 256-byte page boundaries. The bit assignment is shown below. The values placed in bits D7-D0 will be used to initialize the higher order address (A8-A15) of the Local DMA for transmission. The lower order bits (A7-A0) are initialized to zero.

Bit Assignment

	7	6	5	4	3	2	1	0
TPSR	A15	A14	A13	A12	A11	A10	A9	A8

(A7-A0 Initialized to zero)

#### TRANSMIT BYTE COUNT REGISTER 0,1 (TBCR0, TBCR1)

These two registers indicate the length of the packet to be transmitted in bytes. The count must include the number of

bytes in the source, destination, length and data fields. The maximum number of transmit bytes allowed is 64k bytes. The NIC will not truncate transmissions longer than 1500 bytes. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
TBCR1	L15	L14	L13	L12	L11	L10	L9	L8

	7	6	5	4	3	2	1	0
TBCR0	L7	L6	L5	L4	L3	L2	L1	L0

### 10.6 LOCAL DMA RECEIVE REGISTERS

#### PAGE START STOP REGISTERS (PSTART, PSTOP)

The Page Start and Page Stop Registers program the starting and stopping address of the Receive Buffer Ring. Since the NIC uses fixed 256-byte buffers aligned on page boundaries only the upper eight bits of the start and stop address are specified.

#### PSTART, PSTOP bit assignment

	7	6	5	4	3	2	1	0
PSTART, PSTOP	A15	A14	A13	A12	A11	A10	A9	A8

#### BOUNDARY (BRNY) REGISTER

This register is used to prevent overflow of the Receive Buffer Ring. Buffer management compares the contents of this register to the next buffer address when linking buffers together. If the contents of this register match the next buffer address the Local DMA operation is aborted.

	7	6	5	4	3	2	1	0
BRNY	A15	A14	A13	A12	A11	A10	A9	A8

## 10.0 Internal Registers (Continued)

### CURRENT PAGE REGISTER (CURR)

This register is used internally by the Buffer Management Logic as a backup register for reception. CURR contains the address of the first buffer to be used for a packet reception and is used to restore DMA pointers in the event of receive errors. This register is initialized to the same value as PSTART and should not be written to again unless the controller is Reset.

	7	6	5	4	3	2	1	0
CURR	A15	A14	A13	A12	A11	A10	A9	A8

### CURRENT LOCAL DMA REGISTER 0,1 (CLDA0,1)

These two registers can be accessed to determine the current local DMA Address.

	7	6	5	4	3	2	1	0
CLDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CLDA0	A7	A6	A5	A4	A3	A2	A1	A0

## 10.7 REMOTE DMA REGISTERS

### REMOTE START ADDRESS REGISTERS (RSAR0,1)

Remote DMA operations are programmed via the Remote Start Address (RSAR0,1) and Remote Byte Count (RBCR0,1) registers. The Remote Start Address is used to point to the start of the block of data to be transferred and the Remote Byte Count is used to indicate the length of the block (in bytes).

	7	6	5	4	3	2	1	0
RSAR1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
RSAR0	A7	A6	A5	A4	A3	A2	A1	A0

### 6.4.3.2 REMOTE BYTE COUNT REGISTERS (RBCR0,1)

	7	6	5	4	3	2	1	0
RBCR1	BC15	BC14	BC13	BC12	BC11	BC10	BC9	BC8

	7	6	5	4	3	2	1	0
RBCR0	BC7	BC6	BC5	BC4	BC3	BC2	BC1	BC0

**Note:**

RSAR0 programs the start address bits A0-A7.  
 RSAR1 programs the start address bits A8-A15.  
 Address incremented by two for word transfers, and by one for byte transfers.  
 Byte Count decremented by two for word transfers and by one for byte transfers.  
 RBCR0 programs LSB byte count.  
 RBCR1 programs MSB byte count.

### CURRENT REMOTE DMA ADDRESS (CRDA0, CRDA1)

The Current Remote DMA Registers contain the current address of the Remote DMA. The bit assignment is shown below:

	7	6	5	4	3	2	1	0
CRDA1	A15	A14	A13	A12	A11	A10	A9	A8

	7	6	5	4	3	2	1	0
CRDA0	A7	A6	A5	A4	A3	A2	A1	A0

## 10.8 PHYSICAL ADDRESS REGISTERS (PAR0-PAR5)

The physical address registers are used to compare the destination address of incoming packets for rejecting or accepting packets. Comparisons are performed on a byte-wide basis. The bit assignment shown below relates the sequence in PAR0-PAR5 to the bit sequence of the received packet.

	D7	D6	D5	D4	D3	D2	D1	D0
PAR0	DA7	DA6	DA5	DA4	DA3	DA2	DA1	DA0
PAR1	DA15	DA14	DA13	DA12	DA11	DA10	DA9	DA8
PAR2	DA23	DA22	DA21	DA20	DA19	DA18	DA17	DA16
PAR3	DA31	DA30	DA29	DA28	DA27	DA26	DA25	DA24
PAR4	DA39	DA38	DA37	DA36	DA35	DA34	DA33	DA32
PAR5	DA47	DA46	DA45	DA44	DA43	DA42	DA41	DA40

	Destination Address						Source		
P/S	DA0	DA1	DA2	DA3	.....	DA46	DA47	SA0	...

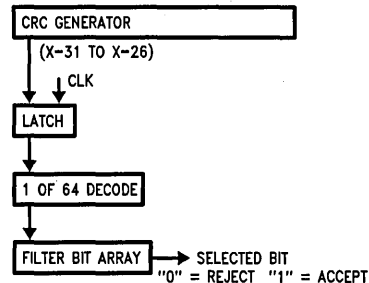

**Note:**

P/S = Preamble, Synch  
 DA0 = Physical/Multicast Bit

## 10.9 MULTICAST ADDRESS REGISTERS (MAR0-MAR7)

The multicast address registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 most significant bits of the CRC generator are latched. These 6 bits are then decoded by a 1 of 64 decode to index a unique filter bit (FB0-63) in the multicast address registers. If the filter bit selected is set, the multicast packet is accepted. The system designer would use a program to determine which filter bits to set in the multicast registers. All multicast filter bits that correspond to multicast address accepted by the node are then set to one. To accept all multicast packets all of the registers are set to all ones.

**Note:** Although the hashing algorithm does not guarantee perfect filtering of multicast address, it will perfectly filter up to 64 multicast addresses if these addresses are chosen to map into unique locations in the multicast filter.

TL/F/8582-62

## 10.0 Internal Registers (Continued)

	D7	D6	D5	D4	D3	D2	D1	D0
MAR0	FB7	FB6	FB5	FB4	FB3	FB2	FB1	FB0
MAR1	FB15	FB14	FB13	FB12	FB11	FB10	FB9	FB8
MAR2	FB23	FB22	FB21	FB20	FB19	FB18	FB17	FB16
MAR3	FB31	FB30	FB29	FB28	FB27	FB26	FB25	FB24
MAR4	FB39	FB38	FB37	FB36	FB35	FB34	FB33	FB32
MAR5	FB47	FB46	FB45	FB44	FB43	FB42	FB41	FB40
MAR6	FB55	FB54	FB53	FB52	FB51	FB50	FB49	FB48
MAR7	FB63	FB62	FB61	FB60	FB59	FB58	FB57	FB56

If address Y is found to hash to the value 32 (20H), then FB32 in MAR4 should be initialized to "1". This will cause the NIC to accept any multicast packet with the address Y.

### NETWORK TALLY COUNTERS

Three 8-bit counters are provided for monitoring the number of CRC errors, Frame Alignment Errors and Missed Packets. The maximum count reached by any counter is 192 (C0H). These registers will be cleared when read by the CPU. The count is recorded in binary in CT0-CT7 of each Tally Register.

#### Frame Alignment Error Tally (CNTR0)

This counter is incremented every time a packet is received with a Frame Alignment Error. The packet must have been recognized by the address recognition logic. The counter is cleared after it is read by the processor.

	7	6	5	4	3	2	1	0
CNTR0	CT7	CT6	CT5	CT4	CT3	CT2	CT1	CT0

#### CRC Error Tally (CNTR1)

This counter is incremented every time a packet is received with a CRC error. The packet must first be recognized by the address recognition logic. The counter is cleared after it is read by the processor.

	7	6	5	4	3	2	1	0
CNTR1	CT7	CT6	CT5	CT4	CT3	CT2	CT1	CT0

#### Frames Lost Tally Register (CNTR2)

This counter is incremented if a packet cannot be received due to lack of buffer resources. In monitor mode, this counter will count the number of packets that pass the address recognition logic.

	7	6	5	4	3	2	1	0
CNTR2	CT7	CT6	CT5	CT4	CT3	CT2	CT1	CT0

### FIFO

This is an eight bit register that allows the CPU to examine the contents of the FIFO after loopback. The FIFO will contain the last 8 data bytes transmitted in the loopback packet. Sequential reads from the FIFO will advance a pointer in the FIFO and allow reading of all 8 bytes.

	7	6	5	4	3	2	1	0
FIFO	DB7	DB6	DB5	DB4	DB3	DB2	DB1	DB0

**Note:** The FIFO should only be read when the NIC has been programmed in loopback mode.

### NUMBER OF COLLISIONS (NCR)

This register contains the number of collisions a node experiences when attempting to transmit a packet. If no collisions are experienced during a transmission attempt, the COL bit of the TSR will not be set and the contents of NCR will be zero. If there are excessive collisions, the ABT bit in the TSR will be set and the contents of NCR will be zero. The NCR is cleared after the TXP bit in the CR is set.

	7	6	5	4	3	2	1	0
NCR	—	—	—	—	NC3	NC2	NC1	NC0

## 11.0 Initialization Procedures

The NIC must be initialized prior to transmission or reception of packets from the network. Power on reset is applied to the NIC's reset pin. This clears/sets the following bits:

Register	Reset Bits	Set Bits
Command Register (CR)	TXP, STA	RD2, STP
Interrupt Status (ISR)		RST
Interrupt Mask (IMR)	All Bits	
Data Control (DCR)		LAS
Transmit Config. (TCR)	LB1, LB0	

The NIC remains in its reset state until a Start Command is issued. This guarantees that no packets are transmitted or received and that the NIC remains a bus slave until all appropriate internal registers have been programmed. After initialization the STP bit of the command register is reset and packets may be received and transmitted.

### Initialization Sequence

The following initialization procedure is mandatory.

- 1) Program Command Register for Page 0 (Command Register = 21H)
- 2) Initialize Data Configuration Register (DCR)
- 3) Clear Remote Byte Count Registers (RBCR0, RBCR1)
- 4) Initialize Receive Configuration Register (RCR)
- 5) Place the NIC in LOOPBACK mode 1 or 2 (Transmit Configuration Register = 02H or 04H)
- 6) Initialize Receive Buffer Ring: Boundary Pointer (BNDRY), Page Start (PSTART), and Page Stop (PSTOP)
- 7) Clear Interrupt Status Register (ISR) by writing 0FFh to it.
- 8) Initialize Interrupt Mask Register (IMR)
- 9) Program Command Register for page 1 (Command Register = 61H)
  - i) Initialize Physical Address Registers (PAR0-PAR5)
  - ii) Initialize Multicast Address Registers (MAR0-MAR7)
  - iii) Initialize CURRent pointer
- 10) Put NIC in START mode (Command Register = 22H). The local receive DMA is still not active since the NIC is in LOOPBACK.
- 11) Initialize the Transmit Configuration for the intended value. The NIC is now ready for transmission and reception.

## 11.0 Initialization Procedures

(Continued)

Before receiving packets, the user must specify the location of the Receive Buffer Ring. This is programmed in the Page Start and Page Stop Registers. In addition, the Boundary and Current Page Registers must be initialized to the value of the Page Start Register. These registers will be modified during reception of packets.

## 12.0 Loopback Diagnostics

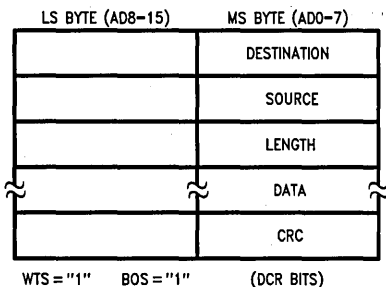

Three forms of local loopback are provided on the NIC. The user has the ability to loopback through the deserializer on the DP8390D NIC, through the DP8391 SNI, and to the coax to check the link through the transceiver circuitry. **Because of the half duplex architecture of the NIC, loopback testing is a special mode of operation with the following restrictions:**

### Restrictions During Loopback

The FIFO is split into two halves, one used for transmission the other for reception. Only 8-bit fields can be fetched from memory so two tests are required for 16-bit systems to verify integrity of the entire data path. During loopback the maximum latency from the assertion of BREQ to BACK is 2.0  $\mu$ s. Systems that wish to use the loopback test yet do not meet this latency can limit the loopback packet to 7 bytes without experiencing underflow. Only the last 8 bytes of the loopback packet are retained in the FIFO. The last 8 bytes can be read through the FIFO register which will advance through the FIFO to allow reading the receive packet sequentially.

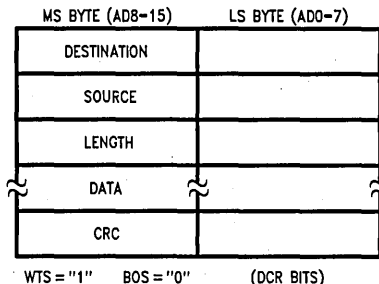

DESTINATION ADDRESS	= (6 bytes) Station Physical Address
SOURCE ADDRESS	
LENGTH	2 bytes
DATA	= 46 to 1500 bytes
CRC	Appended by NIC if CRC = "0" in TCR

When in word-wide mode with Byte Order Select set, the loopback packet must be assembled in the even byte locations as shown below. (The loopback only operates with byte wide transfers.)

TL/F/6582-15

When in word-wide mode with Byte Order Select low, the following format must be used for the loopback packet.

TL/F/6582-16

**Note:** When using loopback in word mode 2n bytes must be programmed in TBCRO, 1. Where n = actual number of bytes assembled in even or odd location.

To initiate a loopback the user first assembles the loopback packet then selects the type of loopback using the Transmit Configuration register bits LB0, LB1. The transmit configuration register must also be set to enable or disable CRC generation during transmission. The user then issues a normal transmit command to send the packet. During loopback the receiver checks for an address match and if CRC bit in the TCR is set, the receiver will also check the CRC. The last 8 bytes of the loopback packet are buffered and can be read out of the FIFO using the FIFO read port.

### Loopback Modes

**MODE 1: Loopback Through the Controller (LB1 = 0, LB0 = 1).**

If the loopback is through the NIC then the serializer is simply linked to the deserializer and the receive clock is derived from the transmit clock.

**MODE 2: Loopback Through the SNI (LB1 = 1, LB0 = 0).**

If the loopback is to be performed through the SNI, the NIC provides a control (LPBK) that forces the SNI to loopback all signals.

**MODE 3: Loopback to Coax (LB1 = 1, LB0 = 1).**

Packets can be transmitted to the coax in loopback mode to check all of the transmit and receive paths and the coax itself.

**Note:** In MODE 1, CRS and COL lines are not indicated in any status register, but the NIC will still defer if these lines are active. In MODE 2, COL is masked and in MODE 3 CRS and COL are not masked. It is not possible to go directly between the loopback modes, it is necessary to return to normal operation (00H) when changing modes.

### Reading the Loopback Packet

The last eight bytes of a received packet can be examined by 8 consecutive reads of the FIFO register. The FIFO pointer is incremented after the rising edge of the CPU's read strobe by internally synchronizing and advancing the pointer. This may take up to four bus clock cycles, if the pointer has not been incremented by the time the CPU reads the FIFO register again, the NIC will insert wait states

**Note:** The FIFO may only be read during Loopback. Reading the FIFO at any other time will cause the NIC to malfunction.

## 12.0 Loopback Diagnostics (Continued)

### Alignment of the Received Packet in the FIFO

Reception of the packet in the FIFO begins at location zero, after the FIFO pointer reaches the last location in the FIFO, the pointer wraps to the top of the FIFO overwriting the previously received data. This process continues until the last byte is received. The NIC then appends the received byte count in the next two locations of the FIFO. The contents of the Upper Byte Count are also copied to the next FIFO location. The number of bytes used in the loopback packet determines the alignment of the packet in the FIFO. The alignment for a 64-byte packet is shown below.

FIFO LOCATION	FIFO CONTENTS		
0	LOWER BYTE COUNT	→	First Byte Read
1	UPPER BYTE COUNT	→	Second Byte Read
2	UPPER BYTE COUNT		•
3	LAST BYTE		•
4	CRC1		•
5	CRC2		•
6	CRC3		•
7	CRC4	→	Last Byte Read

For the following alignment in the FIFO the packet length should be  $(N \times 8) + 5$  Bytes. Note that if the CRC bit in the TCR is set, CRC will not be appended by the transmitter. If the CRC is appended by the transmitter, the last four bytes, bytes N-3 to N, correspond to the CRC.

FIFO LOCATION	FIFO CONTENTS		
0	BYTE N-4	→	First Byte Read
1	BYTE N-3 (CRC1)	AR	Second Byte Read
2	BYTE N-2 (CRC2)		•
3	BYTE N-1 (CRC3)		•
4	BYTE N (CRC4)		•
5	LOWER BYTE COUNT		•
6	UPPER BYTE COUNT	→	Last Byte Read
7	UPPER BYTE COUNT		

### LOOPBACK TESTS

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the DP8390D NIC prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

- 1) Verify integrity of data path. Received data is checked against transmitted data.
- 2) Verify CRC logic's capability to generate good CRC on transmit, verify CRC on receive (good or bad CRC).
- 3) Verify that the Address Recognition Logic can
  - a) Recognize address match packets
  - b) Reject packets that fail to match an address

### LOOPBACK OPERATION IN THE NIC

Loopback is a modified form of transmission using only half of the FIFO. This places certain restrictions on the use of loopback testing. When loopback mode is selected in the TCR, the FIFO is split. A packet should be assembled in memory with programming of TPSR and TBCR0, TBCR1 registers. When the transmit command is issued the following operations occur:

#### Transmitter Actions

- 1) Data is transferred from memory by the DMA until the FIFO is filled. For each transfer TBCR0 and TBCR1 are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
- 2) The NIC generates 56 bits of preamble followed by an 8-bit synch pattern.
- 3) Data transferred from FIFO to serializer.
- 4) If CRC=1 in TCR, no CRC calculated by NIC, the last byte transmitted is the last byte from the FIFO (Allows software CRC to be appended). If CRC=0, NIC calculates and appends four bytes of CRC.
- 5) At end of Transmission PTX bit set in ISR.

#### Receiver Actions

- 1) Wait for synch, all preamble stripped.
- 2) Store packet in FIFO, increment receive byte count for each incoming byte.
- 3) If CRC=0 in TCR, receiver checks incoming packet for CRC errors. If CRC=1 in TCR, receiver does not check CRC errors, CRC error bit always set in RSR (for address matching packets).
- 4) At end of receive, receive byte count written into FIFO, receive status register is updated. The PRX bit is typically set in the RSR even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the RS to be set.

### EXAMPLES

The following examples show what results can be expected from a properly operating NIC during loopback. The restrictions and results of each type of loopback are listed for reference. The loopback tests are divided into two sets of tests. One to verify the data path, CRC generation and byte count through all three paths. The second set of tests uses internal loopback to verify the receiver's CRC checking and address recognition. For all of the tests the DCR was programmed to 40h.

PATH	TCR	RCR	TSR	RSR	ISR
NIC Internal	02	00	53(1)	02(2)	02(3)

**Note 1:** Since carrier sense and collision detect inputs are blocked during internal loopback, carrier and CD heartbeat are not seen and the CRS and CDH bits are set.

**Note 2:** CRC errors are always indicated by receiver if CRC is appended by the transmitter.

**Note 3:** Only the PTX bit in the ISR is set, the PRX bit is only set if status is written to memory. In loopback this action does not occur and the PRX bit remains 0 for all loopback modes.

**Note 4:** All values are hex.

## 12.0 Loopback Diagnostics (Continued)

PATH	TCR	RCR	TSR	RSR	ISR
NIC External	04	00	43(1)	02	02

**Note 1:** CDH is set, CRS is not set since it is generated by the external encoder/decoder.

PATH	TCR	RCR	TSR	RSR	ISR
NIC External	06	00	03(1)	02	02(2)

**Note 1:** CDH and CRS should not be set. The TSR however, could also contain 01H,03H,07H and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** Will contain 08H if packet is not transmittable.

**Note 3:** During external loopback the NIC is now exposed to network traffic, it is therefore possible for the contents of both the Receive portion of the FIFO and the RSR to be corrupted by any other packet on the network. Thus in a live network the contents of the FIFO and RSR should not be depended on. The NIC will still abide by the standard CSMA/CD protocol in external loopback mode. (i.e. The network will not be disturbed by the loopback packet).

**Note 4:** All values are hex.

### CRC AND ADDRESS RECOGNITION

The next three tests exercise the address recognition logic and CRC. These tests should be performed using internal loopback only so that the NIC is isolated from interference from the network. These tests also require the capability to generate CRC in software.

The address recognition logic cannot be directly tested. The CRC and FAE bits in the RSR are only set if the address of the packet matches the address filters. If errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch. The following sequence of packets will test the address recognition logic. The DCR should be set to 40H, the TCR should be set to 03H with a software generated CRC.

Packet Contents			Results
Test	Address	CRC	RSR
Test A	Matching	Good	01(1)
Test B	Matching	Bad	02(2)
Test C	Non-Matching	Bad	01

**Note 1:** Status will read 21H if multicast address used.

**Note 2:** Status will read 22H if multicast address used.

**Note 3:** In test A, the RSR is set up. In test B the address is found to match since the CRC is flagged as bad. Test C proves that the address recognition logic can distinguish a bad address and does not notify the RSR of the bad CRC. The receiving CRC is proven to work in test A and test B.

**Note 4:** All values are hex.

### NETWORK MANAGEMENT FUNCTIONS

Network management capabilities are required for maintenance and planning of a local area network. The NIC supports the minimum requirement for network management in hardware, the remaining requirements can be met with software counts. There are three events that software alone can not track during reception of packets: CRC errors, Frame Alignment errors, and missed packets.

Since errored packets can be rejected, the status associated with these packets is lost unless the CPU can access the Receive Status Register before the next packet arrives. In situations where another packet arrives very quickly, the CPU may have no opportunity to do this. The NIC counts the number of packets with CRC errors and Frame Alignment errors. 8-bit counters have been selected to reduce overhead. The counters will generate interrupts whenever their MSBs are set so that a software routine can accumulate the network statistics and reset the counters before overflow occurs. The counters are sticky so that when they reach a count of 192 (COH) counting is halted. An additional counter is provided to count the number of packets NIC misses due to buffer overflow or being offline.

The structure of the counters is shown below:

TL/F/8582-63

Additional information required for network management is available in the Receive and Transmit Status Registers. Transmit status is available after each transmission for information regarding events during transmission.

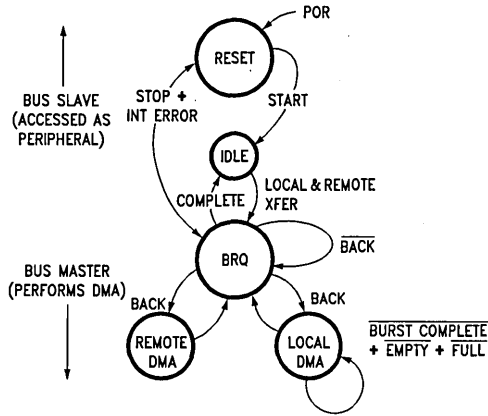

Typically, the following statistics might be gathered in software:

- Traffic:
  - Frames Sent OK
  - Frames Received OK
  - Multicast Frames Received
  - Packets Lost Due to Lack of Resources
  - Retries/Packet
- Errors:
  - CRC Errors
  - Alignment Errors
  - Excessive Collisions
  - Packet with Length Errors
  - Heartbeat Failure

### 13.0 Bus Arbitration and Timing

The NIC operates in three possible modes:

- BUS MASTER (WHILE PERFORMING DMA)
- BUS SLAVE (WHILE BEING ACCESSED BY CPU)
- IDLE

TL/F/8582-64

Upon power-up the NIC is in an indeterminate state. After receiving a Hardware Reset the NIC comes up as a slave in the Reset State. The receiver and transmitter are both disabled in this state. The reset state can be reentered under three conditions, soft reset (Stop Command), hard reset (RESET input) or an error that shuts down the receiver or transmitter (FIFO underflow or overflow). After initialization of registers, the NIC is issued a Start command and the NIC enters Idle state. Until the DMA is required the NIC remains in an idle state. The idle state is exited by a request from the FIFO in the case of receive or transmit, or from the Remote/DMA in the case of Remote DMA operation. After acquiring the bus in a BREQ/BACK handshake the Remote or Local DMA transfer is completed and the NIC reenters the idle state.

#### DMA TRANSFERS TIMING

The DMA can be programmed for the following types of transfers:

- 16-Bit Address, 8-bit Data Transfer
- 16-Bit Address, 16-bit Data Transfer
- 32-Bit Address, 8-bit Data Transfer
- 32-Bit Address, 16-bit Data Transfer

All DMA transfers use BSCK for timing. 16-Bit Address modes require 4 BSCK cycles as shown below:

TL/F/8582-65

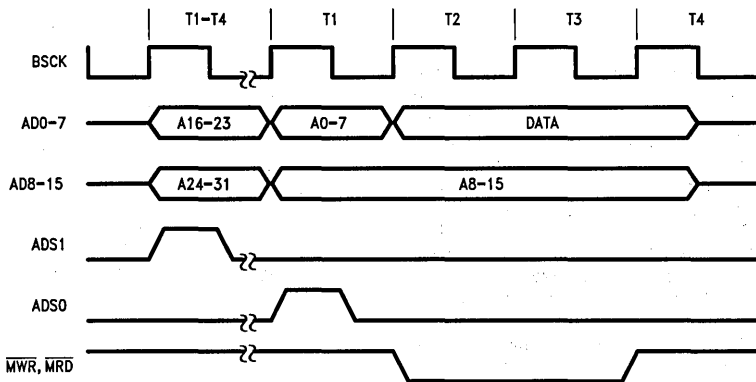

### 13.0 Bus Arbitration and Timing (Continued)

16-Bit Address, 16-Bit Data

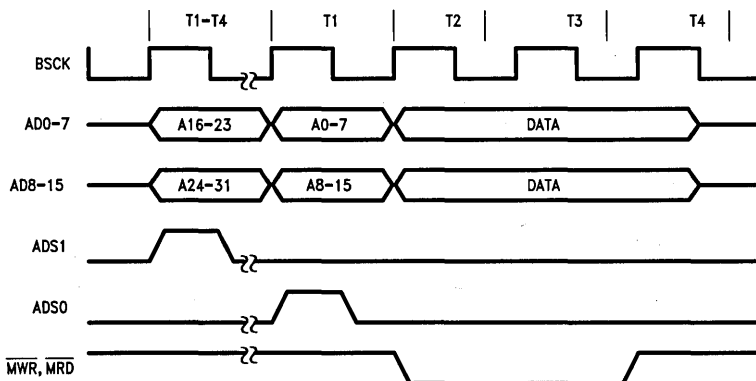

TL/F/8582-66

32-Bit Address, 8-Bit Data

TL/F/8582-67

32-Bit Address, 16-Bit Data

TL/F/8582-68

Note: In 32-bit address mode, ADS1 is at TRI-STATE after the first T1-T4 states; thus, a 4.7k pull-down resistor is required for 32-bit address mode.

### 13.0 Bus Arbitration and Timing (Continued)

When in 32-bit mode four additional BSCK cycles are required per burst. The first bus cycle (T1'-T4') of each burst is used to output the upper 16-bit addresses. This 16-bit address is programmed in RSAR0 and RSAR1 and points to a 64k page of system memory. All transmitted or received packets are constrained to reside within this 64k page.

#### FIFO BURST CONTROL

All Local DMA transfers are burst transfers, once the DMA requests the bus and the bus is acknowledged, the DMA will

transfer an exact burst of bytes programmed in the Data Configuration Register (DCR) then relinquish the bus. If there are remaining bytes in the FIFO the next burst will not be initiated until the FIFO threshold is exceeded. If BACK is removed during the transfer, the burst transfer will be aborted. **(DROPPING BACK DURING A DMA CYCLE IS NOT RECOMMENDED.)**

TL/F/8582-69

where N = 1, 2, 4, or 6 Words or N = 2, 4, 8, or 12 Bytes when in byte mode

#### INTERLEAVED LOCAL OPERATION

If a remote DMA transfer is initiated or in progress when a packet is being received or transmitted, the Remote DMA transfer will be interrupted for higher priority Local DMA

transfers. When the Local DMA transfer is completed the Remote DMA will re-arbitrate for the bus and continue its transfers. This is illustrated below:

TL/F/8582-70

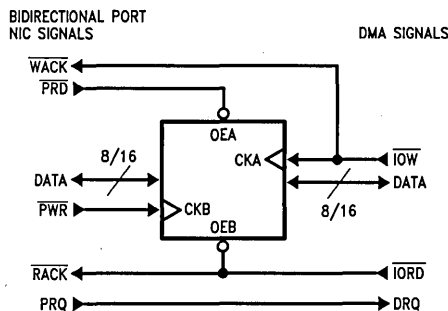

Note that if the FIFO requires service while a remote DMA is in progress, BREQ is not dropped and the Local DMA burst is appended to the Remote Transfer. When switching from a local transfer to a remote transfer, however, BREQ is dropped and raised again. This allows the CPU or other devices to fairly contend for the bus.

This transfer is arbitrated on a byte by byte basis versus the burst transfer used for Local DMA transfers. This bidirectional port is also read/written by the host. All transfers through this port are asynchronous. At any one time transfers are limited to one direction, either from the port to local buffer memory (Remote Write) or from local buffer memory to the port (Remote Read).

#### REMOTE DMA-BIDIRECTIONAL PORT CONTROL

The Remote DMA transfers data between the local buffer memory and a bidirectional port (memory to I/O transfer).

#### Bus Handshake Signals for Remote DMA Transfers

TL/F/8582-71

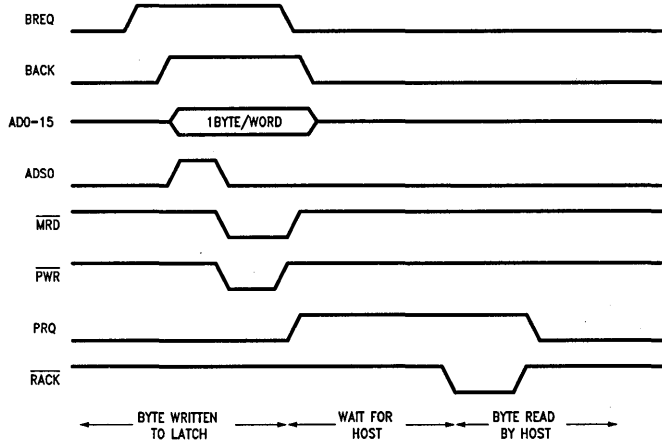

### 13.0 Bus Arbitration and Timing (Continued)

#### REMOTE READ TIMING

- 1) The DMA reads byte/word from local buffer memory and writes byte/word into latch, increments the DMA address and decrements the byte count (RBCR0,1).
- 2) A Request Line (PRQ) is asserted to inform the system that a byte is available.
- 3) The system reads the port, the read strobe ( $\overline{\text{RACK}}$ ) is used as an acknowledge by the Remote DMA and it goes back to step 1.

Steps 1-3 are repeated until the remote DMA is complete.

Note that in order for the Remote DMA to transfer a byte from memory to the latch, it must arbitrate access to the local bus via a BREQ, BACK handshake. After each byte or word is transferred to the latch, BREQ is dropped. If a Local DMA is in progress, the Remote DMA is held off until the local DMA is complete.

TL/F/8582-72

#### REMOTE WRITE TIMING

A Remote Write operation transfers data from the I/O port to the local buffer RAM. The NIC initiates a transfer by requesting a byte/word via the PRQ. The system transfers a byte/word to the latch via  $\overline{\text{IOW}}$ , this write strobe is detected by the NIC and PRQ is removed. By removing the PRQ, the Remote DMA holds off further transfers into the latch until the current byte/word has been transferred from the latch, PRQ is reasserted and the next transfer can begin.

- 1) NIC asserts PRQ. System writes byte/word into latch. NIC removes PRQ.

- 2) Remote DMA reads contents of port and writes byte/word to local buffer memory, increments address and decrements byte count (RBCR0,1).

- 3) Go back to step 1.

Steps 1-3 are repeated until the remote DMA is complete.

TL/F/8582-73

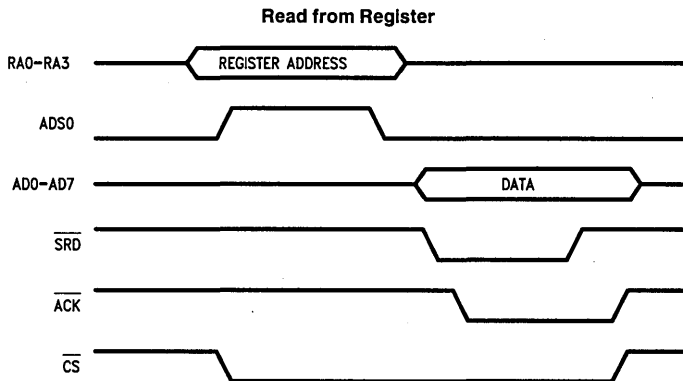

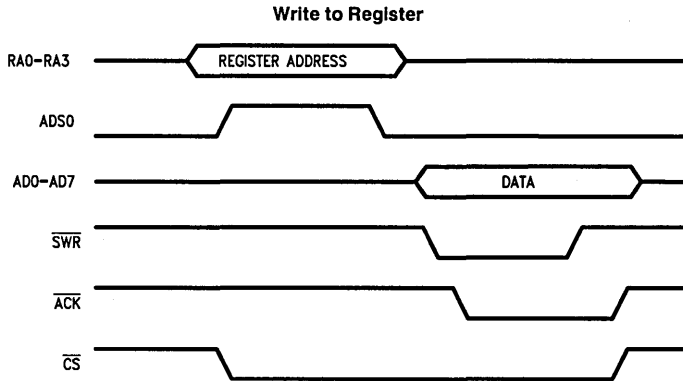

### 13.0 Bus Arbitration and Timing (Continued)

#### SLAVE MODE TIMING

When  $\overline{CS}$  is low, the NIC becomes a bus slave. The CPU can then read or write any internal registers. All register access is byte wide. The timing for register access is shown below. The host CPU accesses internal registers with four address lines, RA0-RA3,  $\overline{SRD}$  and  $\overline{SWR}$  strobes.

ADS0 is used to latch the address when interfacing to a multiplexed, address data bus. Since the NIC may be a local bus master when the host CPU attempts to read or write to the controller, an  $\overline{ACK}$  line is used to hold off the CPU until the NIC leaves master mode. Some number of BSCK cycles is also required to allow the NIC to synchronize to the read or write cycle.

#### TIME BETWEEN CHIP SELECTS

The NIC requires that successive chip selects be no closer than 4 bus clocks (BSCK) together, below. If the condition is violated, the NIC may glitch/ $\overline{ACK}$ . CPUs that operate from pipelined instructions (i.e. 386) or have a cache (i.e.

486) can execute consecutive I/O cycles very quickly. The solution is to delay the execution of consecutive I/O cycles by either breaking the pipeline or forcing the CPU to access outside its cache.

## 14.0 Preliminary Electrical Characteristics

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to +7.0V
DC Input Voltage ( $V_{IN}$ )	-0.5V to $V_{CC} + 0.5V$
DC Output Voltage ( $V_{OUT}$ )	-0.5V to $V_{CC} + 0.5V$
Storage Temperature Range ( $T_{STG}$ )	-65°C to +150°C
Power Dissipation (PD)	500 mW
Lead Temp. (TL) (Soldering, 10 sec.)	260°C
ESD rating ( $R_{ZAP} = 1.5k, C_{ZAP} = 120$ pF)	1600V

### Preliminary DC Specifications $T_A = 0^\circ\text{C}$ to $70^\circ\text{C}$ , $V_{CC} = 5V \pm 5\%$ , unless otherwise specified

Symbol	Parameter	Conditions	Min	Max	Units
$V_{OH}$	Minimum High Level Output Voltage (Notes 1, 4)	$I_{OH} = -20 \mu\text{A}$	$V_{CC} - 0.1$		V
		$I_{OH} = -2.0 \text{ mA}$	3.5		V
$V_{OL}$	Minimum Low Level Output Voltage (Notes 1, 4)	$I_{OL} = 20 \mu\text{A}$		0.1	V
		$I_{OL} = 2.0 \text{ mA}$		0.4	V
$V_{IH}$	Minimum High Level Input Voltage (Note 2)		2.0		V
$V_{IH2}$	Minimum High Level Input Voltage for RACK, WACK (Note 2)		2.7		V
$V_{IL}$	Minimum Low Level Input Voltage (Note 2)			0.8	V
$V_{IL2}$	Minimum Low Level Input Voltage For RACK, WACK (Note 2)			0.6	V
$I_{IN}$	Input Current	$V_I = V_{CC}$ or GND	-1.0	+1.0	$\mu\text{A}$
$I_{OZ}$	Maximum TRI-STATE Output Leakage Current	$V_{OUT} = V_{CC}$ or GND	-10	+10	$\mu\text{A}$
$I_{CC}$	Average Supply Current (Note 3)	TXCK = 10 MHz RXCK = 10 MHz BSCK = 20 MHz $I_{OUT} = 0 \mu\text{A}$ $V_{IN} = V_{CC}$ or GND		40	mA

**Note 1:** These levels are tested dynamically using a limited amount of functional test patterns, please refer to AC Test Load.

**Note 2:** Limited functional test patterns are performed at these input levels. The majority of functional tests are performed at levels of 0V and 3V.

**Note 3:** This is measured with a 0.1  $\mu\text{F}$  bypass capacitor between  $V_{CC}$  and GND.

**Note 4:** The low drive CMOS compatible  $V_{OH}$  and  $V_{OL}$  limits are not tested directly. Detailed device characterization validates that this specification can be guaranteed by testing the high drive TTL compatible  $V_{OL}$  and  $V_{OH}$  specification.

## 15.0 Switching Characteristics AC Specs DP8390D Note: All Timing is Preliminary

### Register Read (Latched Using ADS0)

TL/F/8582-76

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	13		ns
aswi	Address Strobe Width In	15		ns
ackdv	Acknowledge Low to Data Valid		55	ns
rdz	Read Strobe to Data TRI-STATE	15	70	ns
rackl	Read Strobe to $\overline{ACK}$ Low (Notes 1, 3)		$n * bcyc + 30$	ns
rackh	Read Strobe to $\overline{ACK}$ High		30	ns
rsrsl	Register Select to Slave Read Low, Latched RS0-3 (Note 2)	10		ns

**Note 1:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SRD}$  are low and the NIC has synchronized to the register access. The NIC will insert an integral number of Bus Clock cycles until it is synchronized. In Dual Bus systems additional cycles will be used for a local or remote DMA to complete. Wait states must be issued to the CPU until  $\overline{ACK}$  is asserted low.

**Note 2:**  $\overline{CS}$  may be asserted before or after  $\overline{SRD}$ . If  $\overline{CS}$  is asserted after  $\overline{SRD}$ , rackl is referenced from falling edge of  $\overline{CS}$ .  $\overline{CS}$  can be de-asserted concurrently with  $\overline{SRD}$  or after  $\overline{SRD}$  is de-asserted.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns, enabling other devices to drive these lines with no contention.

## 15.0 Switching Characteristics (Continued)

Register Read (Non Latched, ADS0 = 1)

TL/F/8582-77

Symbol	Parameter	Min	Max	Units
rsrs	Register Select to Read Setup (Notes 1, 3)	10		ns
rsrh	Register Select Hold from Read	0		ns
ackdv	ACK Low to Valid Data		55	ns
rdz	Read Strobe to Data TRI-STATE (Note 2)	15	70	ns
rackl	Read Strobe to ACK Low (Note 3)		$n \cdot \text{bcyc} + 30$	ns
rackh	Read Strobe to ACK High		30	ns

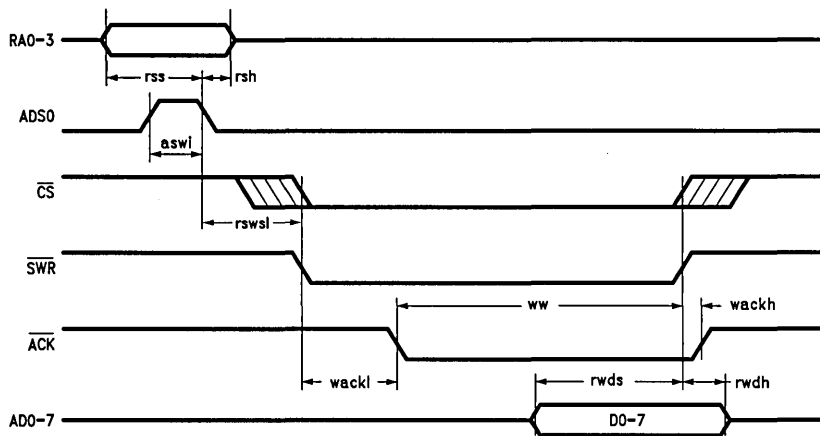

**Note 1:** rsrs includes flow-through time of latch.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns enabling other devices to drive these lines with no contention.

**Note 3:** CS may be asserted before or after RA0-3, and SRD, since address decode begins when ACK is asserted. If CS is asserted after RA0-3, and SRD, rack1 is referenced from falling edge of CS.

## 15.0 Switching Characteristics (Continued)

Register Write (Latched Using ADS0)

TL/F/8582-78

Symbol	Parameter	Min	Max	Units
rss	Register Select Setup to ADS0 Low	10		ns
rsh	Register Select Hold from ADS0 Low	17		ns
aswi	Address Strobe Width In	15		ns
rwds	Register Write Data Setup	20		ns
rwdh	Register Write Data Hold	21		ns
ww	Write Strobe Width from $\overline{ACK}$	50		ns
wackh	Write Strobe High to $\overline{ACK}$ High		30	ns
wackl	Write Low to $\overline{ACK}$ Low (Notes 1, 2)		$n \cdot \text{bcyc} + 30$	ns
rsysl	Register Select to Write Strobe Low	10		ns

**Note 1:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SWR}$  are low and the NIC has synchronized to the register access. In Dual Bus Systems additional cycles will be used for a local DMA or Remote DMA to complete.

**Note 2:**  $\overline{CS}$  may be asserted before or after  $\overline{SWR}$ . If  $\overline{CS}$  is asserted after  $\overline{SWR}$ , wackl is referenced from falling edge of  $\overline{CS}$ .

## 15.0 Switching Characteristics (Continued)

Register Write (Non Latched, ADS0 = 1)

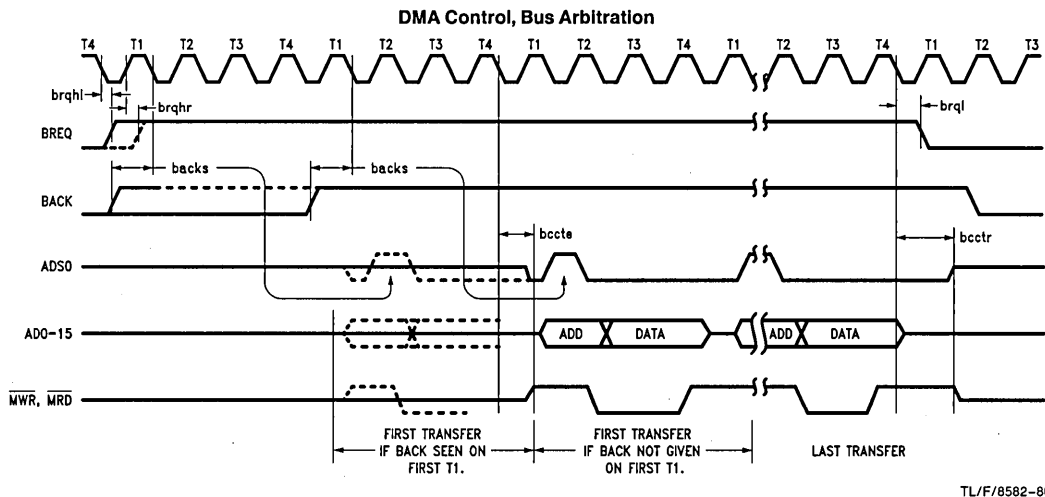

TL/F/8582-79

Symbol	Parameter	Min	Max	Units
rsws	Register Select to Write Setup (Note 1)	15		ns
rswl	Register Select Hold from Write	0		ns
rlds	Register Write Data Setup	20		ns
rldh	Register Write Data Hold	21		ns
wackl	Write Low to $\overline{ACK}$ Low (Note 2)		$n \cdot \text{bcyc} + 30$	ns
wackh	Write High to $\overline{ACK}$ High		30	ns
ww	Write Width from $\overline{ACK}$	50		ns

**Note 1:** Assumes ADS0 is high when RA0-3 changing.

**Note 2:**  $\overline{ACK}$  is not generated until  $\overline{CS}$  and  $\overline{SWR}$  are low and the NIC has synchronized to the register access. In Dual Bus systems additional cycles will be used for a local DMA or remote DMA to complete.

## 15.0 Switching Characteristics (Continued)

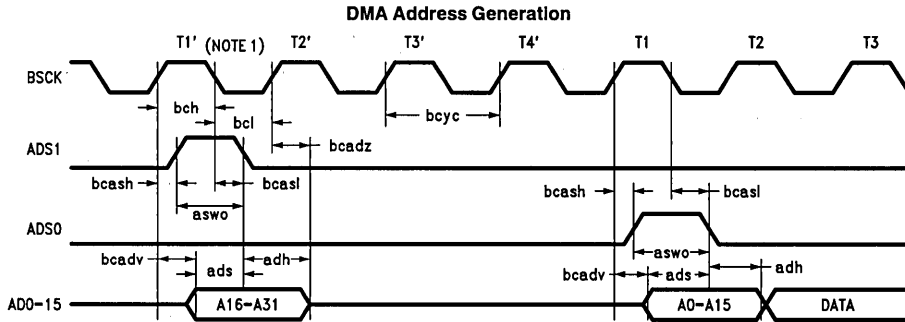

Symbol	Parameter	Min	Max	Units
brqhl	Bus Clock to Bus Request High for Local DMA		43	ns
brqhr	Bus Clock to Bus Request High for Remote DMA		38	ns
brql	Bus Request Low from Bus Clock		55	ns
backs	Acknowledge Setup to Bus Clock (Note 1)	2		ns
bccte	Bus Clock to Control Enable		60	ns
bcctr	Bus Clock to Control Release (Notes 2, 3)		70	ns

**Note 1:** BACK must be setup before T1 after BREQ is asserted. Missed setup will slip the beginning of the DMA by four bus clocks. The Bus Latency will influence the allowable FIFO threshold and transfer mode (empty/fill vs exact burst transfer).

**Note 2:** During remote DMA transfers only, a single bus transfer is performed. During local DMA operations burst mode transfers are performed.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns enabling other devices to drive these lines with no contention.

## 15.0 Switching Characteristics (Continued)

TL/F/8582-81

Symbol	Parameter	Min	Max	Units
bcyc	Bus Clock Cycle Time (Note 2)	50	1000	ns
bch	Bus Clock High Time	22.5		ns
bcl	Bus Clock Low Time	22.5		ns
bcash	Bus Clock to Address Strobe High		34	ns
bcasl	Bus Clock to Address Strobe Low		44	ns
aswo	Address Strobe Width Out	bch		ns
bcadv	Bus Clock to Address Valid		45	ns
bcadz	Bus Clock to Address TRI-STATE (Note 3)	15	55	ns
ads	Address Setup to ADS0/1 Low	bch - 15		ns
adh	Address Hold from ADS0/1 Low	bcl - 5		ns

**Note 1:** Cycles T1', T2', T3', T4' are only issued for the first transfer in a burst when 32-bit mode has been selected.

**Note 2:** The rate of bus clock must be high enough to support transfers to/from the FIFO at a rate greater than the serial network transfers from/to the FIFO.

**Note 3:** These limits include the RC delay inherent in our test method. These signals typically turn off within 15 ns, enabling other devices to drive these lines with no contention.

### 15.0 Switching Characteristics (Continued)

TL/F/8582-82

Symbol	Parameter	Min	Max	Units
bcrh	Bus Clock to Read Strobe Low		43	ns
bcrh	Bus Clock to Read Strobe High		40	ns
ds	Data Setup to Read Strobe High	25		ns
dh	Data Hold from Read Strobe High	0		ns
drw	DMA Read Strobe Width Out	$2 \cdot \text{bcyc} - 15$		ns
raz	Memory Read High to Address TRI-STATE (Notes 1, 2)		bch + 40	ns
asds	Address Strobe to Data Strobe		bcl + 10	ns
dsada	Data Strobe to Address Active	$\text{bcyc} - 10$		ns
avrh	Address Valid to Read Strobe High	$3 \cdot \text{bcyc} - 15$		ns

**Note 1:** During a burst A8-A15 are not TRI-STATE if byte wide transfers are selected. On the last transfer A8-A15 are TRI-STATE as shown above.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within bch + 15 ns, enabling other devices to drive these lines with no contention.

### 15.0 Switching Characteristics (Continued)

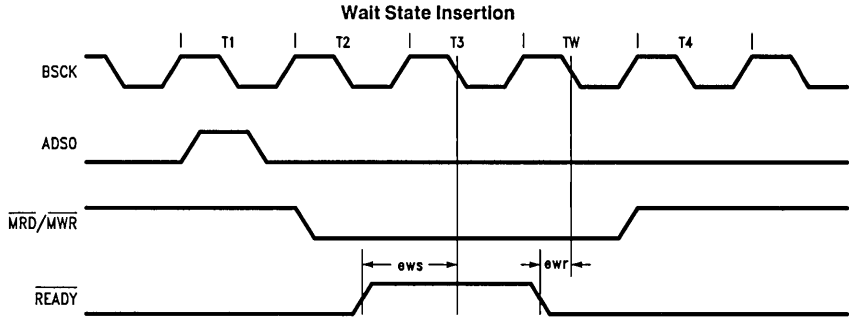

TL/F/8582-83

Symbol	Parameter	Min	Max	Units
bcwl	Bus Clock to Write Strobe Low		40	ns
bcwh	Bus Clock to Write Strobe High		40	ns
wds	Data Setup to $\overline{WR}$ High	$2 * bcyc - 30$		ns
wdh	Data Hold from $\overline{WR}$ Low	$bch + 7$		ns
waz	Write Strobe to Address TRI-STATE (Notes 1, 2)		$bch + 40$	ns
asds	Address Strobe to Data Strobe		$bcl + 10$	ns
aswd	Address Strobe to Write Data Valid		$bcl + 30$	ns

**Note 1:** When using byte mode transfers A8-A15 are only TRI-STATE on the last transfer, waz timing is only valid for last transfer in a burst.

**Note 2:** These limits include the RC delay inherent in our test method. These signals typically turn off within  $bch + 15$  ns, enabling other devices to drive these lines with no contention.

### 15.0 Switching Characteristics (Continued)

TL/F/8582-45

Symbol	Parameter	Min	Max	Units
e <sub>ws</sub>	External Wait Setup to T <sub>3</sub> ↓ Clock (Note 1)	10		ns
e <sub>wr</sub>	External Wait Release Time (Note 1)	15		ns

**Note 1:** The addition of wait states affects the count of deserialized bytes and is limited to a number of bus clock cycles depending on the bus clock and network rates. The allowable wait states are found in the table below. (Assumes 10 Mbit/sec data rate.)

BSCCK (MHz)	# of Wait States	
	Byte Transfer	Word Transfer
8	0	1
10	0	1
12	1	2
14	1	2
16	1	3
18	2	3
20	2	4

Table assumes 10 MHz network clock.

The number of allowable wait states in byte mode can be calculated using:

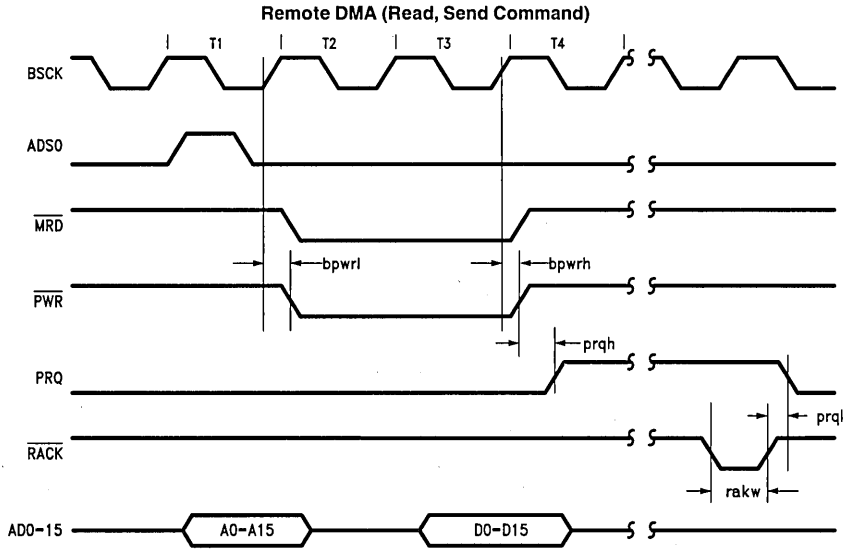

$$\#W_{(\text{byte mode})} = \left( \frac{8 \text{tnw}}{4.5 \text{tbck}} - 1 \right)$$

#W = Number of Wait States  
 tnw = Network Clock Period  
 tbck = BSCCK Period

The number of allowable wait states in word mode can be calculated using:

$$\#W_{(\text{word mode})} = \left( \frac{5 \text{tnw}}{2 \text{tbck}} - 1 \right)$$

### 15.0 Switching Characteristics (Continued)

TL/F/8582-84

Symbol	Parameter	Min	Max	Units
bpwrl	Bus Clock to Port Write Low		43	ns
bpwrh	Bus Clock to Port Write High		40	ns
prqh	Port Write High to Port Request High (Note 1)		30	ns
prql	Port Request Low from Read Acknowledge High		45	ns
rakw	Remote Acknowledge Read Strobe Pulse Width	20		ns

**Note 1:** Start of next transfer is dependent on where RACK is generated relative to BSCCK and whether a local DMA is pending.

### 15.0 Switching Characteristics (Continued)

Remote DMA (Read, Send Command) Recovery Time

TL/F/8582-85

Symbol	Parameter	Min	Max	Units
bpwrl	Bus Clock to Port Write Low		43	ns
bpwrh	Bus Clock to Port Write High		40	ns
prqh	Port Write High to Port Request High (Note 1)		30	ns
prql	Port Request Low from Read Acknowledge High		45	ns
rakw	Remote Acknowledge Read Strobe Pulse Width	20		ns
rhpwh	Read Acknowledge High to Next Port Write Cycle (Notes 2,3,4)	11		BUSCK

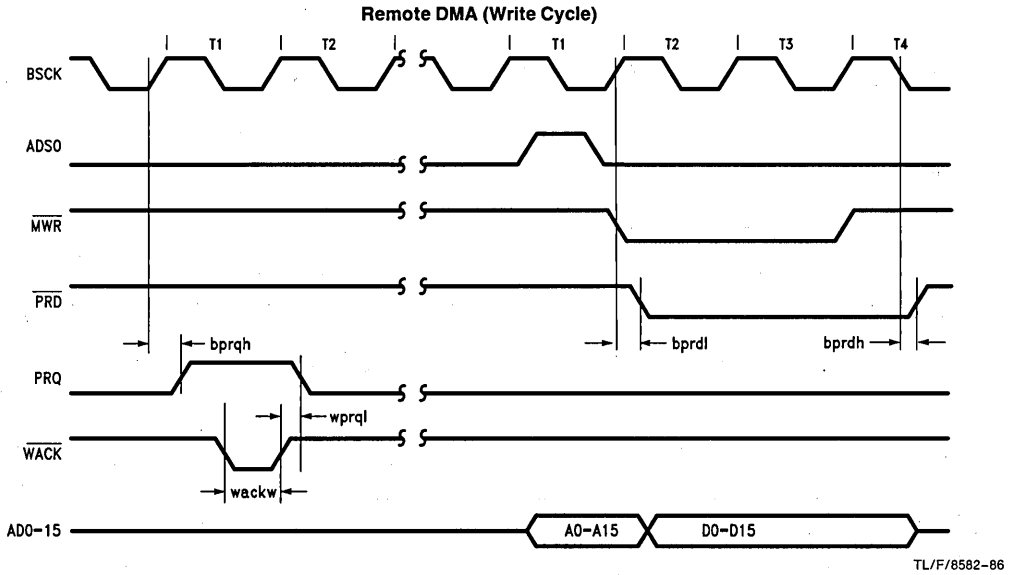

**Note 1:** Start of next transfer is dependent on where  $\overline{RACK}$  is generated relative to BSCCK and whether a local DMA is pending.

**Note 2:** This is not a measured value but guaranteed by design.

**Note 3:**  $\overline{RACK}$  must be high for a minimum of 7 BUSCK.

**Note 4:** Assumes no local DMA interleave, no  $\overline{CS}$ , and immediate BACK.

### 15.0 Switching Characteristics (Continued)

Symbol	Parameter	Min	Max	Units
bprqh	Bus Clock to Port Request High (Note 1)		42	ns
wprql	WACK to Port Request Low		45	ns
wackw	WACK Pulse Width	20		ns
bprdl	Bus Clock to Port Read Low (Note 2)		40	ns
bprdh	Bus Clock to Port Read High		40	ns

**Note 1:** The first port request is issued in response to the remote write command. It is subsequently issued on T1 clock cycles following completion of remote DMA cycles.

**Note 2:** The start of the remote DMA write following WACK is dependent on where WACK is issued relative to BUSCK and whether a local DMA is pending.

## 15.0 Switching Characteristics (Continued)

Remote DMA (Write Cycle) Recovery Time

TL/F/8582-87

Symbol	Parameter	Min	Max	Units
bprqh	Bus Clock to Port Request High (Note 1)		40	ns
wprql	$\overline{WACK}$ to Port Request Low		45	ns
wackw	$\overline{WACK}$ Pulse Width	20		ns
bprdl	Bus Clock to Port Read Low (Note 2)		40	ns
bprdh	Bus Clock to Port Read High		40	ns
wprq	Remote Write Port Request to Port Request Time (Notes 3,4,5)	12		BUSCK

**Note 1:** The first port request is issued in response to the remote write command. It is subsequently issued on T1 clock cycles following completion of remote DMA cycles.

**Note 2:** The start of the remote DMA write following  $\overline{WACK}$  is dependent on where  $\overline{WACK}$  is issued relative to BUSCK and whether a local DMA is pending.

**Note 3:** Assuming wackw < 1 BUSCK, and no local DMA interleave, no  $\overline{CS}$ , immediate  $\overline{BACR}$ , and  $\overline{WACK}$  goes high before T4.

**Note 4:**  $\overline{WACK}$  must be high for a minimum of 7 BUSCK.

**Note 5:** This is not a measured value but guaranteed by design.

## 15.0 Switching Characteristics (Continued)

Serial Timing—Receive (Beginning of Frame)

TL/F/8582-88

Symbol	Parameter	Min	Max	Units
rch	Receive Clock High Time	40		ns
rcl	Receive Clock Low Time	40		ns
rcyc	Receive Clock Cycle Time	80	120	ns
rds	Receive Data Setup Time to Receive Clock High (Note 1)	20		ns
rdh	Receive Data Hold Time from Receive Clock High	17		ns
pts	First Preamble Bit to Synch (Note 2)	8		rcyc cycles

**Note 1:** All bits entering NIC must be properly decoded, if the PLL is still locking, the clock to the NIC should be disabled or CRS delayed. Any two sequential 1 data bits will be interpreted as Synch.

**Note 2:** This is a minimum requirement which allows reception of a packet.

Serial Timing—Receive (End of Frame)

TL/F/8582-89

Symbol	Parameter	Min	Max	Units
rxrck	Minimum Number of Receive Clocks after CRS Low (Note 1)	5		rcyc cycles
tdrb	Maximum of Allowed Dribble Bits/Clocks (Note 2)		3	rcyc cycles
tifg	Receive Recovery Time (Notes 4,5)		40	rcyc cycles
tcsl	Receive Clock to Carrier Sense Low (Note 3)	0	1	rcyc cycles

**Note 1:** The NIC requires a minimum number of receive clocks following the de-assertion of carrier sense (CRS). These additional clocks are provided by the DP8391 SNI. If other decoder/PLLs are being used additional clocks should be provided. Short clocks or glitches are not allowed.

**Note 2:** Up to 5 bits of dribble bits can be tolerated without resulting in a receive error.

**Note 3:** Guarantees to only load bit N, additional bits up to tdrb can be tolerated.

**Note 4:** This is the time required for the receive state machine to complete end of receive processing. This parameter is not measured but is guaranteed by design. This is not a measured parameter but is a design requirement.

**Note 5:** CRS must remain de-asserted for a minimum of 2 RXC cycles to be recognized as end of carrier.

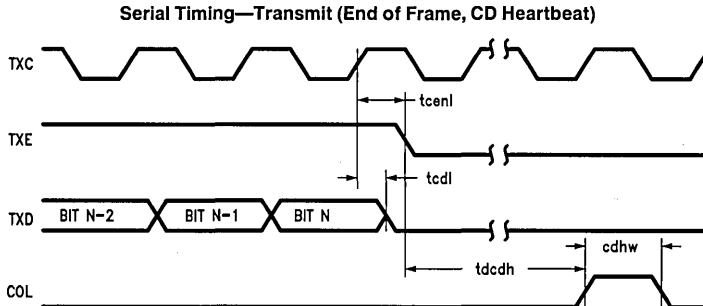

## 15.0 Switching Characteristics (Continued)

TL/F/8582-90

Symbol	Parameter	Min	Max	Units
txch	Transmit Clock High Time	36		ns
txcl	Transmit Clock Low Time	36		ns
txcyc	Transmit Clock Cycle Time	80	120	ns
txcenh	Transmit Clock to Transmit Enable High (Note 1)		48	ns
txcsdv	Transmit Clock to Serial Data Valid		67	ns
txcsdh	Serial Data Hold Time from Transmit Clock High	10		ns

**Note 1:** The NIC issues TXEN coincident with the first bit of preamble. The first bit of preamble is always a 1.

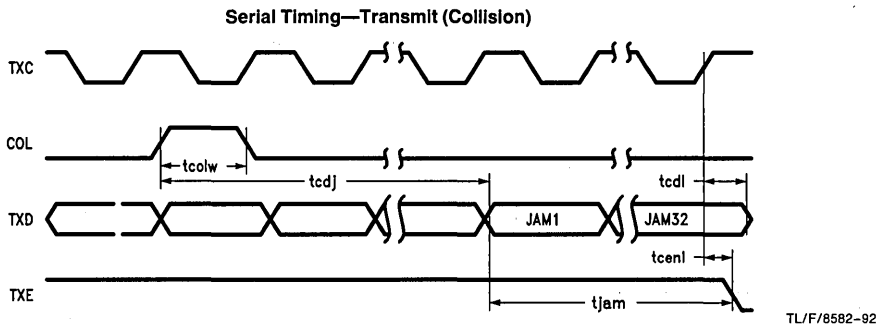

TL/F/8582-91

Symbol	Parameter	Min	Max	Units
tcdl	Transmit Clock to Data Low		55	ns
tcenl	Transmit Clock to TXEN Low		55	ns
tdcdh	TXEN Low to Start of Collision Detect Heartbeat (Note 1)	0	64	txcyc cycles
cdhw	Collision Detect Width	2		txcyc cycles

**Note 1:** If COL is not seen during the first 64 TX clock cycles following de-assertion of TXEN, the CDH bit in the TSR is set.

## 15.0 Switching Characteristics (Continued)

Symbol	Parameter	Min	Max	Units
tcolw	Collision Detect Width	2		txcyc. cycles
tcdj	Delay from Collision to First Bit of Jam (Note 1)		8	txcyc. cycles
tjam	Jam Period (Note 2)		32	txcyc. cycles

**Note 1:** The NIC must synchronize to collision detect. If the NIC is in the middle of serializing a byte of data the remainder of the byte will be serialized. Thus the jam pattern will start anywhere from 1 to 8 TXC cycles after COL is asserted.

**Note 2:** The NIC always issues 32 bits of jam. The jam is all 1's data.

Symbol	Parameter	Min	Max	Units
rstw	Reset Pulse Width (Note 1)	8		BSCK Cycles or TXC Cycles (Note 2)

**Note 1:** The RESET pulse requires that BSCK and TXC be stable. On power up, RESET should not be raised until BSCK and TXC have become stable. Several registers are affected by RESET. Consult the register descriptions for details.

**Note 2:** The slower of BSCK or TXC clocks will determine the minimum time for the RESET signal to be low.

If BSCK < TXC then RESET = 8 × BSCK

If TXC < BSCK then RESET = 8 × TXC

## AC Timing Test Conditions

Input Pulse Levels	GND to 3.0V
Input Rise and Fall Times	5 ns
Input and Output Reference Levels	1.3V
TRI-STATE Reference Levels	Float ( $\Delta V$ ) $\pm 0.5V$
Output Load (See Figure below)	

TL/F/8582-94

**Note 1:**  $C_L = 50$  pF, includes scope and jig capacitance.

**Note 2:** S1 = Open for timing tests for push pull outputs.

S1 =  $V_{CC}$  for  $V_{OL}$  test.

S1 = GND for  $V_{OH}$  test.

S1 =  $V_{CC}$  for High Impedance to active low and active low to High Impedance measurements.

S1 = GND for High Impedance to active high and active high to High Impedance measurements.

## Pin Capacitance $T_A = 25^\circ C, f = 1$ MHz

Parameter	Description	Typ	Max	Unit
$C_{IN}$	Input Capacitance	7	15	pF
$C_{OUT}$	Output Capacitance	7	15	pF

**Note:** This parameter is sampled and not 100% tested.

### DERATING FACTOR

Output timings are measured with a purely capacitive load for 50 pF. The following correction factor can be used for other loads:

$C_L \geq 50$  pf:  $+0.3$  ns/pF (for all outputs except TXE, TXD, and LBK)

# DP8390 Network Interface Controller: An Introductory Guide

National Semiconductor  
Application Note 475

## OVERVIEW

A general description of the DP8390 Network Interface Controller (NIC) is given in this application note. The emphasis is placed on how it operates and how it can be used. This description should be read in conjunction with the DP8390 data sheet.

## 1.0 INTRODUCTION

The DP8390 Network Interface Controller provides all the Media Access Control layer functions required for transmission and reception of packets in accordance with the IEEE 802.3 CSMA/CD standard. The controller acts as an advanced peripheral and serves as a complete interface between the system and the network. The onboard FIFO and DMA channels work together to form a straight-forward packet management scheme, providing (local) DMA transfers at up to 10 megabytes per second while tolerating typical bus latencies.

A second set of DMA channels (remote DMA) is provided on chip, and is integrated into the packet management scheme to aid in the system interface. The DP8390 was designed with the popular 8, 16 and 32 bit microprocessors in mind, and gives system designers several architectural options. The NIC is fabricated using National Semiconductor's double metal 2 micron microCMOS process, yielding high speed with very low power dissipation.

## 2.0 METHOD OF OPERATION

The NIC is used as a standard peripheral device and is controlled through an array of on-chip registers. These registers are used during initialization, packet transmission and reception, and remote DMA operations. At initialization, the physical address and multicast address filters are set, the receiver, transmitter and data paths are configured, the DMA channels are prepared, and the appropriate interrupts are masked. The Command Register (CR) is used to initiate transmission and remote DMA operations.

Upon packet reception, end of packet transmission, remote DMA completion or error conditions, an interrupt is generated to indicate that an action should be taken. The processor's interrupt driven routine then reads the Interrupt Status Register (ISR) to determine what type of interrupt occurred, and performs the appropriate actions.

## 3.0 PACKET TRANSMISSION

The NIC transmits packets in accordance with the CSMA/CD protocol, scheduling retransmission of packets up to 15 times on collisions according to the truncated binary exponential backoff algorithm. No additional processor intervention is required once the transmit command is given.

TL/F/9141-1

FIGURE 1. Transmit Packet Format

## 3.1 Transmission Setup

After a packet that conforms to the IEEE 802.3 specification is set up in memory, with 6 bytes of the destination address, followed by 6 bytes of the source address, followed by the data byte count and the data, it is ready for transmission (see Figure 1). To transmit a packet, the NIC is given the starting address of the packet (TPSR), the length of the packet (TBCRO, TBCR1), and then the PTX (transmit packet) bit of the Command Register is set to initiate the transmission (see Figure 2).

TL/F/9141-2

FIGURE 2. Packet Transmission

### 3.2 Transmission Process

Once the transmit command is given, if no reception is in progress, the transmit prefetch begins. The high speed local DMA channel bursts data into the NIC's FIFO. After the first DMA transfer of the prefetch burst, if no carrier is present on the network, and the NIC is not deferring, the TXE (transmit enable) signal is asserted and the transmission begins. After the 62 bits of preamble (alternating ONES and ZEROS) and the start of frame delimiter (two ONES) are sent out, the data in the FIFO is serialized, and sent out as NRZ data (pin TxD) with a clock (TxC), while the CRC is calculated. When the FIFO reaches a threshold (X bytes empty) a new DMA burst is initiated. This process continues until the byte count (TBCR0 and TBCR1) reaches zero. After the last byte is serialized, the four bytes of the calculated CRC are serialized and appended to complete the packet.

Should a collision occur, the current transmission stops, a jam sequence (32 Ones) transmitted (to ensure that every node senses a collision), and a retransmission of the packet is scheduled according to the truncated Binary Exponential Backoff Routine.

### 3.3 Transmission Status

After the transmission is complete, an interrupt is generated and either the PTX bit (complete packet transmitted) or the TXE bit (packet transmission aborted) of the ISR (Interrupt Status Register) is set. The interrupt driven routine then reads the RSR (Receive Status Register) and TSR (Transmit Status Register) to find out details of the transmission. If the PTX bit is set, the RSR will reveal if a carrier was present when the transmission was initiated (DFR). The TSR will identify if the carrier was lost during the transmission (CRS—this would point to a short somewhere on the network), if the collision detect circuitry is working properly (CDH), and if collision occurred (COL). Whenever a collision is encountered during transmission, the collision count register (NCR) is incremented. Should a collision occur outside the 512 bit window (slot time), the OWC (Out of Window Collision) bit of the TSR is set.

The TXE bit of the ISR is set if 16 collisions or a FIFO underrun occurs. If the transmission is aborted due to 16 collisions, the ABT bit of the TSR is set. (If this occurs it is likely that there is an open somewhere on the network.) If the local DMA channel can not fill the FIFO faster than data is sent to the network, the FU bit (FIFO Underrun) of the TSR is set and the transmission is also aborted. This is a result of a system bandwidth problem and points to a system design flaw. System bandwidth considerations are discussed further in Section 5.1.3.

## 4.0 PACKET RECEPTION

The bus topology used in CSMA/CD networks allows every node to receive every packet transmitted on the network. The receive filters determine which packets will be buffered to memory. Since every packet is not of interest, only packets having a destination address that passes the node's receive filters will be transferred into memory. The NIC offers many options for the receive filters and implements a complete packet management scheme for storage of incoming packets.

### 4.1 Reception Process

When a carrier is first sensed on the network (i.e. CRS signal is active), the controller sees the alternating ONE - ZERO preamble and begins checking for two consecutive ONES, denoting the start of frame delimiter (SFD). Once the SFD is detected, the serial stream of data is deserialized and pushed into the FIFO, a byte at a time. As the data is being transferred into the FIFO, the first six bytes are checked against the receive address filters. If an address match occurs, the packet is DMAed from the FIFO into the receive buffer ring. If the address does not match, the packet is not buffered and the FIFO is reset.

Each time the FIFO threshold is reached, a DMA burst begins and continues for the proper number of transfers. DMA bursts continue until the end of the packet (Section 5.1.2). At the end of a reception, the NIC prepares for an immediate reception while writing the status of the previous reception to memory. An interrupt is issued to indicate that a packet was received, and is ready to be processed.

The CRC generator is free running and is reset whenever the SFD is detected. At every byte boundary the calculated value of the CRC is compared with the last four received bytes. When the CRS signal goes LOW, denoting the end of a packet, if the calculated CRC matches the received CRC on the last byte boundary, the packet is a good packet and is accepted. However, if the calculated and received CRCs do not match on the last byte boundary before CRS goes LOW, a CRC error is flagged (CRC bit of RSR set) and the packet is rejected, i.e. the receive buffer ring pointer (CURR) is not updated (Section 4.5). If the CRS signal does not go LOW on a byte boundary and a CRC error occurs, the incoming packet is misaligned, and a frame alignment error is flagged (FAE bit of RSR set). Frame alignment errors only occur with CRC errors.

### 4.2 Address Matches

The first bit received after the SFD indicates whether the incoming packet has a physical or multicast address. A ZERO indicates a physical address, that is, a unique map-

FIGURE 3. Packet Reception

TL/F/9141-3

ping between the received address and the node's 48 bit physical address as programmed at initialization (PAR0-PAR5). A ONE indicates a multicast address, meaning a packet intended for more than one node.

Multicast addressing is useful where one node needs to send a packet to multiple nodes, as in a query command. Multicast addressing provides a very fast way to perform address filtering in real time, by using an on-chip hashing table. A hashing algorithm based on the CRC is used to map the multicast address into the 64 bit Multicast Address Filter (MAF0-7).

After the CRC has been calculated on the destination address, the upper six bits of the CRC are used as an index into the Multicast Address Filter (MAF). If the selected filter bit is ONE, the packet is accepted, if the MAF bit is ZERO the packet is not accepted.

A special multicast address is the broadcast address, which denotes a packet intended to be received by all nodes. The broadcast packet has an address of all ONES (this address also maps into a bit in the MAF).

The DP8390 also provides the ability to accept all packets on the network with a physical address. Promiscuous physical mode causes any packet with a physical address to be buffered into memory. To receive all multicast packets it is necessary to set all of the MAF bits to ONE.

#### 4.3 Network Statistics

Three eight bit counters are provided for monitoring receive packet errors. After an address match occurs if a Frame Alignment or CRC error occurs, or if a packet is lost due to insufficient buffer resources (see below), the appropriate counter is incremented. These counters are cleared when read. The counters trigger an interrupt when they reach a value of 128 (if not masked) to force the processor to read (and thus clear) their contents. The counters have a maximum value of 192, providing a large latency between when the interrupt is asserted and when the counter overflows. When a CNT interrupt occurs, all three tally counters should be read and added into larger counters maintained by the processor.

#### 4.4 Setting the Receive Configuration Register

The Receive Configuration Register (RCR) is used in conjunction with the physical and multicast addresses to determine which packets should be accepted and placed in the receive buffer ring. The RCR is initialized to accept physical, multicast and/or broadcast packets, or alternatively to place the receiver in promiscuous mode to accept all packets with a physical address. If the MON bit of the RCR is set, placing the receiver in monitor mode, the receiver still checks the addresses of incoming packets according to the set up address filter, and network statistics are still gathered, but packets are not buffered into memory.

The minimum packet size in standard 802.3 networks is 64 bytes long. Packets less than 64 bytes are considered runt packets and are normally rejected. However, in some applications it may be desirable to accept such packets. By setting the AR bit of the RCR, runt packets are accepted.

For diagnostic purposes it may be desirable to examine errored packets, and not overwrite them with good packets as is done in normal operation. By setting the SEP bit of the RCR, errored packets are saved and their status is written to memory.

#### 4.5 Receive Buffer Ring

As packets are received they are placed into the receive buffer ring, and as they are processed they are removed from this ring. At initialization, an area of memory is allocated to act as the receive buffer ring, and the NIC's buffer management scheme then makes efficient use of this memory. The ring pointers are contained on chip and the DMA channels can work at up to a 10 Mbyte/sec transfer rate. A second DMA channel, the remote DMA channel, is available for transferring packets out of the receive buffer ring.

The buffer management scheme effectively works as a large packet FIFO and is very appropriate for most networking applications because packets are generally processed in the order they are received.

Four pointers are used to control the ring; the page start (PSTART) and page stop (PSTOP) pointers determine the size of the buffer ring, the current page (CURR) pointer determines where the next packet will be loaded,

FIGURE 4. The Receive Buffer

TL/F/9141-4

TL/F/9141-5

TL/F/9141-6

FIGURE 5. Receive Packet Buffering

and the boundary (BNRY) pointer indicates where the next packet to be unloaded (or processed) begins. As packets are received, the current pointer moves ahead of the boundary pointer around the ring. The page start and stop pointers remain unchanged during operation.

The receive buffer ring is divided into 256 byte buffers, and these buffers are linked together as required by the received packets (see Figure 4). Up to 256 of these buffers can be linked together in the receive buffer ring, yielding a maximum buffer size of 64K bytes. Since all NIC registers are 8 bits wide, the ring pointers refer to 256 byte boundaries within a 64K byte space.

At initialization, PSTART register is loaded with the beginning page address of the ring, and PSTOP is loaded with the ending page address of the ring.

On a valid reception, the packet is placed in the ring at the page pointed to by CURR plus a 4 byte offset (see Figure 5). The packet is transferred to the ring, a DMA burst at a time. When necessary, buffers are automatically linked together, until the complete packet is received. The last and first buffers of the ring buffer are linked just as the first and second buffers. At the end of a reception, the status from the Receive Status Register (RSR), a pointer to the next

packet, and the byte count of the current packet are written into the 4 byte offset.

If a receive error occurs (FAE, CRC) CURR is not updated at the end of a reception, so the next packet received overwrites the bad packet (see Figure 6). This feature can be disabled (by setting the save errored packet (SEP) bit in the RCR) to allow examination of errored packets.

At receiving nodes, collision fragments may be seen as runt packets. A runt packet is a packet less than 64 bytes (512 bits) long, and since a collision must occur in the first 512 bit times, the packet will be truncated to less than 64 bytes. After runt packets are received, the CURR is not updated, so the next packet received will overwrite the runt packet. This standard feature can be suppressed by setting the AR bit in the TCR. This is useful when it is desirable to examine collision fragments, and in non-standard applications where smaller packets are used.

Once packets are in the receive ring they must be processed. However, the amount of processing that occurs while the packet is in the buffer ring varies according to the implementation. As packets are removed from the buffer ring, the boundary pointer (BNRY) must be updated. The BNRY always follows CURR around the ring (see Figure 7).

TL/F/9141-7

FIGURE 6. Packet Rejection

TL/F/9141-8

FIGURE 7. Removing Packets From Receive Buffer Ring

If the current local DMA address ever reaches BNR<sub>Y</sub>, the ring is full. In this case, the current and any additional receptions are aborted and tallied until the BNR<sub>Y</sub> pointer is updated. Packets already present in the ring will not be overwritten (see Figure 8). All missed packets will increment the missed packet tally counter. When enough memory is allocated for the receive buffer ring, the overwrite warning (setting of the OVW bit of the ISR) should seldom occur.

TL/F/9141-9

FIGURE 8. Receive Buffer Ring Overwrite Protection

A second set of DMA channels has been included on the DP8390 to aid in the transfer of packets out of the buffer ring. These Remote DMA channels can work in close co-operation with the receive buffer ring to provide a very effective system interface.

If the BNR<sub>Y</sub> is placed outside of the buffer ring, no overwrite protection will be present, and incoming packets may overwrite packets that have not been processed. This may be useful when evaluating the DP8390, but in normal operation it is not recommended.

5.0 SYSTEM/NETWORK INTERFACE

The DP8390 offers considerable flexibility when designing a system/network interface. This flexibility allows the designer to choose the appropriate price/performance combination while easing the actual design process.

5.1 Interfacing Considerations

Several features have been included on the NIC to allow it to easily be integrated into many systems. The size of the data paths, the byte ordering, and the bus latencies are all programmable. In addition, the clock used for the DMA channels is not coupled to the network clock, so the NIC's DMA can easily be integrated into memory systems.

5.1.1 Data Path

The NIC can interface with 8, 16, and 32 bit microprocessors. The data paths are configurable for both byte-wide and word-wide transfers (bit WTS in DCR). When in word-wide mode, the byte ordering is programmable to accommodate both popular byte ordering schemes. All NIC registers are 8 bits wide to allow 8, 16 and 32 bit processors to access them with no additional hardware. If the NIC's 16 address lines (64K bytes) do not provide an adequate address space, the two DMA channels can be concatenated to form a 32 bit DMA address (bit LAS in DCR).

5.1.2 Local DMA

The DMA transfers between the FIFO and memory during transmission and reception occur in bursts. The bursts begin when the FIFO threshold is reached. Since only a single FIFO is required (because a node cannot receive and transmit simultaneously), the threshold takes on different meanings during transmission and reception. During reception the FIFO threshold refers to the number of bytes in the FIFO. During transmission the FIFO threshold refers to the number of empty bytes in the FIFO (16 - # bytes in FIFO). The FIFO threshold is set to 2, 4, 8 or 12 bytes (1, 2, 4 or 6 words) in the DCR (bits FT0, FT1).

The number of transfers that occur in a burst is equal to the FIFO threshold (see Figure 9).

where N = 1, 2, 4 or 6 Words or N = 2, 4, 8, or 12 Bytes when in byte mode

TL/F/9141-10

FIGURE 9. Local DMA Burst

Before a burst can begin, the NIC must first arbitrate to become master of the bus. It requests the bus by activating the BREQ signal and waiting for acknowledgment with the BACK signal. Once the NIC becomes the master of the bus, the byte/word transfers may begin. The frequency of the DMA clock is not related to the network clock, and can be input (pin 25) as any frequency up to 20 MHz. For 10 Mbit/sec networks the DMA clock can be as slow as 6 MHz. This allows tailoring of the DMA channel, to the system. The local DMA channel can burst data into and out of the FIFO at up to 10 Mbyte/sec (8X the speed of standard Ethernet). This means that during transmission or reception the network interface could require as little as one eighth of the bus bandwidth.

### 5.1.3 Bus Analysis

Two parameters useful in analysis of bus systems are the Bus Latency and the Bus Utilization. The Bus Latency is the maximum time between the NIC assertion of BREQ and the system granting of BACK. This is of importance because of the finite size of the NIC's internal FIFO. If the bus latency becomes too great, the FIFO overflows during reception (FIFO overrun error) or underflows during transmission (FIFO underrun error). Both conditions result in an error that aborts the reception or transmission. In a well designed system these errors should never occur. The Bus Utilization is the fraction of time the NIC is the master of the bus. It is desirable to minimize the time the NIC occupies the bus, in order to maximize its use by the rest of the system. When designing a system it is necessary to guarantee the NIC a certain Bus Latency, and it is desirable to minimize the Bus Utilization required by the NIC.

Associated with each DMA burst is a DMA set up and recovery time. When a packet is being transferred either to or from memory it will be transferred in a series of bursts. If more byte/word transfers are accomplished in each burst, fewer bursts are required to transfer the complete packet, and less time is spent on DMA set up and recovery. Thus, when longer bursts are used, less bus bandwidth is required to complete the same packet transfer.

## 6.0 INTERFACE OPTIONS

The network interface can be incorporated into systems in several ways. The network interface can be controlled by either a system processor or a dedicated processor, and can utilize either system memory or buffer memory. This section covers the basic interface architectures.

### 6.1 Single Bus System

The least complex implementation places the NIC on the same bus as the processor (see *Figure 10*). The DP8390 acts as both a master and a slave on this bus; a master during DMA bursts, and a slave during NIC register accesses. This architecture is commonly seen on motherboards in personal computers and low cost workstations, but until recently without an integrated network interface. A major issue in such designs is the bus bandwidth for use by the processor. The DP8390 is particularly suitable for such applications because of its bus utilization characteristics. During transmissions and receptions, the only time the NIC becomes a bus master, the DP8390 can require as little as one-eighth the bus bandwidth. In addition, the bus tailoring features ease its integration into such systems.

TL/F/9141-11

**FIGURE 10. Single Bus Configuration**

The design must be able to guarantee the NIC a maximum bus latency ( $< 1.6 \mu\text{s}$  for 10 Mbit/s networks), because of the finite size of the on-chip FIFO. In bus systems where the NIC is the highest priority device, this should present no problem. However, if the bus contains other devices such as Disk, DMA and Graphic controllers that require the bus for more than  $10 \mu\text{s}$  during high priority or real time activities, meeting this maximum bus latency criteria could present a problem.

Likewise, many existing single bus systems make no provision for external devices to become bus masters, and if they do, it is only under several restrictions. In such cases, an interface without the mentioned bus latency restrictions is highly desirable.

## 6.2 Dual Port Memory

One popular method of increasing the apparent bus latency of an interface, has the added effect of shielding the system bus from the high priority network bandwidth. In this application, the Dual Port Memory (DPM) allows the system bus to access the memory through one port, while the network interface accesses it through the other port. In this way, all of the high priority network bandwidth is localized on a dedicated bus, with little effect on the system bus (see *Figure 11*).

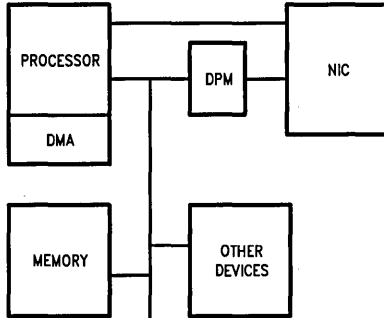

FIGURE 11. DPM Configuration

TL/F/9141-12

Dual Port Memories are typically smaller than the main memory and little, if any, processing can occur while the packets are in the DPM. Therefore, the processor (or if available, DMA controller) must transfer data between the DPM and the main memory before beginning packet processing. In this example, the DPM acts as a large packet FIFO.

Such configurations provide popular solutions. Aside from the extra complexity of the software and the DPM contention logic, higher performance can be achieved.

## 6.3 Dual Port Memory Equivalent

The functional equivalent of a Dual Port Memory implementation can be realized for low cost with the DP8390. This configuration makes use of the NIC's Remote DMA capabilities and requires only a buffer memory, and a bidirectional I/O port (see *Figure 12*). The complete network interface, with 8k x 8 of buffer memory, easily fits onto a half size IBM-PC card (as in the Network Interface Adapter, NIA, for the IBM-PC.)

TL/F/9141-13

FIGURE 12. DPM Equivalent Configuration

The high priority network bandwidth is decoupled from the system bus, and the system interacts with the buffer memory using a lower priority bi-directional I/O port. For example, when a packet is received the local DMA channel transfers it into the buffer memory, part of which has been configured as the receive buffer ring. The remote DMA channel then transfers the packet on a byte by byte (or word by word) basis to the I/O port. At this point, as in the previous example, the processor (or if available, DMA channel), through a completely asynchronous protocol, transfers the packet into the main memory.

## 6.4 Dual Processor Configuration

For higher performance applications, it is desirable to off-load the lower-level packet processing functions from the main system (see *Figure 11*). A processor placed on a local bus with the NIC, memory and a bi-directional I/O port could accomplish these lower-level tasks, and communicate with the system processor through a higher level protocol. This processor could be responsible for sending acknowledgement packets, establishing and breaking logical links, assembling and disassembling files, executing remote procedure calls, etc.

TL/F/9141-14

FIGURE 13. Dual Processor Configuration

## 7.0 REMOTE DMA

A set of DMA channels is built into the DP8390 to aid in the system integration (as discussed above). Using a simple asynchronous protocol, the Remote DMA channels are used to transfer data between dedicated network memory, and common system memory. In normal operation, the remote DMA channels transfer data between the network memory and an I/O port, and the system transfers between the I/O port and the system memory. The system transfers are typically accomplished using either the processor, or a DMA controller.

The Remote DMA channels work in both directions: transmission packets are transferred into the network memory and received packets are transferred out of the network memory. Transfers into the network memory are known as remote write operations, and transfers out of the network memory are known as remote read operations. A special remote read operation, send packet, automatically removes a packet from the receive buffer ring.

### 7.1 Performing Remote DMA Operations

Before beginning a remote DMA operation, the controller must be informed of the network memory it will be using.

Both the starting address (RSAR0,1) and length (RBCR0,1) are set before initiating the remote DMA operation. The remote DMA operation begins by setting the appropriate bits in the Command Register (RDO-RD3). When the remote DMA operation is complete (all of the bytes transferred), the RDC bit (Remote DMA Complete) in the ISR (Interrupt Status Register) is set and the processor receives an interrupt, whereupon it takes the appropriate action. When the Send packet command is used, the controller automatically loads the starting address, and byte count (from the receive buffer ring) for the remote read operation, and upon completion updates the boundary pointer (BNRY) for the receive buffer ring. Only one remote DMA operation can be active at a time.

### 7.2 Hardware Considerations

The Remote DMA capabilities of the NIC are designed to require minimal external components and provide a simple implementation. An eight bit bi-directional port can be implemented using just two 374 latches (see the DP8390 Hardware Design Guide). All of the control circuitry is provided on the DP8390. In addition, bus arbitration with the local DMA is accomplished within the NIC in such a way as to not lock out other devices on the bus (see the DP8390 Data-sheet).

# Ethernet Network Interface Adapter for the Apple Macintosh II NuBus

National Semiconductor  
Application Note 686  
Andrew C. Pagnon

## INTRODUCTION

The gradual move in recent years towards distributed processing units with a need for these to communicate and the increasing demand for peripheral usage optimization has resulted in the fast growth of Local Area Networks. In an attempt to standardize communications between networks the International Standards Organization (ISO) has proposed a seven layer reference model called the Open System Interconnect (OSI) which provides an independent framework for all the emerging network standards. The IEEE has defined a number of these standards (802.3 to 802.6) covering the two lower layer functions, physical and data link layers.

National Semiconductor provides a three chip set which supports the Ethernet/Thin-wire Ethernet standard (a subset of IEEE802.3) the DP8390 Network Interface Controller (NIC), DP83910 Serial Network Interface (SNI), and DP8392 Coaxial Transceiver Interface (CTI).

The aim of this application note is to describe the implementation of a Macintosh II, IIx and IIcx to Ethernet/Thin-wire Ethernet interface solution using the NSC chip set. This solution takes the form of a network interface adapter card which on one side plugs into any of the six Macintosh II NuBus expansion slots and on the other supports two physical layer options, Ethernet and thin-wire Ethernet.

The board easily interfaces to the Macintosh II NuBus interface with few external components. This application note assumes the reader is familiar with NSC's Ethernet chip set and the Macintosh II NuBus.

The note begins with a hardware overview of the adapter card, and a background description of the NuBus interface. This is followed by a detailed description of hardware supported by the main sequencer/arbitrator state diagram. This covers arbitration and a detailed description of all the cycle types implemented on the card. The PAL equations and part list are included at the end of the note along with a detailed schematic and timing diagrams.

## HARDWARE OVERVIEW

The main function of this adapter card is to transfer Ethernet packet data to/from the Macintosh CPU via NuBus during LAN transmissions and receptions. The card supports a NuBus interface to the CPU and an Ethernet interface to the network. Data transfers between the interfaces are routed on the card's local bus through 8k words of shared buffer memory which temporarily stores ethernet packet data, thus decoupling data transfers across the two interfaces. The 8k buffer memory can be expanded to 32k by simply replacing the memory ICs.

Figure 1 shows a simplified block diagram of the adapter. Besides the basic DP8390 chip set this diagram illustrates the connection of the slot and cycle decode logic used to select the card, and generate read/write cycles. The arbiter controls whether the NIC or NuBus can access the buffer RAM. The RAM contains the transmit/received packet data, and the ROMs (actually one chip) contain the Ethernet Address and the Macintosh configuration information. The ad-

dress bus interface latches store the NuBus address from the multiplexed address/data bus, and the data bus interface consists of buffers and latches to assemble the 16-bit RAM buffer data into a 32-bit word for the NuBus.

## Transmission/Reception

For Ethernet transmissions the host CPU writes data into the transmit area of the adapter card buffer memory over the NuBus interface. The host CPU then sets up the NIC to transmit the data by writing to its internal registers. The NIC responds by fetching the data into its internal FIFO using its local DMA channel, from where it is sent to the SNI-CTI and onto the Ethernet cable. Once the data has been transmitted the NIC issues an interrupt back to the host CPU and sets a status bit in its internal register.

For Ethernet receptions data is loaded from the Ethernet cable into the internal FIFO of the NIC from the SNI and CTI. When a programmable threshold is reached in the FIFO, the NIC transfers the data into the receive area of the adapter card buffer memory using its local DMA channel. Once a complete packet has been loaded into memory, the NIC sets up a pointer in its internal register, issues an interrupt to the host CPU and sets a status bit in its internal register. The host processor responds by reading the packet from the adapter card memory over the NuBus interface and updating the packet pointers stored in the NICs internal register.

## General Adapter Architecture Considerations

A shared memory architecture has been chosen for this design to maximize data throughput while not adding any extra cost or intelligence on the card. The buffer memory is mapped into the NuBus address space and a NuBus slave interface plus local bus arbitration logic is implemented on the adapter card. The reasoning for this decision is given below.

The DP8390 efficiently supports an input/output port architecture, in which the adapter card makes use of the NICs Remote DMA facility to transfer network data between the buffer RAM and an input/output port interfacing to the NuBus and to the host CPU. This implementation is a slightly less expensive option than others however the throughput of the port interface is somewhat limiting, and there are no memory addressing limitations on the NuBus that would require an I/O port technique.

A bus master architecture, in which the adapter card can gain ownership of the host CPU bus and transfer data directly into system memory is significantly more costly and with the current generation of controllers will not yield significantly better performance across NuBus without going to the expense of adding an on-card processor.

Thus, using a buffer RAM that is addressed directly by the NuBus and the Ethernet Controller, provides the flexibility of reading/writing data via the NuBus at fast speeds, and since the DP8390's local DMA only utilizes a small percentage of the RAM's total access time (12%) the RAM is mostly free for NuBus activity.

FIGURE 1. General Block Diagram for the NuBus Shared RAM Adapter

TL/F/10805-1

Once the Shared Adapter RAM approach is chosen another architectural consideration is the width of the Buffer RAM and of the CPU bus transfers supported. Table I shows the options considered. The 16-bit Buffer memory and 32-bit NuBus transfer option was chosen as the best compromise on data throughput and component count/cost.

#### General Hardware Overview

Figure 2 shows a more detailed block diagram of the Adapter. This shows each block, and details the chips used to implement each block.

The Ethernet to buffer memory interface is implemented using National Semiconductor chip set. The DP8390 Network Interface Controller is a CMOS VLSI device designed to ease interfacing with IEEE 802.3 Ethernet type Local Area Networks. It implements all Media Access Control MAC functions (a subset of the ISO data link layer) for transmission and reception of packets in accordance with the IEEE 802.3 standard. Its dual DMA channels and internal FIFO provide a simple yet efficient packet management design. All bus arbitration and memory support logic required by its dual DMA channels are integrated into the NIC.

The DP83910 Serial Network Interface is a CMOS combined analog and digital device which provides the Manchester encoding and decoding functions of IEEE 802.3 Ethernet type Local Area Networks. It contains ECL like balanced drivers and receivers, collision signal translator and a diagnostic loopback circuit.

The DP8392 Coaxial Transceiver Interface is a bipolar device used as a coaxial cable line driver/receiver for IEEE 802.3 Ethernet Local Area Networks. In Ethernet applications the transceiver is usually mounted within a dedicated enclosure (Media Access Unit) and connected to the SNI via a drop cable, while for Thin-wire Ethernet (low cost ver-

sion of Ethernet) the CTI is mounted on the same board as the SNI. Signal and power isolation requirements are met by placing a set of pulse transformers between the SNI and the CTI, and using a DC to DC converter to provide the CTI's -9V supply.

The adapter card supports a 32-bit NuBus interface to the host CPU, implemented using synchronous sequencer logic in the registered PAL 16R4. This interface supports transfers to the Network Interface Controller registers, the "Ethernet address/Mac configuration" ROM and the buffer memory. The two card interfaces must request use of the local bus before they can initiate a transfer to any of the on card devices. These requests are processed by arbitration logic which gives priority to the Ethernet interface.

The 256 x 8 ROM (LS471) contains the unique Physical Address assigned to each Ethernet board and the Configuration data required on each NuBus board which supplies identifying information about the board. This ROM can also contain device driver data.

The address/data interface to NuBus consists of four F651s data transceivers to transfer 32-bit data from/onto the NuBus, and three F533s and an F373 used to latch the address and the transfer mode signals onto the adapter card. Data on NuBus is inverted and byte swapped, so inverting transceivers and latches are used. An exception to this is the F373 which is a non-inverting version of the F533 used to latch AD24-31 which are then compared with the ID lines of the particular NuBus slot. Also the card performs a hardware byte swap on the NuBus data.

On NuBus transfers, an F521 8-bit comparator aids in the address decode function by determining whether or not the transfer is intended for the adapter card.

## NUBUS BACKGROUND

This section describes the NuBus implemented in the Macintosh II expansion slots, and the Ethernet adapter card implementation of its interface. It covers NuBus' main features and signals as used by the card, followed by a description of the address space and addressing modes and ending with a description of the NuBus interface protocol.

NuBus is the bus chosen by Apple to drive the expansion slots of the Macintosh II. Its main features are:

- 32-bit wide multiplexed address data lines
- Synchronous 10 MHz clock cycle (75% duty cycle)
- Read and Write cycles (Mac II does not support block transfers)
- I/O and interrupts are memory mapped
- Geographical addressing lines

Each slot has its own geographical addressing lines onto the adapter board. This is illustrated in *Figure 3* by the super slot space in which each card has its own 256 Mbytes of memory space. Therefore no board configuration is required. (Described later.)

The Ethernet adapter card only implements a NuBus slave interface and therefore arbitration logic to gain bus mastery has not been implemented. Note also that no parity generating/checking logic has been implemented either.

The Ethernet adapter board uses the following NuBus signals:

- Clock
- Reset

- Card Slot Identification
- Non-Master Request
- Address/Data Signals/AD<31..0>
- Control Signals /TM<1..0>, /START, /ACK(knowledge)

The evaluation board supports single word transfers to the NIC registers, Address/Configuration ROM and the Buffer RAM. During the Start clock of a NuBus cycle the NuBus address and transfer mode lines are decoded on the card as shown in *Figure 3*, and as follows:

- TM<1..0> determine the type of transfer (read/write),
- AD<24..31> determine which NuBus slot is accessed.
- AD<19..18> determine which adapter card device is accessed (NIC, ROM or RAM)
- AD<15..2> are used to access a particular location within the device.
- AD<0..1> & <20..23> are ignored by the address decode

The adapter card responds to all NuBus cycles which address the card by generating an acknowledge signal ACK for one clock period and driving a status code on the transfer mode lines. Only two of the four NuBus defined transfer modes are supported by the card, transfer complete or bus error (see Table III).

TABLE III. NuBus Status Codes

TM0	TM1	Acknowledge
H	H	Transfer Complete
L	H	Bus Error

FIGURE 3. NuBus and Adapter Card Address Space Mapping

TL/F/10805-3

If the CPU requests a transfer to the adapter card NuBus slot which does not address a device on the card, or requests a write transfer to ROM, the board will respond with an error status encoding of the TM<1..0> lines during the ACK clock of the NuBus cycle. Otherwise a "Bus Transfer Complete" code is returned.

Typical NuBus read and write cycle timings are shown in Figures 4 and 5. The first NuBus cycle asserts the START line going low and presenting the address and the transfer mode. A number of clock cycles may follow before the last cycle presents the data and status on the bus, and asserting the ACK signal.

The adapter card does not implement the two other status codes supported by NuBus, "bus time out error", and "try again later". The design of the adapter card ensures that all NuBus cycles will be acknowledged within the NuBus time-out period.

**NuBus Address Space**

With a 32-bit architecture, the NuBus provides a 4 Gigabytes of address space, Figure 3. The 4 Gigabyte space is divided into sixteen 256 Megabyte Super Slots. The Super Slot being accessed is determined by decoding AD<31..28>. The top Super Slot is divided into sixteen Slot spaces by 16 Megabytes each determined by decoding AD<27..24>. Six of these slots (\$9 to \$E) are implemented as NuBus expansion board connectors on the MAC II. The interface adapter board may be plugged into any of these connectors. No hardware configuration on the adapter card is required.

**24/32 Bit Addressing Modes**

The adapter card, by ignoring address bits AD<23..20>, supports both 32- and 24-bit addressing modes.

When addressing the card in 24-bit mode, addresses of the form "\$sx xxxx" where s is the slot number can be used. The Mac II hardware translates this into a 32-bit address of the form "\$Fs0x xxxx".

When addressing the card in 32-bit mode addresses of the form "\$Fsxx xxxx" can be used. Note that as the adapter card ignores address bits AD<23..20>, addresses of the form "\$Fsxx xxxx" access the same adapter card location in both 32- and 24-bit modes, and as Apple have indicated that to ensure compatibility with future versions of the Macintosh designers should not rely on 24-bit mode addressing, it is suggested that addresses of the form "\$Fsxx xxxx" are always used.

Although supporting 24-bit mode addressing limits the memory range of each slot from 16M to 1M, this sufficiently covers the need of an Ethernet adapter card and simplifies software development. The Macintosh slot manager puts the system in 24-bit addressing mode by default and the memory manager plus some toolbox routines do not currently function properly in 32-bit mode.

**Adapter Card Address Space**

Once the slot is selected, the Network Interface Adapter's memory space is subdivided into four 256 kbyte blocks of memory determined by decoding AD<19..18>.

FIGURE 4. NuBus Read Cycle

TL/F/10805-4

FIGURE 5. NuBus Write Cycle

TL/F/10805-5

Figure 3 shows the sub-division of the Super Slot, Slot, and Adapter Board address space.

It is important to note the following points when developing high level software to address the adapter card. If the NIC registers or the ROM are accessed as 8-bit devices, (by declaring a pointer to a character in Macintosh Programmers Workshop (MPW) for example) or as 16-bit devices (by declaring a pointer to a short integer), incrementing these pointers will usually only modify the transfer mode (by incrementing AD<1..0>) rather than increment the address to the device (NIC or RAM). It is therefore recommended that if this form of addressing is used, the RAM, ROM and NIC are declared as 32-bit devices (by accessing them with a pointer to an integer). This will ensure only word transfers take place and each NuBus address increment will also increment the address to the onboard device.

**NuBus Timing Diagrams**

The NuBus clock has a 100 ns period (10 MHz) with a 75% duty cycle (75 ns "high" and 25 ns "low"). NuBus signals are driven at the rising edge and sampled at the falling edge of the clock. A transfer (read/write cycle) is initiated when the master asserts /START, drives the address on AD<31..0>, and drives the transfer mode signals TM<1..0> with the appropriate code to indicate the desired transfer. A transfer is completed when the slave responds by asserting /ACK and driving the transfer mode signals with the appropriate status code. Please refer to Figure 4 and Figure 5 for the NuBus read/write cycles.

For a read operation, once the master has acquired the bus, a read bus transaction involves the following steps:

- R(1): The bus master asserts /START and the appropriate /ADx and /TMx lines to initiate the transfer.
- F(1): The bus slaves sample the /ADx and /TMx lines.

- R(2): The bus master releases the /ADx, /TMx, and /START lines and waits for /ACK.
- R(N): The bus slave places the requested data onto the /ADx lines, asserts /ACK, and places the appropriate status code on /TM0 and TM1 lines. (Note N may be from 2 to 256)
- F(N): The bus master samples the /ADx, /ACK, and TMx lines to receive the data and note and error condition.
- R(N + 1): The bus slave releases the /ADx and /ACK lines and the /TMx lines. This may be the R(1) transition of the next transaction.

For a write operation, once the master has acquired the bus, a write bus transaction involves the following steps:

- R(1): The bus master asserts /START and the appropriate /ADx and /TMx lines to initiate the transfer.
- F(1): The bus slaves sample the /ADx and /TMx lines.
- R(2): The bus master places the data on the /ADx lines, releases /TMx, and /START lines and waits for /ACK.
- F(2)-F(N): The bus slave samples the /ADx lines to capture the data. The data may be sampled before or during the assertion of /ACK.
- R(N): The bus slave asserts /ACK, and places the appropriate status code on /TM0 and TM1 lines when the data is accepted. (Note N may be from 2 to 256)
- F(N): The bus master samples the /ACK and TMx lines to determine the end of a transaction.
- R(N + 1): The bus master releases the /ADx while the bus slave releases the /ACK lines and the /TMx lines.

#### DETAILED HARDWARE DESCRIPTION

The card's main function is to transfer Ethernet packet data from the NuBus interface to the Ethernet cable during packet transmission, and from the Ethernet cable to the NuBus interface during packet reception, via an 8k x 16 Buffer RAM, expandable to 32k x 16. In addition to this the NuBus interface is allowed direct read and write access to the NICs registers to control and monitor the NIC's operations, and read access to the "Ethernet address/Mac configuration" ROM.

This transfer of packet data from Ethernet to host CPU is executed in two distinct stages, transfers between host CPU and buffer Memory, and transfers between buffer memory and Ethernet. The former is performed by the on-card NuBus slave interface whereas the latter is performed by the NIC chip set.

A synchronous sequencer/arbitrator implemented in a PAL16R4 running on the 10 MHz NuBus clock controls all transfers supported by the adapter card. The state diagram for its operation is shown in *Figure 6*. States S1 to S5 support the NuBus slave interface, and state S6 supports the NICs interface. State S0 is the idle state. The sequence of states for each bus cycle type is shown in Table IV.

#### Arbitration for Local Card Bus by NIC/NuBus

All addressable devices on the card (Buffer RAM, NIC registers and ROM) share the common non-multiplexed local address and data buses. The two potential masters of this bus, the NuBus interface and the NIC, request access to the bus. Arbitration logic and the state sequencer resolve these requests. The sequencer only responds to master's requests during the idle state (S0). Therefore cycles already in progress are always allowed to complete before the bus is re-

allocated. Cycles always complete by returning to the idle state (S0). This prevents bus contention on the common local address bus at switchover time (NuBus/NIC) and enables arbitration to take place after every NuBus cycle or NIC local DMA burst. The NIC is given priority over the NuBus interface, so that if a NIC and a NuBus interface request are active when the sequencer is idle, the NIC cycle will be serviced first. The following bus latency discussion shows there is no real need to give one master priority over the other.

#### Bus Latency Requirements

This is defined as the time between a master issuing a request and receiving an acknowledge.

The NuBus interface bus latency allowable is determined by its 25.6  $\mu$ s bus timeout period. The maximum NuBus bus latency that can be expected on this card, that is, the longest Bus Request from the NIC, occurs if a packet ends just as the NIC performs its last FIFO burst. The local DMA burst plus the End of Packet processing operations add up to just over 4  $\mu$ s, well within the allowable 25.6  $\mu$ s.

The NIC bus latency allowable is determined by the need to prevent its internal FIFO from overflowing during packet reception. The worst case bus latency the NIC can accommodate running on a 20 MHz clock is a little more than 1  $\mu$ s (refer to the DP8390 Datasheet addendum). The maximum NIC bus latency that can be expected on this card, that is, the longest NuBus cycle to the card, is 0.5  $\mu$ s (five NuBus Clocks), well within the allowable 1  $\mu$ s.

Again, Table IV shows all the cycles supported by the card, and the state sequence followed by each one. The figures quoted display the timing diagram for each case.

## NUBUS MASTER CYCLES

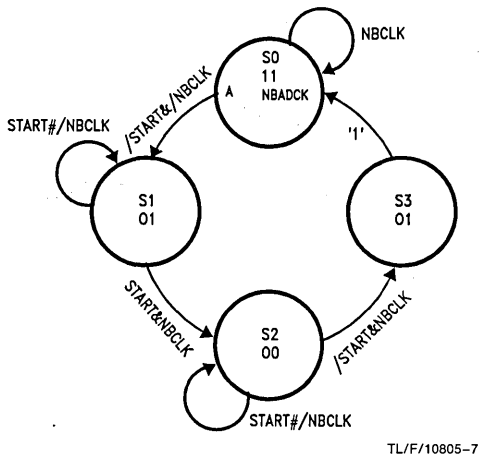

The CPU initiates NuBus cycles by driving the address and transfer mode onto NuBus and asserting the Start signal during the first clock of the bus access.

The adapter card latches the address onto the local bus on the falling edge of the first clock. A transparent latch is used so that the address is available on the local bus as soon as it is driven onto NuBus and address recognition can begin. A small asynchronous state machine in a control PAL<sup>®</sup> generates the address latching signal, which opens the latch when START becomes active and latches the address on the next falling edge of the clock. *Figure 7* shows the state machine diagram.

The address is enabled onto the local bus by NBADOE provided that the NIC is not already the bus master nor has issued a request while the sequencer is in the idle state.

The top 8 bits of the address are compared with the slot ID driven from NuBus.

The card, in response to the start signal, generates an enable signal (EBSLOT) which allows the sequencer to proceed onto the next NuBus cycle state (S1), provided the NIC bus request is not active and the above address comparison is successful (MYSLOT is active). This enable signal is cleared at the end of the NuBus cycle when ACK becomes active and prevents addresses not generated with a START signal from triggering the sequencer onto the S1 state. *Figure A-4* shows a detailed timing diagram of the address recognition operation. Note that FAST devices have been selected for the address latches and comparator to enable address recognition to meet the set up time of the sequencer.

A = State Variable (Not Used)

NBADCK = NuBus Address Clock

**FIGURE 7. State Diagram for Clock to Latch NuBus Address onto Ethernet Card**

States S1 to S4 cover the data portion of a NuBus transfer. The signal DASB (Data Strobe) is generated to qualify all the data enabling signals (NICCS, ROMCS, RAMOE, NBDBOE, DBNBOE). Note that during S2 DASB has to be released so that the state has a separate state number. This only affects NuBus to RAM cycles. Therefore during S2 the signal TOP is used to qualify the data enabling signals (RAMOE, NBDBOE, DBNBOE).

During S1 the address is further decoded with four possible outcomes. Each of the possible transfers initiated by NuBus are described.

### Bus Error Transfer

If the address is not recognized by any of the on-card devices or it is recognized by the ROM with transfer mode defining a write cycle, a bus error condition is flagged to the CPU. The sequencer enters state S5 where the DASB signal is cleared, ACK is generated to signal the end of the cycle, and a bus error code is driven onto the NuBus transfer mode lines. The sequencer then returns to idle on the next clock beat. *Figure 8* shows a timing diagram for a NuBus error cycle.

### NuBus ROM Transfer

If the address and transfer mode are decoded as a read cycle to ROM, the address decoding PAL generates a ROM enabling signal to the ROM chip select input which drives its data onto the local bus. The control PALs generate the "Data bus to NuBus output enable" signal DBNBOE to enable this data from the local bus onto NuBus. The sequencer transfers to state S4 on the next clock beat where ACK is driven onto NuBus together with the "transfer complete" code on the transfer mode signals. *Figures 8* and *A-1* show a basic and detailed timing diagram of the ROM read operation. Note that ROM set up times are easily met. Very slow ROMs can be used on this design, up to 135 ns data enable time or 210 ns address access time.

### NuBus NIC Transfer

If the address and transfer mode are decoded as a read or write cycle to the NIC register, the address decoding PAL generates the NIC chip select signal NICCS, and the bottom four bits of the local address are sent to the NIC to select one of sixteen possible NIC registers. The sequencer, *Figure 6*, remains in state S1 until the NIC generates acknowledge signal NICACK. This signal is synchronized to the NuBus clock before it is fed into the synchronous state sequencer PAL. The sequencer then proceeds onto state S4. See *Figure 9* for a functional timing diagram of NuBus to NIC read and write cycles.

If the cycle is a write, the control PAL generates the NBDBOET signal to enable the NuBus write data onto the local bus, and a small asynchronous state machine in the PAL generates the write enable signal to the NIC, SWR. *Figure 10* shows the state machine diagram. This signal is cleared on the falling edge of the clock during the S4 state to provide the necessary write data hold time to the NIC. See *Figure A-3* detailed timing diagram.

If the cycle is a read, the control PAL generates DBNBOE to enable the NIC read data from the local bus onto NuBus. See *Figure A-2* for a detailed timing diagram.

FIGURE 11. Write Enable Bottom State Diagram

**NuBus to RAM Transfer**

The address and transfer mode are decoded as a read or write cycle to the buffer RAM. The adapter card supports 32-bit NuBus transfers to the 16-bit buffer RAM. This is done by reading/writing to the RAM twice on every NuBus to RAM access, once during states S1 and S2 to access the least significant 16 bits of the NuBus word, and again during states S3 and S4 to access the most significant 16 bits of the NuBus word, after having incremented the bottom local address bit to the RAM (see the state diagram Figure 6). Therefore the NIC sees the buffer memory as an 8k x 16 RAM whereas the NuBus sees it as a 4k x 32 RAM. Figure 12 shows a basic timing diagram for a NuBus to RAM read and write cycle.

For read cycles' data from the RAM read during states S1 and S2 is stored in the top two NuBus transceivers by setting the transceivers in storage mode and clocking them on the falling edge of the NuBus clock during state S2 with the TBCK (Top Bus Clock) signal. This data is enabled on NuBus bits 16-31 with the signal NBDBOET. During states S3 and S4 the next RAM location is read and its data driven onto NuBus bits 0-15 through the bottom two NuBus transceivers, which are not set in storage mode (real time data mode).

Therefore by the time the adapter card drives ACK back to NuBus during state S4, the least significant 16 bits of data, corresponding to the first RAM location read, which were stored during S2, are being enabled onto NuBus bits 16-31 through the top two transceivers, and the most significant 16 bits of data, corresponding to the second RAM location read, are being enabled onto NuBus bits 0-15 through the bottom two NuBus transceivers. Figure A-4 at the end of this note, shows a detailed timing diagram of a NuBus to RAM read cycle.

Note that the adapter card performs a hardware byte swap of NuBus data through the transceivers, so that the least significant byte of data from the RAM (Bits 0-7 on the local data bus of the first RAM location read) are driven onto byte 3 of NuBus (bits 24-31). This byte will be carried on byte lane 3 in the MACII system onto byte 3 of the MC68020 (data line bits 0-7).

For write cycles, during states S1 and S2, the top two NuBus transceivers (NuBus bits 16-31) are enabled onto the local data bus and their NuBus write data written into the Buffer RAM, with the bottom local address bit clear. During the next two states S3 and S4 the bottom two NuBus transceivers (NuBus bits 0-15) are enabled onto the local data bus and their NuBus write data written into the next Buffer RAM location with the bottom local address bit set. Two separate write enable signals are generated (RAMWET and RAMWEB) and ANDed together on the card to generate RAMWE. Two small asynchronous state machines are used to generate these signals. Figure 10 and 11 show their state diagram. Figure A-5 shows a detailed timing diagram of a NuBus write cycle to RAM.

Supporting 32-bit transfers on NuBus rather than 16 only introduces one extra wait state per NuBus cycle to the RAM while doubling the data throughput per transfer.

**NIC MASTER CYCLE**

The NIC initiates local DMA cycles by driving its Bus Request line active. The sequencer/arbitrator PAL, if in idle state S0, will enter state S6 where it acknowledges the request and hands over control of the local bus to the NIC. Any requests from the NuBus interface will be held until the NIC completes its local DMA burst and clears its request line allowing the sequencer PAL to return to the idle state S0.

Figure 14 shows an NIC to RAM cycle, its request coinciding with the start of a NuBus cycle, thus illustrating the arbitration process.

Note the NIC runs on a separate 20 MHz clock, asynchronous to the NuBus clock. Therefore NIC signals to the arbitrator sequencer are first synchronized to the NuBus clock with a D-type latch (F175) before they are used by the synchronous sequencer PAL running on the NuBus clock. The signals affected are BREQ and NICACK.

# DP839EB-ATN IBM® PC-AT® Compatible DP83901 SNIC Serial Network Interface Controller Evaluation Board

National Semiconductor  
Application Note 729  
Larry Wakeman

## OVERVIEW

The National Semiconductor SNIC Evaluation Board design provides IBM AT's and AT Compatibles with Thick Ethernet, Thin Ethernet, and Twisted Pair connections. This low parts count evaluation board is compatible with the AT bus and requires only a 1/2 size slot for insertion. Besides using the DP83901 Serial Network Interface Controller (SNIC), the Coaxial Transceiver Interface (CTI) and the Twisted Pair Interface (TPI) are also employed. The dual DMA (local and remote) capabilities of the SNIC, along with 16 kbytes of buffer RAM, allow the entire Network Interface Adapter to appear as a standard I/O Port to the system. The NIC's local DMA channel buffers packets between the local memory (16 kbytes of buffer RAM) and the network, while the NIC's remote DMA channel passes data between the local memory and the system by way of an I/O Port. This I/O Port architecture which isolates the CPU from the network traffic proves to be the simplest method to interface the DP83901 to the system.

## HARDWARE FEATURES

- Fits in half-size IBM PC-AT I/O card form factor
- Utilizes DP83901 Serial Network Interface Controller (SNIC) and DP83922 Twisted Pair Transceiver (TPI)
- 16 kbyte on-board packet buffer

- Simple I/O port interface to IBM PC-AT
- Interfaces to thick Ethernet, thin Ethernet, and twisted pair
- Boot EPROM socket

## NETWORK INTERFACE OPTIONS

The evaluation board supports three physical layer options: Thick Ethernet, Thin Ethernet, and Twisted Pair. These can be seen in *Figure 1*. When using Thick Ethernet, a drop cable is connected to an external transceiver which is in turn connected to a standard Ethernet network. For this physical layer, there is no need for an internal transceiver since it already has an external one. This configuration may be obtained by connecting the pins on JB3 while leaving JB1 and JB2 open. When using Thin Ethernet, a transceiver (the CTI) is available on-board to allow the direct connection to the network via the evaluation board. This transceiver (the CTI) forms the link between the differential ECL signals of the SNI and the non-differential ECL signal of the thin-wire coaxial cable. For proper operation, the CTI requires a DC-DC Converter to provide an isolated ground and a -9V source. In order to put this Thin Ethernet solution into operation, the pins on JB2 need to be connected while JB1 and JB3 should be open.

FIGURE 1. Physical Layer Adapter Interface Block Diagram

TL/F/10800-1

When using the Twisted Pair (telephone cable), another transceiver (the TPI) is available on-board which also allows direct connection to the network. The voltage regulator (the LM317) provides the TPI chip with a constant +7V supply. The remaining portion of the TPI circuit includes a common mode choke and a transformer. The transformer decouples the DC component and eliminates any possible voltage spikes. This twisted pair interface can be selected by using JB1 and leaving JB2 and JB3 open. Each of these three physical layer options can be selected simply by the placement of a jumper block (no software changes are needed).

**BUS INTERFACE**

The block diagram, *Figure 2*, illustrates the architecture of the SNIC Evaluation Board. The SNIC Board as seen by the system appears only to be an I/O port. With this architecture the SNIC board has its own local bus to access the board memory. The system never has to intrude further than the I/O ports for any packet data operation. This I/O architecture isolates the system bus and the local bus, thereby preventing interference by the system when the SNIC is doing real-time accesses such as transmitting and receiving packets.

**BOARD ARCHITECTURE**

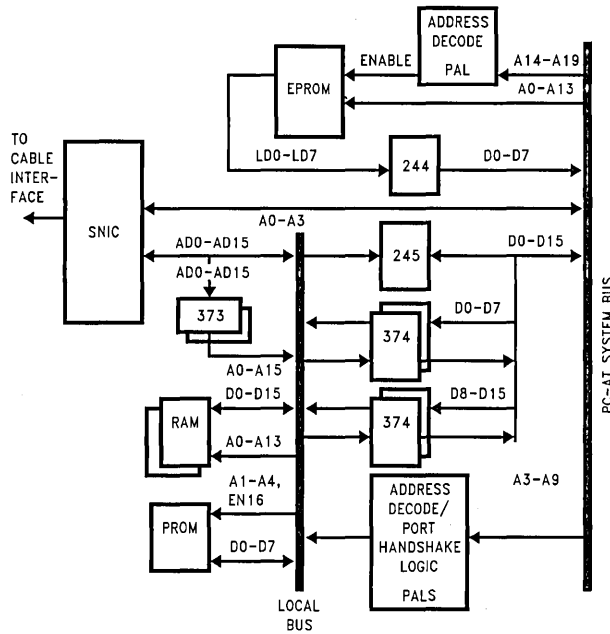

**I/O Map of SNIC Board**

The SNIC Board requires a 32-byte I/O space to allow for decoding the data buffers, the reset port, and the SNIC registers. The first 16 bytes (300h-30Fh) are used to address the SNIC registers (8 bits wide) and the next 8 bytes (310h-317h) are used to address the data buffers which are 16 bits wide. Finally, the reset port may be addressed by 318h-31Fh.

**TABLE I. I/O Map in PC-AT**

Address	Part Addressed
300h-30Fh	SNIC Chip Select
310h-317h	Data Buffers
318h-31Fh	Reset

Although in the description above the I/O map is positioned at the addresses 300-31F, it may also be placed in the following address spaces: 320-33F, 340-35F, 360-37F. These alternate address spaces may be selected by the two jumpers (JP1 and JP0).

**FIGURE 2. Block Diagram of SNIC Evaluation Board's System Interface**

TL/F/10800-2

TABLE II. Optional Address Spaces

Jumpers		
JP1	JP0	I/O Address Space
On	On	300h-31Fh
On	Off	320h-33Fh
Off	On	340h-35Fh
Off	Off	360h-37Fh

**DP83901's Local Memory Map**

There are only two items mapped into the local memory space. These two items being the 8k x 16 buffer RAM and the ID address PROM. The buffer RAM is used for temporary storage of transmit and receive packets. For transmit packets, the remote DMA puts data from the I/O ports into the RAM and the local DMA moves the data from the RAM to the SNIC. For the receive packets, the local DMA carries the data from the SNIC to the RAM and the remote DMA moves the data from the RAM to the I/O ports. The ID address PROM (74S288 32 x 8) contains the physical address of the evaluation board. Each PROM holds its own unique physical address which is installed during its manufacture. The PROM also contains a checksum. This checksum, calculated by exclusive OR-ing the six address bytes with each other, is provided in order to check the addresses. At the initialization of the evaluation board the software commands the SNIC to transfer the PROM data to the I/O Port where it is read by the CPU. The CPU then verifies the checksum and loads the SNIC's physical address registers. The following chart shows the contents of the PROM.

TABLE III. SNIC's Local Memory Map

7FFFh	RAM
4000h	
3FFFh	
0000h	PROM

TABLE IV. PROM Contents

PROM Location	Location Contents
00h	Ethernet Address 0 (Most Significant Byte)
01h	Ethernet Address 1
02h	Ethernet Address 2
03h	Ethernet Address 3
04h	Ethernet Address 4
05h	Ethernet Address 5
06h-0Dh	00h
0Eh	57h
0Fh	57h
10h-15h	Same as 00h-05h
16h-1Dh	00h
1Eh	42h
1Fh	42h

**Data and Address Paths**

For the following paragraph, refer to the block diagram shown in *Figure 2*. Twenty address lines from the PC go onto the SNIC Board, but only four of them actually go to the SNIC. These four addresses along with the NIOR (low-asserted I/O read) or NIOW (low-asserted I/O write) and the CS (SNIC chip select signal) allow the PC to read or write to the SNIC's registers. If the system wants to read from or write to the SNIC registers, the data (only 8 bits) must pass through the 245 buffer. All of the packet data will pass through the I/O ports (the 374's). Each 374 is unidirectional and can only drive 8 bits, therefore it is necessary to have four 374's. Two of which drive data from the ports to the board memory and two of which drive the data from the ports to the AT bus. Even the PROM, which can only be addressed by the SNIC, sends its 8 bits of data out through the 374's. When the PROM does this, two of the 374's will be enabled but only the lower 8 bits will be read by the system. The RAM is also accessed by the SNIC. However, it is addressed by 14 bits and drives out 16 bits of data. The PALs® receive 7 address lines among many other signals such as NIOR, NIOW, NACK, MRD, etc. With these signals the PALs do all of the decodes, such as selecting the SNIC Board, the SNIC chip, the RAM, and the PROM.

**EPROM Socket**

The EPROM socket is provided so that the user may add an EPROM to the board. This EPROM would normally contain a program and a driver to enable the PC-AT to be booted up through the network. The chips necessary to interface the EPROM to the system are the 27128 (EPROM), a 16L8 (PAL), and a 74ALS244 (buffer). Also, JB8 must be placed in the proper selection as described in the jumper section. A PAL decodes SA14-SA19, along with SMRDC (system memory read), in order to generate the EPROMEN signal. This signal, issued when the PC desires to execute the program contained in the EPROM, enables the EPROM and the 244 buffer.

**EVALUATION BOARD OPERATION**

The following pages will describe the slave accesses to the SNIC and the local DMA and remote DMA operation.

**Register Operations**

Accesses to the board are register operations to the DP83901, which are done to set up the SNIC and to control the operation of the SNIC's DMA channels.

**Register Read**

To begin the register read, the CPU drives the four address lines (SA0-SA3) to the SNIC and the SA3-SA9 address lines to the PAL. These address lines are decoded by the PAL in order to generate a chip select to the SNIC. The CPU also drives the NIOR line which the SNIC sees as the NSRD (slave read). Once the SNIC receives this NSRD, it then sends out a high assertion on NACK, acknowledging that it is in slave mode but not yet ready to complete the read. The NACK signal is used by the PAL to assert the IOCHRDY signal false. The SNIC then drives out the data from its internal registers to the 245 buffer. The 245 buffer is then enabled and the data is driven onto the AT BUS. When the SNIC is ready, it asserts NACK true and the PAL asserts IOCHRDY true. As a result, NIOR is driven high by

the CPU, thereby deasserting the NSRD. On the rising edge of the NIOR, the data which is on the AT BUS is latched into the system. The addresses are removed at the same time, causing the SNIC chip select to become deasserted and therefore ending the register read cycle.

#### Register Write

To begin the register write, the CPU drives the SA0-SA3 address lines to the SNIC and the SA4-SA9 address lines to the PAL. With these address lines, the PAL decodes to 300-30F (the SNIC registers) thereby enabling the chip select for the SNIC. The CPU then drives the NIOW strobe which the SNIC sees as NSWR (slave write). Once the SNIC receives this NSWR it sends back a low assertion on NACK to acknowledge that it is in slave mode and ready to perform the write. When the CPU receives this signal, it puts data out onto the AT BUS where it goes into the 245 buffer. The 245 buffer then drives the data to the SNIC, but the data is not latched into the SNIC until the rising edge of NIOW. The system drives NIOW high, thereby deasserting the NSWR and latching the data. The addresses also are taken away and the chip select then goes high (deasserted). This thereby ends the cycle of the register write.

#### Remote Transfers

Remote DMA transfers are operations performed by the SNIC on the board. These operations occur when the SNIC is programmed to transfer packet data between the PC-AT and the card's on-board RAM. These transfers take place through the I/O Port interface.

#### Remote Read

To program the SNIC for a remote read, the CPU must make five slave accesses to the SNIC. The CPU must write the Remote Start Address (2 bytes), the Remote Byte Count (2 bytes) and issue the Remote DMA Read Command. The addresses and byte count require two transfers because they are both 16 bits, yet only 8 bits can be written per transfer.

Once the SNIC has received all of the above data, it drives out BREQ and waits for BACK. For this design the SNIC immediately receives the BACK because it is tied to the BREQ line (BREQ can be tied to BACK because there are no other devices contending for the local bus). After receiving the BACK, the SNIC drives out the address from which the data will be read. This address flows into the 373's and is latched by ADS0. From here, the address flows to the RAM. The RAM waits until it receives NMRD from the SNIC and then it drives the data out of the address it was given and into the 374 ports. The 374 ports then latch the data on the rising edge of the NPWR strobe from the SNIC. PRQ is then sent out by the SNIC to let the system know that there is data waiting in the ports.

If the AT reads the I/O ports before the SNIC has loaded the 374's, then the port request (PRQ) from the SNIC will not yet be driven. This unasserted PRQ signal causes the AT's ready line to be set low, indicating that the SNIC has yet to load the data. After the data is in the ports, the system

must then read the 374 data ports. This begins with the AT driving out an address which is decoded (inside the PAL) to the data I/O Ports (310-317). The PAL then drives RACK to the SNIC, indicating that the CPU is ready to accept data. This RACK signal then reads the data from the 374 ports onto the AT BUS. The system deasserts NIOR which finishes the cycle.

#### Remote Write

Like the remote read, the remote write cycle also begins with five slave accesses into the internal registers. The CPU must write the Remote Start Address (2 bytes), the Remote Byte Count (2 bytes) and issue the Remote DMA Read Command. The SNIC then issues a PRQ. The CPU responds by sending a NIOW, indicating that it is ready to write to the ports. The CPU also drives out the address which corresponds to the I/O Ports. This address goes into the PAL and helps to decode to WACK. This WACK signal latches the data into the 374 ports. The SNIC issues a BREQ and immediately receives a BACK since the two lines are tied together (BREQ can be tied to BACK because there are no other devices contending for the local bus). The SNIC, upon receiving the BACK, drives out address lines to the 373's. These address lines are latched by ADS0 and then are driven to the RAM. SNIC sends out a PRD and a MWR which drives the data from the 374 ports into the already specified address of the onboard memory. Soon afterwards, the PRD and the MWR are deasserted and the cycle ends.

#### Network Transfers

Transfers to and from the network are controlled by the DP83901's local DMA channel which transfers packet data to/from the SNIC's internal FIFO from/to the card's buffer RAM.

#### Receive

The data comes off of the network, is deserialized and is stored in the FIFO inside of the SNIC. The SNIC then issues a BREQ and immediately receives BACK since the lines are tied together. After receiving BACK, the SNIC drives the address lines to the 373's. The 373's are latched by ADS0 and the address is allowed to flow to the RAM. Then the SNIC drives out NMWR along with the data from the FIFO. The data flows into the RAM at the address given earlier. After this, the NMWR strobe is deasserted thereby causing the cycle to end.

#### Transmit

To begin the transmit cycle, the SNIC issues a BREQ and waits for BACK. Since BREQ and BACK lines are tied together, BACK signal is received immediately. Upon reception of this signal, the SNIC drives out the address to the 373's which latch the address with the ADS0 strobe. The address then flows to the onboard memory. NMRD, driven by SNIC, causes the RAM to drive the data out of the given address and into the SNIC. The SNIC then latches the data into the FIFO on the rising edge of NMRD. This high assertion of NMRD signifies the ending of this cycle. From the FIFO, the data is serialized and transmitted onto the network.

## BOARD CONFIGURATION

On the SNIC-AT board there are six jumper blocks as seen in the diagram below. The following pages will explain how to configure these jumpers.

TL/F/10800-3

### Physical Layer

TABLE V. Physical Layer Selection

JB1	JB2	JB3	Physical Layer Selected
on	off	off	twisted pair
off	on	off	thin ethernet
off	off	on	thick ethernet

If JB1 is closed while JB2 and JB3 are open, then the twisted pair interface will be selected. If JB2 is closed while JB1 and JB3 are open, then the thin ethernet will be selected. And finally if JB3 is closed while JB1 and JB2 are open, then the thick ethernet will be selected.

### Interrupt Lines, Board Addresses, and EPROM Addresses

On JB4, there are six possible connections. Four of these are to select an interrupt line. The available interrupt lines include INT3, INT4, INT5, and INT9. The last two possible connections, JP1 and JP0, are used to select the base address for the board. However, if JB6 is connected to V<sub>CC</sub>, then these last two connections select the address of the EPROM also. The possible selections and the jumpers

which should be on (closed) are shown in Table VI. The factory configuration uses the INT3 line for interrupts and has JP1 and JP0 in the on position. This factory configuration is shown in Figure 3, along with the factory configurations for JB5 and JB6.

TABLE VI. Base Address and EPROM Address

JP1	JP0	Base Address	EPROM Address
on	on	300h–31Fh	C800h
on	off	320h–33Fh	CC00h
off	on	340h–35Fh	D000h
off	off	360h–37Fh	D400h

TL/F/10800-4

FIGURE 3. Factory Configuration for JP4, JP5, and JP6

### Low Power SNIC Mode

This low power mode is entirely dependent on JB5. The NLOPWR signal is low-asserted, so in most cases this signal will be jumpered to V<sub>CC</sub>. However, if LAN transmissions are not needed for an extended length of time, the NLOPWR signal may be jumpered to ground. This would turn off the SNI circuitry and conserve power. This feature is primarily provided because the DP83901 enables this function, but can not be practically used in this design.

**PAL EQUATIONS****PAL #1 (U1)**

In this first PAL, the output signals are NIO16, NIOEN, NSNICB, and NCSROM. (The N's before the signals indicate that the signal is low asserted). Since it is necessary to assert NIO16 as soon as possible, this first PAL has been selected to be a 10 ns "D" PAL. The NIO16 signal must be TRI-STATE® when it is not asserted. Therefore, we use an enable signal (NIOEN) which is equal to the decode for the I/O Ports (310-31F) and NAEN high. (NAEN high signifies that the system DMA does not have control of the bus.) The enable signal (NIOEN) loops back into the PAL to bring NIO16 out of TRI-STATE. The NIO16 signal is set to zero so that whenever it is enabled it will be asserted.

The NSNICB signal consists of simple address decodes along with NAEN. The addresses decode to one of four address slots which were mentioned earlier in the board configuration section. The NCSROM is a very simple signal as it consists only of AD14 and NMRD. AD14 comes from the SNIC and selects either the PROM (when low) or the onboard RAM (when high).

## PAL # 2

In this PAL, there are eight outputs which include NRESET, NSOUT, NRDYEN, NIOCHRDY, NCS, NRACK, NWACK and INTO. The first two outputs (NRESET and NSOUT) are part of an R-S flip-flop as shown below:

TL/F/10800-5

FIGURE 4. RS Flip-Flop

NRESET is given by the NOR of the high asserted R-input pin and the NSOUT signal. NSOUT is given by the NOR of the high asserted S-input pin and the NRESET signal. The NOR gates are enabled by the low assertion of NRSTDRV. When the system first boots up, it will disable the NOR gates by asserting the RSTDRV signal. But due to the pull-up and pull-down resistors, the output <NRESET, NSOUT> will be set to <0,1>. Once RSTDRV becomes deasserted, the output will remain at <0,1>. The only way to get out of reset is to assert the S-pin high which is done by an NIOW and an address decode to 318-31F. After the system has booted up, the SNIC may be reset through software. This would be done by setting the R-pin high with an NIOR and an address decode to 318-31F. To escape from reset, we once again set the S-pin high with an NIOW and address decode of 318-31F. The above description of logic is also shown in Truth Table VII.

TABLE VII. R-S Flip-Flop Truth Table

R (NIOR)	S (NIOW)	Q (NRESET)	$\bar{Q}$ (NSOUT)
0	0	0	1
0	1	1	0
0	0	1	0
1	0	0	1
0	0	0	1
0	1	1	0

By using the NIOR and NIOW which are never asserted at the same time, this insures that the R-pin and the S-pin will never be asserted at the same time. The next two signals (NRDYEN and NIOCHRDY) are quite similar to NIOEN and NIO16 in PAL #1. All of the decode takes place in the enable signal (NRDYEN). This decode consists of addresses 300-30F without NACK or the addresses 310-318 without PRQ. If the NRDYEN signal is asserted, then NIOCHRDY will be driven low. At all other times, the NIOCHRDY strobe will be in TRI-STATE. NCS is decoded by NSNICB (from PAL #1) along with the low assertion of SA4 and either NIOR or NIOW. Its decode is in the address range of 300-30F. The last two signals are NRACK and NWACK. NRACK occurs with an address decode to 310-31F, an NIOR, and a PRQ. The NWACK signal only differs from the NRACK by the NIOR/NIOW signal and therefore consists of an address decode to 310-318, an NIOW, and a PRQ. INT is just sent through the PAL to be buffered. The buffered signal which comes out of the PAL is INTO.

end reset;

```

**PAL #3**

The third PAL only does a decode to enable the optional EPROM. This decode consists of an address decode to C800h, CC00h, D000h, or D400h depending on JP1 and JP0 as shown in the board configuration section. JP2 must also be jumpered for selection of the EPROM. NAEN, a low asserted signal should be high to indicate that the DMA does not have control of the bus and the NSMRDC signal should be asserted low since the CPU is doing a system memory read.

A013 output is used to generate a signal to the lower byte RAM. This signal will route A0 to the RAM when EN16 is high enabling 8-bit operation.

# DP83902EB-AT PC-AT® Compatible DP83902 ST-NIC™ Ethernet Evaluation Board

National Semiconductor  
Application Note 752

AN-752

## OVERVIEW

The National Semiconductor ST-NIC Evaluation Board design provides IBM® AT's and AT Compatibles with Thick Ethernet, Thin Ethernet, and Twisted Pair connections. This low parts count Evaluation Board is compatible with the AT bus and requires only a 1/2 size slot for insertion. The board uses the DP83902 (ST-NIC) to interface to twisted pair Ethernet. The ST-NIC also has an AUI Port which allows interface to thick wire Ethernet, or thin wire Ethernet by the addition of the DP8392 Coaxial Transceiver Interface (CTI). The dual DMA (local and remote) capabilities of the ST-NIC, along with 16 Kbytes of buffer RAM, allow the entire Network Interface Adapter to appear as a standard I/O Port to the system. The NIC module's local DMA channel buffers packets between the local memory (16 Kbytes of buffer RAM) and the network, while the NIC module's remote DMA channel passes data between the local memory and the system by way of an I/O Port. This I/O Port architecture which isolates the CPU from the network traffic proves to be the simplest method to interface the DP83902 to the system.

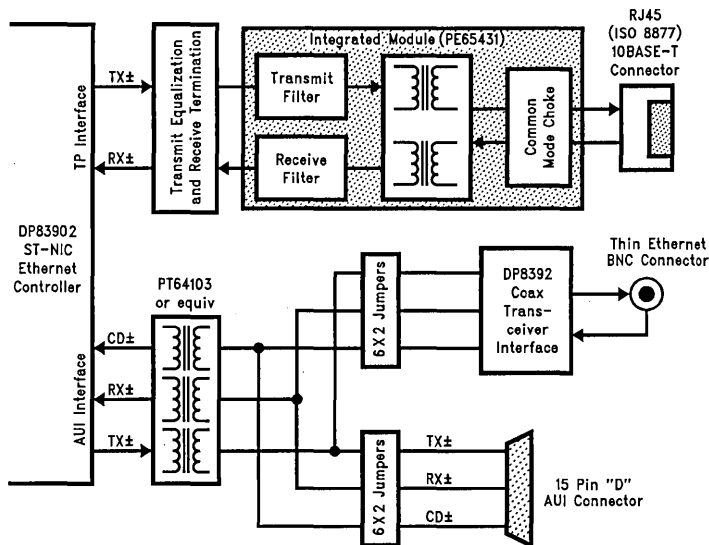

## HARDWARE FEATURES

- Half-size IBM PC-AT I/O Card Form Factor
- Utilizes DP83902 Serial Network Interface Controller for Twisted Pair (ST-NIC)
- 16 Kbyte on-board Packet Buffer
- Simple I/O port interface to IBM PC-AT
- Interfaces to Thick Ethernet, Thin Ethernet, and Twisted Pair
- Boot EPROM Socket

The detailed schematics for this design are shown at the end of this document.

## NETWORK INTERFACE OPTIONS

The evaluation board supports three physical layer options: Thick Ethernet, Thin Ethernet, and Twisted Pair. The block diagram for these interfaces can be seen in *Figure 1*. When using Thick Ethernet, a drop cable is connected to an external transceiver which is in turn connected to a standard Ethernet network, eliminating the need for an internal transceiver. This configuration may be obtained by connecting the pins on JB3 while leaving JB2 open, and connecting JB9 (AUTP) to V<sub>CC</sub>.

TL/F/11158-1

FIGURE 1. Physical Layer Adapter Interface Block Diagram

1

When using Thin Ethernet, a transceiver (the CTI) is available on-board to allow the evaluation board to directly connect to the network. This transceiver (the CTI) forms the link between the differential ECL signals of the SNI module and the non-differential ECL signal of the thin-wire coaxial cable. A DC-DC Converter is provided on the board to supply the CTI with  $-9V$  isolated voltage source. The Thin Ethernet solution is made by connecting the pins on JB2, leaving JB3 open and JB9 (AUTP) should be connected to  $V_{CC}$ .

When using the Twisted Pair, JB9 (AUTP) needs to be connected to ground. The ST-NIC allows direct connection to the network using the RJ-45 phone jack. The remaining circuitry includes pre-emphasis resistors, a filter, a transformer/filter and a common mode choke. The transformer/filter decouples the DC component and eliminates any possible voltage spikes.

The diagram in *Figure 2* illustrates the layout of the board. It shows the various jumpers, ICs, LEDs, and the connectors for the three physical layer options. The transmit pre-emphasis resistors R27-R30 provide equalization to the twisted pair transmit outputs. This boosts the higher harmonics of the signal in order to compensate for losses in these harmonics over the twisted pair cable. R19 and R20 are  $50\Omega$  each and when combined form the required  $100\Omega$  termination on the receive side.

#### BUS INTERFACE

The block diagram, *Figure 3*, illustrates the architecture of the ST-NIC Evaluation Board. The ST-NIC Board as seen by the system appears only to be an I/O port. With this architecture the ST-NIC board has its own local bus to access the board memory. The system never has to intrude further than the I/O ports for any packet data operation. This I/O architecture isolates the system bus and the local bus, thereby preventing interference by the system when the ST-NIC is doing real-time accesses such as transmitting and receiving packets.

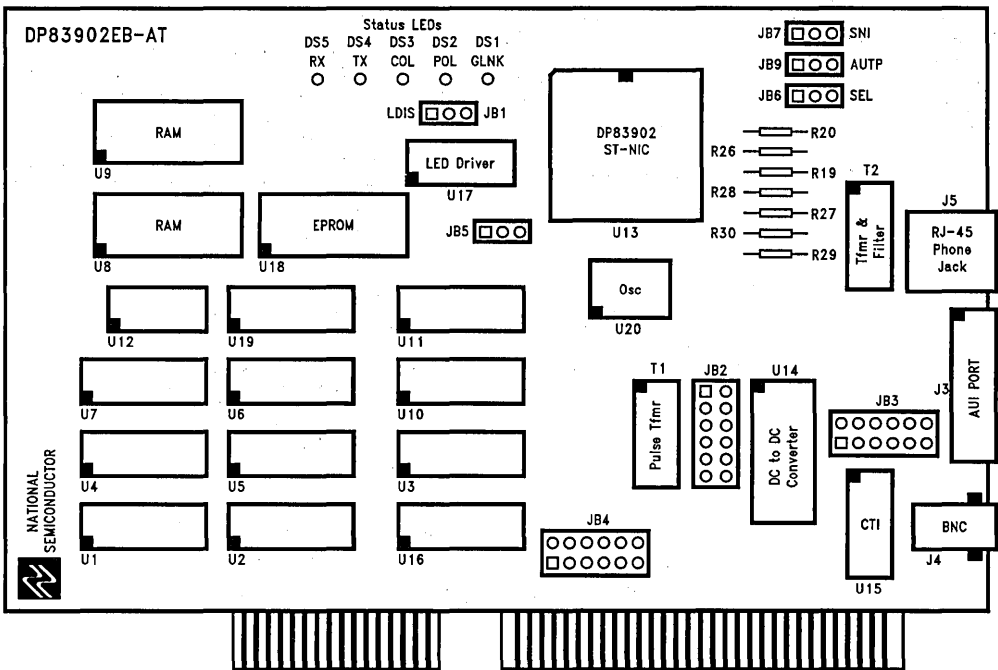

FIGURE 2. Layout of ST-NIC Evaluation Board

TL/F/11158-2

**BOARD ARCHITECTURE**

**I/O Map of ST-NIC Board**

The ST-NIC Board requires a 32-byte I/O space to allow for decoding the data buffers, the reset port, and the ST-NIC registers. The first 16 bytes (300h-30Fh) are used to address the ST-NIC registers (8 bits wide) and the next 8 bytes (310h-317h) are used to address the data buffers which are 16 bits wide. Finally, the reset port (also software selectable) may be addressed by 318h-31Fh.

**TABLE I. I/O MAP in PC-AT**

Address	Part Addressed
300h-30Fh	ST-NIC Chip Select
310h-317h	Data Buffers
318h-31Fh	Reset

Although in the description above the I/O map is positioned at the addresses 300-31F, it may also be placed in the following address spaces: 320-33F, 340-35F, 360-37F.

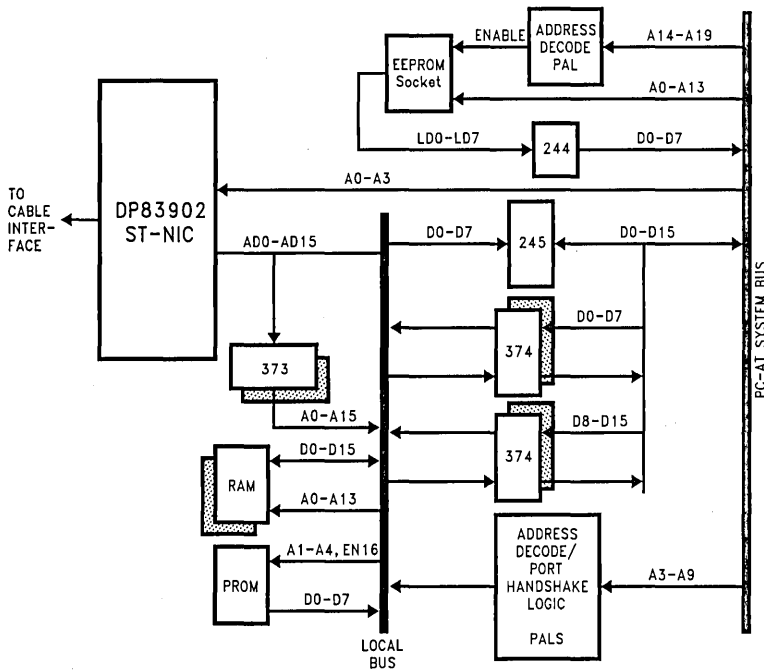

These alternate address spaces may be selected by the two jumper pins JP1 and JP0 (refer to JB4 in *Figure 4* and Appendix A).

**DP83902's Local Memory Map**

There are only two items mapped into the local memory space. These two items being the 8K x 16 buffer RAM and the ID address PROM. The buffer RAM is used for temporary storage of transmit and receive packets.

**TABLE II. ST-NIC's Local Memory Map**

7FFFh	RAM
4000h	
3FFFh	PROM
0000h	

**FIGURE 3. Block Diagram of ST-NIC Evaluation Board's System Interface**

TL/F/111158-3

For transmit packets, the remote DMA puts data from the I/O ports into the RAM and the local DMA moves the data from the RAM to the ST-NIC. For the receive packets, the local DMA carries the data from the ST-NIC to the RAM and the remote DMA moves the data from the RAM to the I/O ports. The ID address PROM (74S288 32 x 8) contains the physical address of the evaluation board. Each PROM holds its own unique physical address which is installed during its manufacture. The PROM also contains some identification bytes that can be checked by the driver software. At the initialization of the evaluation board the software commands the ST-NIC to transfer the PROM data to the I/O Port where it is read by the CPU. The CPU then loads the ST-NIC's physical address registers. The following chart shows the contents of the PROM.

**TABLE III. PROM Contents**

PROM Location	Location Contents
00h	Ethernet Address 0 (Most Significant Byte)
01h	Ethernet Address 1
02h	Ethernet Address 2
03h	Ethernet Address 3
04h	Ethernet Address 4
05h	Ethernet Address 5
06h-0Dh	00h
0Eh, 0Fh	57h
10h-15h	Ethernet Address 0 thru 5
16h-1Dh	Reserved
1Eh, 1Fh	42h

#### Data and Address Paths

For the following paragraph, refer to the block diagram shown in *Figure 3*. Twenty address lines from the PC go onto the ST-NIC Board, but only four of them actually go to the ST-NIC. These four addresses along with the NIOR (low-asserted I/O read) or NIOW (low-asserted I/O write) and the CS (ST-NIC chip select signal) allow the PC to read or write to the ST-NIC's registers. If the system wants to read from or write to the ST-NIC registers, the data (only 8 bits) must pass through the 245 buffer. All of the packet data will pass through the I/O ports (the 374's). Each 374 is unidirectional and can only drive 8 bits, therefore it is necessary to have four 374's. Two of which drive data from the ports to the board memory and two of which drive the data from the ports to the AT bus. Even the PROM, which can only be addressed by the ST-NIC, sends its 8 bits of data out through the 374's. When the PROM does this, two of the 374's will be enabled but only the lower 8 bits will be read by the system. The RAM is also accessed by the ST-NIC. However, it is addressed by 14 bits and drives out 16 bits of data. The PALs receive 7 address lines among many other signals such as NIOR, NIOW, NACK, MRD, etc. With these signals the PALs do all of the decodes, such as selecting the ST-NIC Board, the ST-NIC chip, the RAM, and the PROM.

#### EPROM SOCKET

The EPROM socket is provided so that the user may add an EPROM to the system. This EPROM would normally contain a program and a driver to enable the PC-AT to be booted up through the network. The chips necessary to interface the EPROM to the system are the 27128 (EPROM), a 16L8 (PAL), and a 74ALS244 (buffer). Also, JB5 must be placed in the proper selection as described in the jumper section. The PAL decodes SA14-SA19, along with SMRDC (system memory read), in order to generate the EPROMEN signal. This signal, issued when the PC wants to execute the program stored in the EPROM, enables the EPROM and the 244 buffer.

#### EVALUATION BOARD OPERATION

The following pages will describe the slave accesses to the ST-NIC and the local DMA and remote DMA operation.

#### Register Operations

Accesses to the board are register operations to the DP83902, which are done to set up the ST-NIC and to control the operation of the ST-NIC's DMA channels.

#### REGISTER READ

To begin the register read, the CPU drives the four address lines (SA0-SA3) to the ST-NIC and the SA3-SA9 address lines to the PAL. These address lines are decoded by the PAL in order to generate a chip select to the ST-NIC. The CPU also drives the NIOR line which the ST-NIC sees as the NSRD (slave read). Once the ST-NIC receives this NSRD, it then sends out a high assertion on NACK, acknowledging that it is in slave mode but not yet ready to complete the read. The NACK signal is used by the PAL to assert the IOCHRDY (used to insert wait states) signal false. The ST-NIC then drives out the data from its internal registers to the 245 buffer. The 245 buffer is then enabled and the data is driven onto the AT BUS. When the ST-NIC is ready, it asserts NACK true and the PAL asserts IOCHRDY true. As a result, NIOR is driven high by the CPU, thereby deasserting the NSRD. On the rising edge of the NIOR, the data which is on the AT BUS is latched into the system. The addresses are removed at the same time, causing the ST-NIC chip select to become deasserted, ending the register read cycle.

#### REGISTER WRITE

To begin the register write, the CPU drives the SA0-SA3 address lines to the ST-NIC and the SA4-SA9 address lines to the PAL. With these address lines, the PAL decodes to 300-30F (the ST-NIC registers) thereby enabling the chip select for the ST-NIC. The CPU then drives the NIOW strobe which the ST-NIC sees as NSWR (slave write). Once the ST-NIC receives this NSWR it sends back a low assertion on NACK to acknowledge that it is in slave mode and ready to perform the write. When the CPU receives this signal, it puts data out onto the AT BUS where it goes into the 245 buffer. The 245 buffer then drives the data to the ST-NIC, but the data is not latched into the ST-NIC until the rising edge of NIOW. The system drives NIOW high, thereby deasserting the NSWR and latching the data. The addresses also are taken away and the chip select then goes high (deasserted). This ends the cycle of the register write.

## Remote Transfers

Remote DMA transfers are operations performed by the ST-NIC on the board. These operations occur when the ST-NIC is programmed to transfer packet data between the PC-AT and the card's on-board RAM. These transfers take place through the I/O Port interface.

### REMOTE READ

To program the ST-NIC for a remote read, the CPU must make five slave accesses to the ST-NIC. The CPU must write the Remote Start Address (2 bytes), the Remote Byte Count (2 bytes), and issue the Remote DMA Read Command. The addresses and byte count require two transfers because they are both 16 bits, yet only 8 bits can be written per transfer.

Once the ST-NIC has received all of the above data, it drives out BREQ and waits for BACK. The ST-NIC immediately receives BACK because it is tied to the BREQ line. (BREQ can be tied to BACK because there are no other devices contending for the local bus.) After receiving BACK, the ST-NIC drives out the address from which the data is required to be read. This address flows into the 373's and is latched by ADS0. From here, the address flows to the RAM. The RAM waits until it receives MRD from the ST-NIC and then it drives the data into the 374 ports. The 374 ports then latch the data on the rising edge of the PWR strobe from the ST-NIC. PRQ is then sent out by the ST-NIC to let the system know that there is data waiting in the ports.

If the AT reads the I/O ports before the ST-NIC has loaded the 374's, then the port request (PRQ) from the ST-NIC will not yet be driven. This unasserted PRQ signal causes the AT's ready line to be set low, indicating that the ST-NIC has yet to load the data. After the data is in the ports, the system must then read the 374 data ports. This begins with the AT driving out an address which is decoded (inside the PAL) to the data I/O Ports (310–31F). The PAL then drives RACK to the ST-NIC, indicating that the CPU is ready to accept data. This RACK signal then reads the data from the 374 ports onto the AT BUS. The system deasserts NIOR which finishes the cycle.

### REMOTE WRITE

Like the remote read, the remote write cycle also begins with five slave accesses into the internal registers. The CPU must write the Remote Start Address (2 bytes), the Remote Byte Count (2 bytes), and issue the Remote DMA Write Command. The ST-NIC then issues a PRQ. The CPU responds by sending an NIOW, indicating that it is ready to write to the ports. The CPU also drives out the address which corresponds to the I/O Ports. This address goes into the PAL and helps to decode to WACK. This WACK signal latches the data into the 374 ports. The ST-NIC issues a BREQ and immediately receives a BACK since the two lines are tied together. (BREQ can be tied to BACK because there are no other devices contending for the local bus.) The ST-NIC, upon receiving the BACK, drives out address lines to the 373's. These address lines are latched by ADS0 and then are driven to the RAM. ST-NIC sends out a PRD and a NMWR which drives the data from the 374 ports into the already specified address of the onboard memory. PRD and NMWR are then deasserted and the cycle ends.

## Network Transfers

Transfers to and from the network are controlled by the DP83902's local DMA channel which transfers packet data to/from the ST-NIC's internal FIFO from/to the card buffer's RAM.

### RECEIVE

The data comes off of the network, is deserialized and is stored in the FIFO inside of the ST-NIC. The ST-NIC then issues a BREQ and immediately receives BACK since the lines are tied together. After receiving BACK, the ST-NIC drives the address lines to the 373's. The 373's are latched by ADS0 and the address is allowed to flow to the RAM. Then the ST-NIC drives out NMWR along with the data from the FIFO. The data flows into the RAM under the address given earlier. The NMWR strobe is then deasserted, ending the cycle.

### TRANSMIT

To begin the transmit cycle, the ST-NIC issues a BREQ and waits for the BACK. Since the BREQ and BACK lines are tied together, the BACK signal is received immediately. Upon reception of this signal, the ST-NIC drives out the address to the 373's which latch the address with the ADS0 strobe. The address then flows to the onboard memory. NMRD, driven by ST-NIC, causes the RAM to drive the data out of the given address and into the ST-NIC. The ST-NIC then latches the data into the FIFO on the rising edge of NMRD. This high assertion of NMRD signifies the ending of this cycle. From the FIFO, the data is serialized and transmitted onto the network.

## BOARD CONFIGURATION

On the DP83902EB-AT ST-NIC AT board, there are nine jumper blocks as seen in the diagram below. The following pages will explain how to configure these jumpers.

### Physical Layer

If JB9 is tied to Ground then the twisted pair interface will be selected. If JB2 is closed while JB3 is open, and JB9 is connected to V<sub>CC</sub>, then the Thin Ethernet option will be selected. And finally if JB3 is closed while JB2 is open, and JB9 is high, then the Thick Ethernet option will be selected. Refer to Appendix A for Jumper settings.

### Interrupt Lines, Board Addresses, and EPROM Addresses

On JB4, there are six possible connections. Four of these are to select an interrupt line. The available interrupt lines include INT3, INT4, INT5, and INT9. The last two possible connections, JP1 and JP0, are used to select the base address for the board. However, if JB5 is connected to V<sub>CC</sub>, then these last two connections select the address of the EPROM also. The possible selections and the jumpers are shown in Appendix A. The factory configuration uses the INT3 line for interrupts and has JP1 and JP0 in the on position.

This factory configuration is shown in *Figure 4*, along with the factory configurations for JB1, JB5, JB6, JB7, JB8, and JB9. The square pin indicates pin 1 of the jumpers.

TL/F/11158-4

**FIGURE 4. Factory Configuration for JB1, JB4, JB5, JB6, JB7, JB8 and JB9**

**APPENDIX A**

The following tables show all of the various jumper settings. The shaded boxes are the Factory Configuration default settings.

<b>JB1</b>	High	Link Enabled
	Low	Link Disabled
<b>JB5</b>	High	EPROM Address
	Low	Base Address
<b>JB6</b>	High	Tx+ and Tx- are same in idle state
	Low	Tx+ is positive with respect to Tx- in idle state
<b>JB7</b>	High	Normal Operation
	Low	ENDEC Module Testing
<b>JB8</b>	High	Internal Function Testing
	Low	Normal Operation

<b>JB9</b>	<b>JB2</b>	<b>JB3</b>	<b>Physical Layer Selected</b>
Low	X	X	Twisted Pair

Off	Off	300h-37Fh	D400h

## APPENDIX B: PAL® EQUATIONS

## PAL #1 (U1)

In this first PAL, the output signals are NIO16, NIOEN, NSTNICB, and NCSROM. (The N's before the signals indicate that the signal is low asserted.) Since it is necessary to assert NIO16 as soon as possible, this first PAL has been selected to be a 10 ns "D" PAL. The NIO16 signal must be TRI-STATE® when it is not asserted. Therefore, we use an enable signal (NIOEN) which is equal to the decode for the I/O Ports (310-31F) and NAEN high (NAEN high signifies that the system DMA does not have control of the bus). The

enable signal (NIOEN) loops back into the PAL to bring NIO16 out of TRI-STATE. The NIO16 signal is set to zero so that whenever it is enabled it will be asserted.

The STNICB signal consists of simple address decodes along with NAEN. The addresses decode to one of four address slots which were mentioned earlier in the board configuration section. The NCSROM is a very simple signal as it consists only of AD14 and NMRD. AD14 comes from the ST-NIC and selects either the PROM (when low) or the onboard RAM (when high).

```

TL/F/11158-5

**PAL #2**

In this PAL there are eight outputs: NRESET, NSOUT, NRDYEN, NIOCHRDY, NCS, NRACK, NWACK and INTO. The first two outputs (NRESET and NSOUT) are part of an R-S flip flop as shown below:

TL/F/11158-6

**FIGURE 5. RS Flip-Flop**

NRESET is given by the NOR of the high asserted R-input pin and the NSOUT signal. NSOUT is given by the NOR of the high asserted S-input pin and the NRESET signal. The NOR gates are enabled by the low assertion of NRSTDRV. When the system first boots up, it will disable the NOR gates by asserting the RSTDRV signal. But due to the pull-up and pull-down resistors, the output <NRESET, NSOUT> will be set to <0, 1>. Once RSTDRV becomes deasserted, the output will remain at <0, 1>. The only way to get out of reset is to assert the S-pin high which is done by an NIOW and an address decode to 318-31F. After the system has booted up, the ST-NIC may be reset through software. This would be done by setting the R-pin high with an NIOR and an address decode to 318-31F. To escape from reset, we once again set the S-pin high with an NIOW and address decode of 318-31F. The above description of logic is also shown in Truth Table VII.

**TABLE IV. R-S Flip Flop Truth Table**

R (NIOR)	S (NIOW)	Q (NRESET)	$\bar{Q}$ (NSOUT)
0	0	0	1
0	1	1	0
0	0	1	0
1	0	0	1
0	0	0	1
0	1	1	0

By using the NIOR and NIOW which are never asserted at the same time, this insures that the R-pin and the S-pin will never be asserted at the same time. The next two signals (NRDYEN and NIOCHRDY) are quite similar to NIOEN and NIO16 in PAL#1. All of the decode takes place in the enable signal (NRDYEN). This decode consists of addresses 300-30F without NACK or the addresses 310-318 without PRQ. If the NRDYEN signal is asserted, then NIOCHRDY will be driven low. At all other times, the NIOCHRDY strobe will be in TRI-STATE. This PAL must also be a 10 ns "D" PAL.

NCS is decoded by NSTNICB (from PAL #1) along with the low assertion of SA4 and either NIOR or NIOW. Its decode is in the address range of 300-30F. The last two signals are NRACK and NWACK. NRACK occurs with an address decode to 310-318, an NIOR, and a PRQ. The NWACK signal only differs from the NRACK by the NIOR/NIOW signal and therefore consists of an address decode to 310-31F, an NIOW and a PRQ. INT is just sent through the PAL to be buffered. The buffered signal which comes out of the PAL is INTO.

end reset;

```

TL/F/11158-7

**PAL #3**

The third PAL only does a decode to enable the optional EPROM. This decode consists of an address decode to C800h, CC00h, D000h, or D400h depending on JP1 and JP0 as shown in the board configuration section. JP2 must

also be jumpered for selection of the EPROM. NAEN, a low asserted signal should be high to indicate that the DMA does not have control of the bus and the NSMRDC signal should be asserted high since the CPU is doing a system memory read.

# NM95C12 Applications in a PC-AT® Ethernet® Adapter

National Semiconductor  
 Application Note 792  
 Sean Long

## INTRODUCTION

This application describes a typical Ethernet adapter card designed to be plugged into a PC-AT expansion slot. The board is designed around the National Semiconductor DP83932 SONIC™ Network Controller device. This application note will detail the system design and focus on the functions performed by the NM95C12 EEPROM.

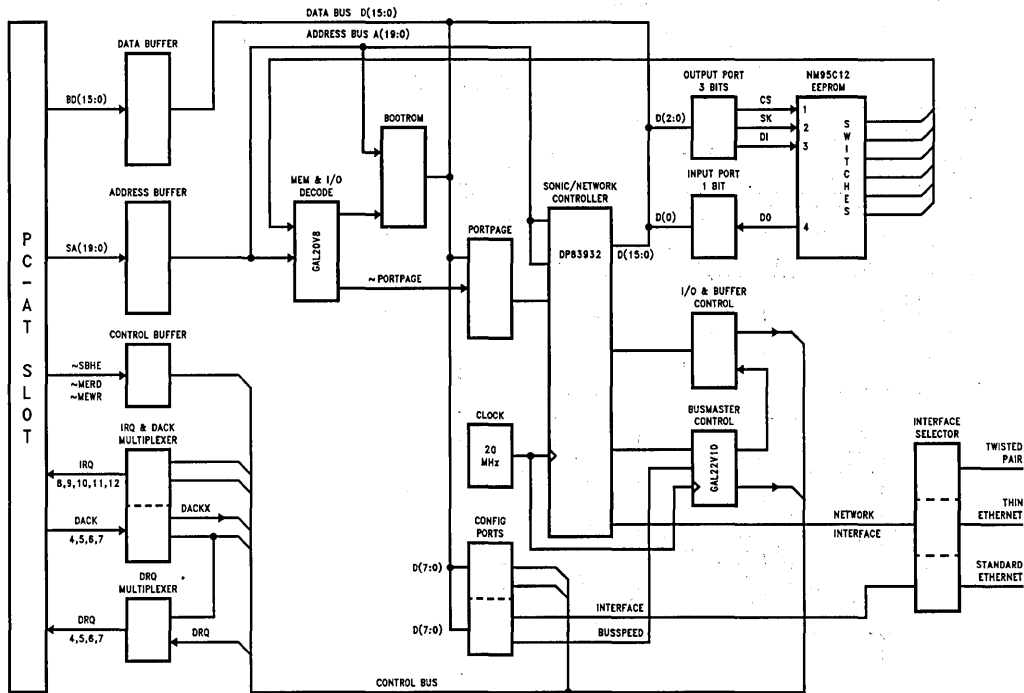

This application note assumes that the reader is familiar with the PC-AT architecture, the DP83932 device, the NM95C12 EEPROM and designing with GAL® Programmable Logic Devices (PLDs).

## SYSTEM DESCRIPTION

The network controller card has been designed to meet the following specifications:

- Designed around high performance 32-bit DP83932 Ethernet Controller
- 16-Bit bus master operation to give higher performance
- Fully software configurable (no jumpers or mechanical DIP switches)
- Extensive test and configuration capabilities
- Supports different media interfaces
- Bootrom option

The system block diagram is shown in *Figure 1*.

TL/D/11265-1

\*Denotes an active low signal.

FIGURE 1. System Block Diagram

## FUNCTIONAL DESCRIPTION OF THE BOARD

The system contains the following logical functions:

1. Network controller (DP83932)
2. Cable interfaces
3. Busmaster interface logic, including data and address buffers
4. EPROM option for remote boot loader

This system uses both the EEPROM locations and the switch logic terminals of the NM95C12 to perform various functions within the system as detailed below.

## FUNCTIONAL DESCRIPTION OF NM95C12 EEPROM

Use of the Switches:

The switch terminals of the NM95C12 EEPROM are used as part of the memory map address decoding and the I/O map decoding circuitry, feeding as inputs to a GAL20V8 which performs the address decoding logic from the system address inputs.

The NM95C12 switches control:

1. The base I/O address of the network controller board.
2. The base memory address of the bootrom EPROM option on the board.

## ADDRESS DECODING

The address decoding is controlled by a GAL20V8 PLD (refer to the 1990 National Semiconductor PLD Databook and Design Guide for further information) as shown in *Figure 2*.

The inputs to the GAL20V8 are the system address lines, the memory and I/O control signals, and the switch terminals

from the NM95C12. The outputs from the GAL20V8 are the various chip select signals for the memory and I/O ports. The system address bus transmits the current address value and the  $M/\sim IO$  signal determines if a memory or I/O cycle is in progress.

Address lines A0-A19 allow up to 1 Meg (0-FFFFFF) of memory to be addressed, while address lines A0-A15 allow up to 64K (0-FFFF) of I/O ports to be addressed. If the control signal  $M/\sim IO$  is logical "1" (high) then the processor is performing a memory cycle and if the  $M/\sim IO$  signal is logical "0" then an I/O cycle is in operation.

For a PC-AT various memory and I/O locations are reserved for standard functions such as system memory and I/O (refer to PC-AT documentation to determine which memory and I/O locations are free for add-in boards).

The switch outputs from the NM95C12 are connected as inputs to the GAL address decode logic and are used to determine the base memory and I/O locations for the add-in card. *Figure 2* shows the typical use of a GAL for address decoding.

The advantage of using a PLD for the address decoding is that it is an easy way to implement different address decode functions by logic equations. The logic equations can be implemented with a standard PLD design compiler such as OPAL™ from National Semiconductor or a third party software package such as ABEL™ from Data I/O. The PLD compiler will take the logic equations and convert them into the GAL fuse map which can be used for programming on a wide range of device programmers. A typical set of logic equations using National Semiconductors OPAL software package is shown in *Figure 3*.

```

FIGURE 3. GAL® Logic Equations

#### USE OF THE NM95C12 EEPROM LOCATIONS

- Three locations are used to store the ethernet address of the card.
- One location is used to store the interrupt number and the DMA channel of the board.
- One location is used to store the busmaster speed setting of the card.
- Two locations are used to store information about the production flow of the board e.g.; the version number of the out-going inspection, and serialization program which stores a unique ethernet address in the EEPROM.
- There are also some EEPROM locations used to enable some special features in the network driver such as protocol, DMA priority, etc.

Figure 4 below shows the memory usage of the NM95C12.

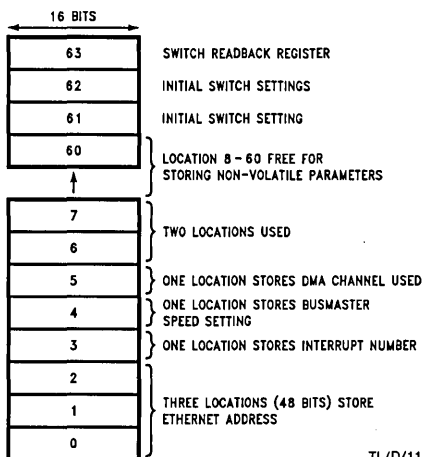

FIGURE 4. Memory Locations Used In NM95C12

#### FUNCTIONAL DESCRIPTION OF THE SOFTWARE

The driver for the card can be supplied in two ways:

1. As a driver which is loaded from the disk.
2. As a bootrom which is located at the card.

The driver determines the base I/O address of the card. This is done by scanning the possible I/O map where the card can be located (seven possible locations) and testing if the NM95C12 EEPROM can be found.

The EEPROM is found if, after an address is shifted in the EEPROM, the DO output from the NM95C12 has become logical "zero". Then the CS pin will be disabled and there will be a check if the DO output pin will become high (this pin is pulled up with a 47K resistor).

When the software finds the base address of the card, it reads the locations which contain the DMA and IRQ number to use and programs these values into the corresponding output latches. These latches will enable and/or multiplex the corresponding DMA (DACKx, DRQx) and INT (IRQx) to the busmaster logic and interrupt logic.

The same operation is done for the busmaster speed, one location in the EEPROM determines the active low and high time for busmaster cycles, the output of this latch will go to the busmaster state machine (implemented in a GAL22V10).

The ethernet address will be read by the driver and copied to a private location in the driver data area for use with the network software.

The bootrom can be located at five locations in memory (controlled by the NM95C12 switch logic) and can be disabled if required.

#### CONCLUSION

This application has shown the many advantages of the NM95C12 EEPROM with DIP Switches. In this example the NM95C12 replaces the functions typically performed by a Bipolar PROM (store ethernet address), mechanical DIP switches/jumpers (select options), and general read/write logic (software testing of the hardware configuration). The use of the switch terminals as part of the address decode logic makes the address decode function more flexible and allows for software control.

The easy interfacing to the NM95C12 (just four pins) and the simple, but powerful instruction set allows the NM95C12 to give the system designer:

- Greater flexibility
- Fully software controllable and testable
- Greater reliability (no mechanical switches or jumpers)
- Reduced component count
- Lower component cost

# The Design and Operation of a Low Cost, 8-Bit PC-XT® Compatible Ethernet Adapter Using the DP83902

National Semiconductor  
Application Note 842  
Larry Wakeman

## OVERVIEW

This 8-Bit Ethernet adapter board design is an inexpensive-low part count design that provides PC-XT and PC-AT® compatibles with Thick, Thin, and Twisted Pair Ethernet connectivity. This design provides an 8-bit interface that is compatible with Novell's 8-bit NE1000, while using the DP83902 (ST-NIC™) to interface to twisted pair Ethernet. The ST-NIC also has an AUI interface which allows interface to thick wire Ethernet, or thin wire Ethernet by the addition of the DP8392 Coaxial Transceiver Interface (CTI). The dual DMA (local and remote) capabilities of the ST-NIC, along with 8 kbytes of buffer RAM, and bus interface logic provide a high performance 8-bit interface. The I/O port architecture used in this design isolates the CPU from the network traffic, proves to be the simplest method to interface the DP83902 to a PC system bus.

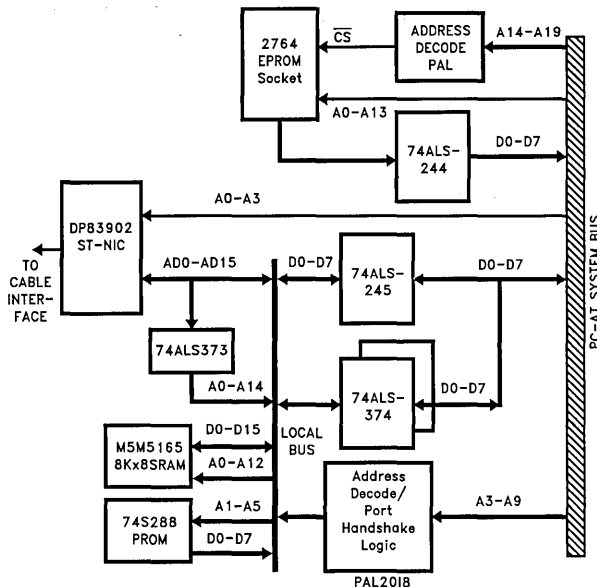

This paper describes the basic design and operation of this 8-bit adapter card, and then follows this with specific design information including the PAL equations and a detailed schematic of the design. For detailed information refer to the schematics at the end of this document.

## HARDWARE FEATURES

- Fits in a half-size IBM XT form factor
- Utilizes DP83902 twisted pair network interface controller (ST-NIC)
- 8 kbyte on-board packet buffer
- Simple I/O port interface software compatible with Novell's NE1000 Ethernet adapter
- Interfaces to Thick (10BASE5), Thin (10BASE2), and Twisted Pair (10BASE-T) Ethernet
- Boot EPROM socket

## BUS INTERFACE

The block diagram for this design is shown in *Figure 1*. The ST-NIC board as seen by the system appears only to be a block of I/O ports. With this architecture the ST-NIC board has its own local bus to access the board's memory. The system never has to intrude further than the I/O ports for any packet data operation. There are two register/memory maps that describe the card. The first is the I/O register map that describes how the PC's processor accesses the card. The second map is the one that describes how the ST-NIC accesses the on-card memory.

TL/F/11492-1

FIGURE 1. System Bus Block Diagram for 8-Bit Ethernet Card

**I/O Map**

The ST-NIC board requires a 32 byte I/O space to allow for decoding the data port, the reset port, and the ST-NIC registers. This is shown in Table I. The first 16 bytes are the ST-NIC registers, the next 16 bytes address the data port and the reset port, which are aliased alternately as shown.

**TABLE I. I/O Map In PC-AT**

Address Offset	Device Accessed
00h-0Fh	ST-NIC Registers
10h-13h	Data I/O Port
14h-17h	Reset Port
18h-1Bh	Data I/O Port
1Ch-1Fh	Reset Port

Additionally there are three jumpers which define the base addresses for the address map shown in Table I. (See the Jumper Configuration section for details.)

**On-Card Memory Map**

There are only two items mapped into the local memory space. These two items being the 8k x 8 buffer RAM and the Ethernet ID address PROM. The buffer RAM is used for temporary storage of transmit and receive packets.

**TABLE II. ST-NIC's Local Memory Map**

	etc.	ST-NIC A13 Low = PROM ST-NIC A13 High = RAM
7FFF	RAM	← The PROM and RAM are Aliased through 64K Address Range.
6000 5FFF		
4000 3FFF	PROM	
2000 1FFF	RAM	
0000	PROM	← The 'S288 PROM Actually Takes 32 Locations and is Aliased for Each 8K Block.

The buffer RAM is used for temporary storage of network packet data that is either being transmitted or received. The ID address PROM (74S288 32 x 8) contains the physical address of the evaluation board. Each PROM holds its own unique physical address which is installed during its manufacture. Besides this address, the PROM also contains some identification bytes that can be checked by the driver software. At the initialization of the evaluation board the software commands the ST-NIC to transfer the PROM data

to the I/O Port where it is read by the CPU. The CPU then loads the ST-NIC's physical address registers. The following table shows the contents of the PROM.

**TABLE III. PROM Contents**

PROM Location	Location Contents
00h	Ethernet Address 0 (Most Significant Byte)
01h	Ethernet Address 1
02h	Ethernet Address 2
03h	Ethernet Address 3
04h	Ethernet Address 4
05h	Ethernet Address 5
06h-0Dh	00h
0Eh, 0Fh	57h
10h-15h	Ethernet Address 0-5
16h-1Dh	Reserved
1Eh, 1Fh	42h

**EPROM INTERFACE**

An EPROM socket is provided so that the end user may add an EPROM to the system. This EPROM would normally contain a program and a driver to enable the PC-AT to be boot up (Operating System loaded) from a designated network server. The ICs necessary to interface the EPROM to a 16L8 (PAL), and a 74ALS244 (buffer). The PAL decodes SA14-SA19, along with system memory read, in order to generate the EPROM enable signal. The '244 provides buffering of the EPROM's data bus to the PC's bus.

**General Bus Interface Operation**

For receiving of packets, the ST-NIC first starts to receive a packet and checks the address of this packet. If the address corresponds to the address for this card, then the data is received by the ST-NIC. The ST-NIC utilizes it's Local DMA channel to buffer the packet into the next available area of the 8k buffer RAM. As each packet is received the ST-NIC's local DMA will buffer it to the next available location in memory. After each packet is buffered the ST-NIC will generate and interrupt to the CPU. If a packet that has an error is loaded into RAM, the ST-NIC will reject the packet and reclaim the memory space that the packet occupied.

Upon recognition of the receive interrupt the CPU should then program the ST-NIC's Remote DMA to read the packet into the I/O port consisting of the two back-to-back 74ALS374s (see Figure 1). As the ST-NIC's Remote DMA does this the CPU handshakes with the DMA to read each byte from the I/O Data Port and store it in the PC's main memory. This is repeated until the packet has been completely transferred.

For packet transmission, the system CPU first programs the ST-NIC's Remote DMA to receive a packet from the system into a predetermined area of the card's buffer RAM. The CPU and the ST-NIC then handshake while the data is sent through the I/O data port.

Once the transmit packet is completely assembled into the local card RAM, the ST-NIC is then programmed to transmit the packet out onto the network. The ST-NIC then reads the transmit data using its Local DMA channel, and then follows the CSMA/CD protocol to transmit the data. When the transmission is complete an interrupt is generated, and the CPU can check the status of the transmit to ensure proper transmission did occur.

**NETWORK INTERFACE**

The evaluation board supports three physical media interfaces options: Thick Ethernet, Thin Ethernet, and Twisted Pair. The block diagram for these interfaces can be seen in *Figure 2*. A single jumper selects between the ST-NIC's Attachment Unit Interface (AUI) and its 10BASE-T interface. When the AUI is selected a second jumper selects the Thin Ethernet interface or the AUI connector. This second jumper shorts/opens the power supply to the transceiver. The AUI interface provides connectivity to an external transceiver which typically connects to Thick Ethernet cable.

The ST-NIC has an integrated 10BASE-T interface so that all that needs to be added are the equalization resistors, and an integrated filter module such as the Valor FL1012.

The Thin Ethernet interface is a little more complicated. This section includes a pulse transformer and a DC-DC Converter (Valor PM7102 or equivalent) to provide the required isolation, and the DP8392 Coax Interface and a few discrete components. The input power to the PM7102 is enabled via the jumper to enable disabling of this interface.

**JUMPER CONFIGURATIONS**

On the DP83902EB-AT ST-NIC AT board, there are nine jumpers as grouped in the one block in the component layout shown in *Figure 3*. The following pages will explain how to configure these jumpers, and what they do.

**Physical Interface**

There are a number of jumper options provided in this design to enable utilizing some of the ST-NIC's pin programmable options. Most of these are set for the normal default and should not have to be changed (in fact most are only provided for experimentation purposes). These jumpers are JP3, JP5, and JP6. JP4 is provided to enable experimentation with different bus clocks should a designer wish. This option is not useful for general operation and the default to use the 20 MHz network clock would normally be used.

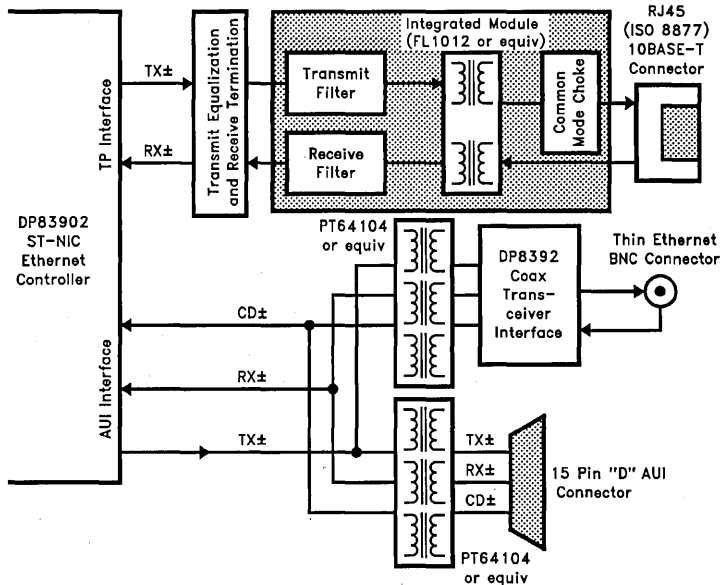

FIGURE 2. Media Interface Block Diagram

TL/F/11492-2

Proposed Component Placement

TL/F/11492-3

FIGURE 3. Proposed Component Placement (Jumpers Located in Center of Board)

TABLE IV. ST-NIC Option Jumpers

Jumper	Position	Description	
JP3	OFF	IEEE Half Step AUI Mode	Default
	ON	Ethernet Full Step AUI Mode	
JP4	ON	Common Network-Bus Clocks	Default
	OFF	Separate Network-Bus Clocks	
JP5	ON	Link LED Off	Default
	OFF	LED Enabled	
JP6	OFF	10BASE-T Link Enabled	Default
	ON	10BASE-T Link Disabled	

Two jumpers select which physical media to use as shown in Table V.

TABLE V. Physical Media Selection

JP8	JP7	Description	
OFF	OFF	Thick Coax (10BASE5)	Default
OFF	ON	Twisted Pair (10BASE-T)	
ON	OFF	Thin Coax (10BASE2)	
ON	ON	Illegal	

For Table V, the selection default is Thin Ethernet, and any of the jumper options may be selected, except shorting both jumpers, JP7 and JP8. If this is done then the Thinnet transceiver is enabled, but the ST-NIC will use the twisted pair interface, since this does not make any sense the option is not useable.

I/O and EPROM Addresses

This design utilizes the same set of I/O address selections and EPROM address selections as NE1000, as shown in Table VI.

TABLE VI. I/O and EPROM Address Options

JP2	JP1	JP0	I/O Address	EPROM Address	
ON	ON	ON	300H	C800H	Default
ON	ON	OFF	300H	Disabled	
ON	OFF	ON	320H	CC00H	
ON	OFF	OFF	320H	Disabled	
OFF	ON	ON	340H	D000H	
OFF	ON	OFF	340H	Disabled	
OFF	OFF	ON	360H	D400H	
OFF	OFF	OFF	360H	Disabled	

As can be seen JP0 actually is the enable for the EPROM, and JP1 and JP2 select the addresses for both the I/O and EPROM. Like the NE1000 the addressing of the I/O and EPROM cannot be set individually.

This design supports the same interrupt selection options as the NE1000, as shown in Table VII. Individual jumpers enable each interrupt to the bus interface. It is important that only one interrupt be selected at any one time.

**TABLE VII. Interrupt Output Selection**

JP12	JP11	JP10	JP9	Interrupt
ON	OFF	OFF	OFF	IRQ6
OFF	ON	OFF	OFF	IRQ4
OFF	OFF	ON	OFF	IRQ3
OFF	OFF	OFF	ON	IRQ9
OFF	OFF	OFF	OFF	NONE

Default

All of these jumper options can be provided in a relatively easy grouping as shown below. (JP5) may not be grouped here as it is better to place it near the ST-NIC to try to minimize clock trace lengths.

TL/F/11492-4

**FIGURE 4. Possible Jumper Configuration**

**LAYOUT CONSIDERATIONS**

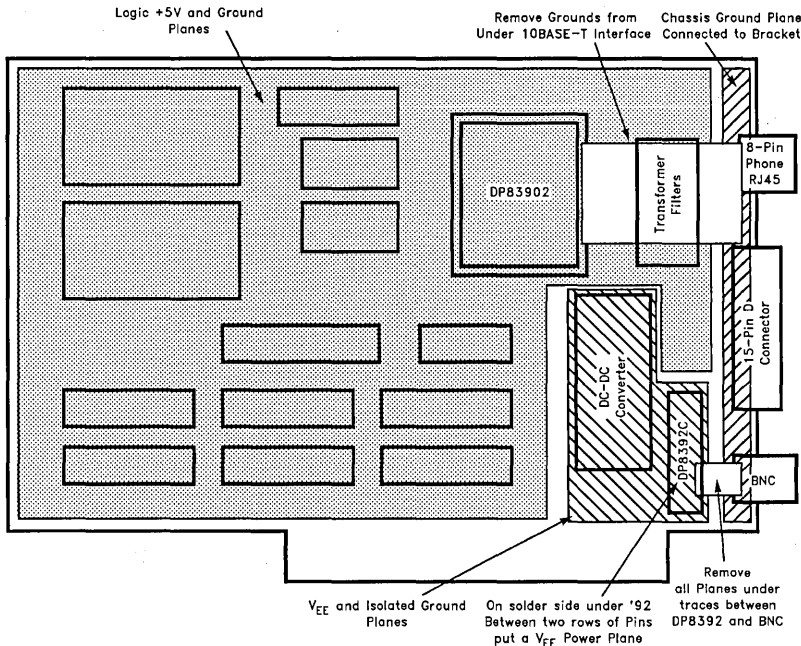

The PCB layout for this design is very similar to most triple media interface designs (most of the layout considerations

revolve around the media interfaces layout). The major component placement decisions are to place the ST-NIC's 10BASE-T port near the RJ45 Connector, and to place the DP8392 close to the BNC connector.

For the ST-NIC placement and layout, it is important to ensure that the power supply noise imparted from the board is minimized. To ensure this adequate decoupling around the 4 sides of the ST-NIC is important. There are two reasons for this. First the ST-NIC is a combined digital and analog function so to maximize the analog circuit performance, noise should be reduced. Secondly, the AUI and twisted pair outputs can conduct power supply noise out to the connectors. Thus power supply noise should be kept to a minimum to reduce RFI emissions. It is recommended that 0.1  $\mu$ F low ESR decoupling capacitors be used along with a couple of 4.7  $\mu$ F-10  $\mu$ F tantalum capacitors.

On the ST-NIC's twisted pair interface, the layout should be compact, and all signal traces should be kept straight and short. It is preferable to have each of the signals in a particular differential pair matched to minimize differential skews (i.e., RX+ and RX- should be matched). Also, the power planes under the twisted pair interface components should be removed to prevent power supply noise from being injected into the twisted pair signals, again to minimize RFI.

For the DP8392 layout there are several considerations. First the CTI power planes must be isolated from the logic power planes by a PCB gap that can withstand 500V. The isolated power plane should be removed from under the signals that interface from the CTI to the BNC connector. This is required to reduce the capacitance as seen from the Thin net (RG58) cable. It is also advisable to add a small heatsink power plane to the solder side layer that encompasses the area between the two rows of pins of the DP8392 package (see datasheet for specific layout recommendations).

**FIGURE 5. Ground/Power Planes and Layout Considerations**

# Guide to Loopback Using the DP8390 Chip Set

National Semiconductor  
Application Note 858

## OVERVIEW

Loopback capabilities are provided to allow certain tests to be performed to validate operation of the DP8390 NIC, the DP8391 SNI, and the DP8392 CTI prior to transmitting and receiving packets on a live network. Typically these tests may be performed during power up of a node. The diagnostic provides support to verify the following:

1. Verify integrity of data path through each chip. Received data is checked against transmitted data.
2. Verify CRC logic's capability to generate good CRC on transmit.
3. Verify CRC recognition capability of the NIC on receive.
4. Verify that the address recognition logic can
  - a. Recognize address match packets
  - b. Reject packets that fail to match an address

## LOOPBACK MODES

Loopback modes are selected by programming the Transmit Configuration Register. Bits LB0 and LB1 select the type of loopback to be performed. The NIC supports three modes of loopback: internal loopback through the DP8390 controller only (*Figure 1*), external loopback through the DP8391 encoder/decoder (*Figure 2*), and external loopback through the DP8392 transceiver (*Figure 3*).

### Loopback Operation in the NIC

To initiate a loopback test, a packet must first be assembled and transferred into the NIC buffer memory. Next, the Transmit Page Start Register, Transmit Byte Count Registers, and Transmit Configuration Register must be programmed. (When loopback mode is selected in the Transmit Configuration Register, the FIFO is split into two halves, one used for transmission and the other for reception.) Finally,

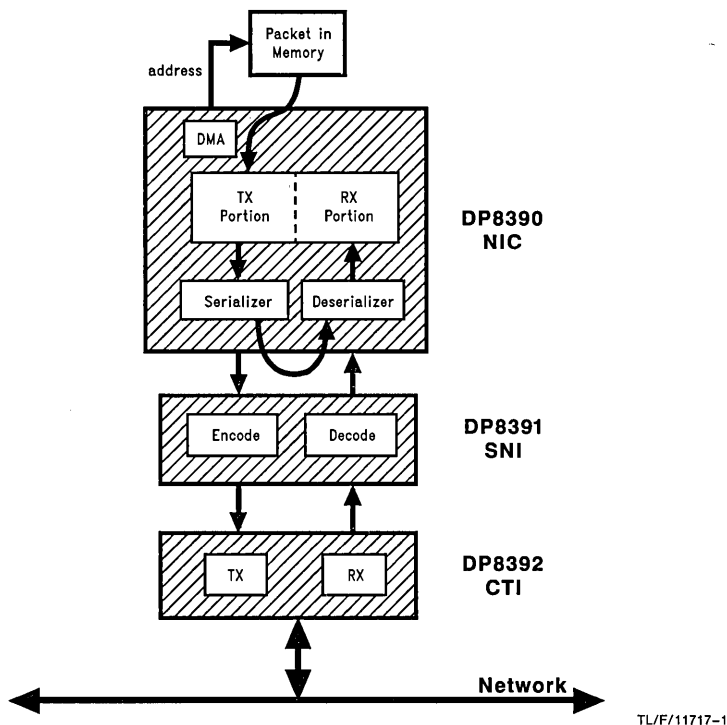

FIGURE 1. Loopback Mode 1: Through the Controller

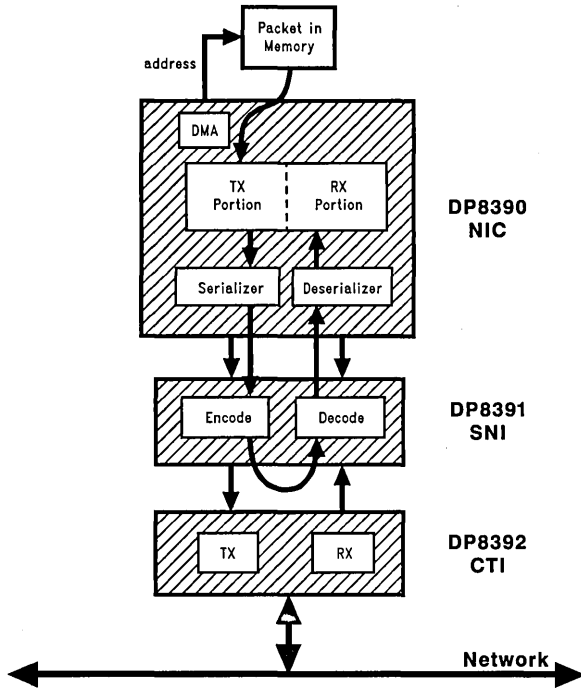

FIGURE 2. Loopback Mode 2: Through the SNI

TL/F/11717-2

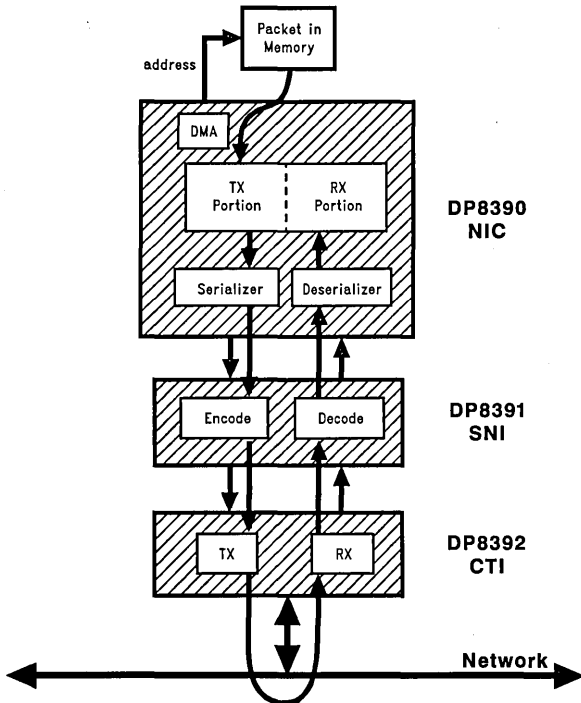

FIGURE 3. Loopback Mode 3: To the Coax

TL/F/11717-3

the transmit command is issued to the Command Register, causing the following operations to occur:

#### Transmitter Actions

1. Data is transferred from memory by local DMA until the FIFO is filled. For each transfer, the Transmit Byte Count Registers (TBCR0 and TBCR1) are decremented. (Subsequent burst transfers are initiated when the number of bytes in the FIFO drops below the programmed threshold.)
2. The NIC generates 56 bits of preamble followed by an 8-bit synch pattern.
3. Data is transferred from the FIFO to the serializer.
4. If the Inhibit CRC bit is set in the Transmit Configuration Register, no CRC is calculated by the NIC, and the last byte transmitted is the last byte from the FIFO (last byte of the packet). This allows a software CRC to be appended. If the Inhibit CRC bit is not set, the NIC calculates and appends four bytes of CRC to the end of the packet.
5. At the end of transmission, the Packet Transmitted bit is set in the Interrupt Status Register.

#### Receiver Actions

1. Wait for synch (Start of Frame Delimiter), all preamble bits are ignored.
2. Store packet in the FIFO, increment receive byte count for each incoming byte.
3. If the Inhibit CRC bit is set in the Transmit Configuration Register, the receiver checks the incoming packet for CRC errors. If the Inhibit CRC bit is not set in the Transmit Configuration Register, the receiver does not check for CRC errors; the CRC error bit is set in the Receive Status Register (for address matching packets).
4. At the end of receive, the receive byte count is written into the FIFO and the Receive Status Register is updated. The Packet Received Intact bit is typically set in the Receive Status Register even if the address does not match. If CRC errors are forced, the packet must match the address filters in order for the CRC error bit in the Receive Status Register to be set.

#### Restrictions Using Loopback

Since the NIC is a half-duplex device, several compromises were required for the implementation of loopback diagnostics. Special attention should be paid to the restrictions placed on the use of loopback diagnostics.

1. The FIFO is split into two halves to allow some buffering of incoming data. The NIC transmits through one half of the FIFO and receives through the second half. Only the last five bytes of a packet can be examined in the FIFO; the DMA does not store the loopback packet in memory. Thus loopback can be considered a modified form of transmission.
2. Splitting of the FIFO has some bus latency implications. The FIFO depth is halved, thus reducing the amount of allowed bus latency. The Loopback Select bit (D3) in the Data Configuration Register should be set to allow all local DMA transfers to continue until the FIFO is filled. In cases where the latency constraints cannot be accommodated, small 7 byte packets can be transmitted. In addition, the FIFO must only be read (by successfully reading port 06h) when in loopback mode; reading the FIFO in other modes will result in the NIC failing to issue the ACK signal properly.
3. The CRC logic is shared by the receiver and the transmitter; thus the NIC cannot generate and check the CRC simultaneously. That is, if the Inhibit CRC bit is not set in the Transmit Configuration Register, the NIC generates and appends the CRC, and software must be used to verify the CRC. On the other hand, if the Inhibit CRC bit is set in the Transmit Configuration Register, the NIC will verify a software generated CRC.
4. Address recognition logic must be checked indirectly through a small series of tests (see Group III Loopback Tests: Address Recognition for further explanation).
5. Between consecutive transmissions in loopback mode, the Transmit Configuration Register must first be set to 00h and the Command Register reset to 21h (followed by a wait state of at least 1.5 ms for the NIC to reset). The desired loopback mode may then be programmed into the Transmit Configuration Register. This step guarantees alignment of the FIFO pointers when data is read from the FIFO.
6. Loopback only operates with byte wide transfers, thus special considerations must be made with word wide transfers. Since the FIFO is split, only half of each word is transferred into the transmit portion of the FIFO. The Byte Order Select bit in the Data Configuration Register can be used to select which half of the word is written into the FIFO (see Figure 4).

**Note:** Although a word is transferred to the NIC, only a byte is transmitted in the loopback packet. To properly transfer all the bytes in the loopback packet, the byte count must be 2 times the actual number of bytes assembled in the loopback packet.

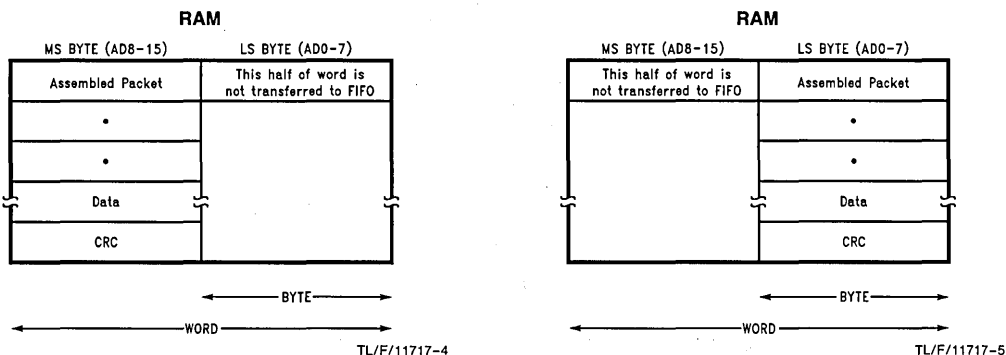

FIGURE 4. Packet Assembly for Loopback Work Wide Transfers

7. During heavily loaded network conditions, external loopback through the SNI and CTI could fail due to interference from the network.

**Alignment of Data in the FIFO**

During loopback, eight bytes of the FIFO are used for transmission and eight bytes are used for reception. Reception of the packet begins at location zero, and after the pointer reaches the last location in the receive portion of the FIFO, the pointer wraps back to location zero, overwriting the previously received data (see *Figure 5*). The pointer continues to circulate through the FIFO until the last byte is received. The NIC then appends the lower receive byte count and two copies of the upper receive byte count into the next three locations in the FIFO. Thus, only the last five bytes of the received packet may be retrieved.

**Note:** Although the size limit of a loopback packet is 64 bytes, the byte counter rolls over at 2048 bytes.

TL/F/11717-6

**FIGURE 5. Continuously Circulating FIFO Write Pointer During Loopback**

To achieve the packet alignment shown in *Figure 6*, the packet length should be  $(N * 8) + 5$  bytes (i.e., 13, 21, etc). If the CRC is appended, the second through fifth byte will be the CRC appended by the NIC. This allows the CRC to be extracted from the NIC and compared to a previously calculated value for verification.

FIFO Location	FIFO Contents	
0	Byte $(N * 8) + 1$	First Byte Read
1	Byte $(N * 8) + 2$ (CRC1)	Second Byte Read
2	Byte $(N * 8) + 3$ (CRC2)	•
3	Byte $(N * 8) + 4$ (CRC3)	•
4	Byte $(N * 8) + 5$ (CRC4)	•
5	Lower Byte Count	•
6	Upper Byte Count	•
7	Upper Byte Count	Last Byte Read

**FIGURE 6. Alignment of Packet in FIFO Following Loopback**

**Loopback Tests**

Three types of loopback tests may be performed to verify the data path through the DP8390 chip set. The tests are as follows:

1. Group I tests verify the CRC generation capability of the NIC. In this case, the NIC generates and appends a CRC to the loopback packet, and software is used to verify a matching CRC.
2. Group II tests verify the CRC recognition capability of the NIC. Here, the NIC verifies a software generated CRC.
3. Group III tests verify the address recognition logic of the NIC.

The loopback tests which follow were performed on the DP839EB. During each of the loopback tests, the Data Configuration Register was programmed to 40h.

**GROUP I LOOPBACK TESTS: CRC GENERATION**

The basic steps necessary to perform the Group I loopback tests (in which the CRC is appended by the NIC) are as follows:

1. Set Command Register to 21h (page 0).
2. Initialize Data Configuration Register to 40h.
3. Initialize Receive Configuration Register to 1Fh (promiscuous mode).
4. Initialize Transmit Byte Count Registers and Transmit Page Start Register.
5. Set Command Register to 22h (start mode).
6. Create loopback packet and transfer into NIC buffer memory.
7. Transmit dummy packet to check for unterminated or unconnected cable:
  - a. Set Transmit Configuration Register to 00h (normal operation).
  - b. Write FFh to Interrupt Status Register to reset.
  - c. Set Command Register to 26h (transmit). Note that the Command Register must first be in start mode (22h) before transmitting (26h).
  - d. Loop until the Packet Transmitted bit is set in the Interrupt Status Register. If the timeout loop completes and this bit is not set, the transmit has timed out, and the cable may not be connected.
  - e. Check Interrupt Status Register for 08h (transmit Error). If the Transmit Error bit is set, excessive collisions have occurred, and the cable may not be terminated.
8. Start loopback mode 1 test (TCR = 02h):
  - a. Reset Transmit Configuration Register to 00h.
  - b. Reset Command Register to 21h. If the NIC is currently receiving a packet, it will wait for the reception of the current packet to complete before it will reset. Thus, a wait state of at least 1.5 ms is necessary to insure that the NIC will completely reset.
  - c. Program the Transmit Configuration Register to the appropriate loopback mode.
  - d. Write FFh to Interrupt Status Register to reset.
  - e. Set Command Register to 22h (start mode).

- f. Set Command Register to 26h (transmit).
  - g. Wait for transmit to complete (Command Register = 22h).
  - h. Check Interrupt Status Register for 06h (good transmission).
  - i. Read FIFO and compare CRC with previously calculated CRC.
9. Start loopback mode 2 test (TCR = 04h): See Step 8.
  10. Transmit a dummy packet to change the contents of the FIFO. If this step is not taken before external loopback through the CTI and the AUI cable is not connected, the NIC does not receive anything into its FIFO. Thus the contents of the FIFO are not changed, and the loopback test reads a good CRC. See Step 7.
  11. Start loopback mode 3 test (TCR = 06h): See Step 8.
  12. If mode 3 loopback fails, transmission may have been aborted due to excessive collisions (check the Transmit Status Register). In this case, network traffic has interfered and the CTI may still be operational.

### GROUP I RESULTS

The following examples show what results can be expected from a properly operating NIC during Group I loopback operations. The restrictions and results of each loopback mode are listed for reference.

#### Internal Loopback through the NIC

Path	TCR	RCR	TSR	RSR	ISR
NIC Internal (Mode 1)	02H	1FH	51H	02H	06H

**Note 1:** Before transmission of the loopback packet, Carrier Sense and Collision inputs are monitored (as required by CSMA/CD protocol). Once the NIC gains access to the network for transmission, the Carrier Sense and Collision Detect inputs are ignored. Thus, the Carrier Sense Lost and CD Heartbeat bits are always set in the Transmit Status Register.

**Note 2:** CRC errors are always indicated by the receiver if the CRC is appended by the transmitter.

**Note 3:** Only the Packet Transmitted and Receive Error bits in the Interrupt Status Register are set; the Packet Received bit is set only if status is written to memory. In loopback this action does not occur, and the Packet Received bit remains 0 for all loopback modes.

#### External Loopback through the SNI

Path	TCR	RCR	TSR	RSR	ISR
NIC External (Mode 2)	04H	1FH	41H	02H	06H

**Note 1:** CD Heartbeat is set in the Transmit Status Register; Carrier Sense Lost is not set since it is generated by the external encoder/decoder.

#### External Loopback through the CTI

Path	TCR	RCR	TSR	RSR	ISR
NIC External (Mode 3)	06H	1FH	01H	02H	06H

**Note 1:** CD Heartbeat and Carrier Sense Lost should not be set. The Transmit Status Register could, however, also contain 01, 03, 07, and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** The Interrupt Status Register will contain 08 if the packet is not transmittable.

During external loopback the NIC is now exposed to network traffic. It is therefore possible for the contents of both the receive portion of the FIFO and the Receive Status Register to be corrupted by any other packet on the network. Thus, in a live network, the contents of the FIFO and Receive Status Register should not be depended on. The NIC will still abide by the standard CSMA/CD protocol in external loopback mode (the network will not be disturbed by the loopback packet).

### GROUP II LOOPBACK TESTS: CRC RECOGNITION

The basic steps necessary to perform the Group II loopback tests (in which a software CRC is appended to the packet) are similar to those outlined previously for the Group I tests, with the following exceptions:

1. The loopback packet created must have a software appended CRC.
2. When programming the Transmit Configuration Register to the desired loopback mode, the Inhibit CRC bit must be set.
3. After the loopback packet has been transmitted, check the Interrupt Status Register and/or the Receive Status Register for CRC errors. If a CRC error has occurred, the loopback test has failed.

### GROUP II RESULTS

The following examples show what results can be expected from a properly operating NIC during Group II loopback operations. The restrictions and results of each loopback mode are listed for reference.

#### Internal Loopback through the NIC

Path	TCR	RCR	TSR	RSR	ISR
NIC Internal (Mode 1)	03H	1FH	51H	01H	02H

**Note 1:** Before transmission of the loopback packet, Carrier Sense and Collision inputs are monitored (as required by CSMA/CD protocol). Once the NIC gains access to the network for transmission, the Carrier Sense and Collision Detect inputs are ignored. Thus, the Carrier Sense Lost and CD Heartbeat bits are always set in the Transmit Status Register.

**Note 2:** Only the Packet Transmitted bit in the Interrupt Status Register is set. The packet received bit is set only if status is written to memory. In loopback this action does not occur, and the Packet Received bit remains 0 for all loopback modes.

#### External Loopback through the SNI

Path	TCR	RCR	TSR	RSR	ISR
NIC External (Mode 2)	05H	1FH	41H	01H	02H

**Note 1:** CD Heartbeat is set in the Transmit Status register; Carrier Sense Lost is not set since it is generated by the external encoder/decoder.

**External Loopback through the CTI**

Path	TCR	RCR	TSR	RSR	ISR
NIC External (Mode 3)	07H	1FH	01H	01H	02H

**Note 1:** CD Heartbeat and Carrier Sense Lost should not be set. The Transmit Status Register could, however, also contain 01, 03, 07, and a variety of other values depending on whether collisions were encountered or the packet was deferred.

**Note 2:** The Interrupt Status Register will contain 08 if the packet is not transmittable.

During external loopback the NIC is now exposed to network traffic. It is therefore possible for the contents of both the received portion of the FIFO and the Receive Status Register to be corrupted by any other packet on the network. Thus, in a live network, the contents of the FIFO and Receive Status Register should not be depended on. The NIC will still abide by the standard CSMA/CD protocol in external loopback mode (the network will not be disturbed by the loopback packet).

**GROUP III LOOPBACK TESTS:  
ADDRESS RECOGNITION**

The address recognition logic cannot be directly tested. However, the CRC Error and Frame Alignment Error bits in the Receive Status Register are set only if the address of the packet matches the address filters. Thus, if errors are expected to be set and they are not set, the packet has been rejected on the basis of an address mismatch.

**GROUP III RESULTS**

One method of testing the address recognition logic would be to transmit two loopback packets, one with a matching physical address, and one with a non-matching address. Both packets should have a CRC appended by the NIC. Expected results for each case follow.

**Internal Loopback through the NIC: Matching  
Physical Address**

Path	TCR	RCR	TSR	RSR	ISR
NIC Internal (Mode 1)	02H	00H	51H	02H	06H

**Note 1:** Before transmission of the loopback packet, Carrier Sense and Collision inputs are monitored (as required by CSMA/CD protocol). Once the NIC gains access to the network for transmission, the Carrier Sense and Collision Detect inputs are ignored. Thus, the Carrier Sense Lost and CD Heartbeat bits are always set in the Transmit Status Register.

**Note 2:** CRC errors should be seen in both the Receive Status Register and the Interrupt Status Register for an address matching packet.

**Note 3:** Only the Packet Transmitted and Receive Error bits in the Interrupt Status Register are set; the Packet Received bit is set only if status is written to memory. In loopback this action does not occur, and the Packet Received bit remains 0 for all loopback modes.

**Internal Loopback through the NIC: Non-Matching  
Physical Address**

Path	TCR	RCR	TSR	RSR	ISR
NIC Internal (Mode 1)	02H	00H	51H	01H	02H

**Note 1:** Before transmission of the loopback packet, Carrier Sense and Collision inputs are monitored (as required by CSMA/CD protocol). Once the NIC gains access to the network for transmission, the Carrier Sense and Collision Detect inputs are ignored. Thus, the Carrier Sense Lost and CD Heartbeat bits are always set in the Transmit Status Register.

**Note 2:** CRC errors should not be detected for a non-matching physical address.

**Note 3:** Only the Packet Transmitted bit in the Interrupt Status Register is set. The packet received bit is set only if status is written to memory. In loopback this action does not occur, and the Packet Received bit remains 0 for all loopback modes.

#### CONCLUSION

### INTRODUCTION

Recently the popularity of networking has grown, and as a result virtually any type of computer system and many peripherals are incorporating facilities to connect to a network. With the integration of the network function onto just a few IC's, the design of the interface circuitry to the network's physical interface is becoming simpler. However, the design of the interface can be implemented many different ways, with varying tradeoffs.

The basic design tradeoffs for interfacing a system to Ethernet are fairly simple:

1. **Performance.** Generally this is measured in terms of the amount of data transmitted and received in a given time period. The more data the better. As shown in *Figure 1*, the purpose of a Network interface is simply to: Move Data. The interface should be as fast and efficient as possible.

TL/F/11784-1

**FIGURE 1. The Success of a Network Interface Is It's Ability to Quickly, and Safely Move Data to/from the User**

2. **Low Cost.** Obviously the user would like to pay as little as possible for the network connection.
3. **Compatibility.** Both software and hardware compatibility to established industry standards is crucial. In the PC market, this means the ability to work with standard software (i.e., Novell's NetWare® and Microsoft's Windows for Workgroups®) and hardware. In the non-PC market, interoperability with other network components is the key to successful integration into an existing network.

Unfortunately, these simple goals can lead to choosing dramatically different designs for the Ethernet interface subsystem. The diversity of computer architectures (both hardware and software) requires a unique balance of all of these criteria.

This paper will concentrate on the application of Ethernet in PC type computer systems (i.e., Intel 286, 386, 486 CPUs). Both hardware and software issues will be addressed as they pertain to performance, cost, and compatibility. The considerations presented here are applicable to other computer systems as well.

### NETWORK PERFORMANCE

Obviously one of the major tradeoffs in developing a network interface solution is performance versus cost.

#### ***But: What is network performance?***

##### Defining Network Performance

Network performance is a measure of the ability of a particular network configuration to move data from one computer to another. Typically, this data movement occurs from a server to a workstation or client. Unfortunately, there is no standard method of measuring and benchmarking performance, due to the multitude of network and node configurations. We shall dissect the components of performance in an attempt to describe the roles that hardware and software play in a typical network.

When a user makes a request for information or data not resident on his own computer (like opening a memo in his word processor when the memo is located on a remote system), the network's pieces must all respond to this request. The user's perception of performance is determined by how long he must wait for the information to appear on his screen.

When an inquiry is made on the network for some information, a complex set of transactions occurs. The user's computer operating system tells the network protocol to send a message to the server asking for the information. The protocol software then instructs the driver to send the request to the hardware interface, which in turn sends data over the cable to the server. After the packet has been received, an acknowledgement is sent to the server indicating that a valid transfer was accomplished.

The reverse procedure occurs on the server end. When the hardware receives the request, the driver is instructed to pass it on to the network protocol. The computer operating system takes the request from the protocol and issues a response (the actual data) which is sent back through the network in a similar fashion.

Each of these software and hardware components manipulates the requests and responses to ensure proper delivery of the data to/from each destination. This process is shown in *Figure 2*. Each step requires time for the software and hardware to execute its piece of the job. The sum total of the time it takes for each operation to occur is the performance of the transaction.

#### WHERE'S THE BOTTLENECK?

There are many variables in the performance equation, and the network interface card is only one factor. Much like

Ethernet cards, the overall performance of a system can be divided into hardware and software issues. On the hardware side, the speed of a network is determined by the performance of the server and all of the attached workstations. The network operating system is a major contributor to the overall latency of a network.

The response time of a server or workstation is affected by CPU speed, bus bandwidth, network loading, and the speed and topology of the transmission media (such as coax, twisted-pair, optical fiber, etc.). The server should provide sufficient disk cache memory and a fast hard disk subsystem to minimize delays. Typically, throughput on a loaded network segment can be reduced to under 20% of maximum by random disk I/O requests. Improving individual workstation throughput has very little impact on the overall network since it only affects a small percentage of the total load. The expense of outfitting a high performance server can be amortized over the cost of the entire network since all users will benefit.

The network operating system (NOS) can also have a dramatic affect on Ethernet throughput. The two main functions of the NOS are to move large blocks of data around in RAM and manage the disk I/O subsystem. Excessive copying of data or poor file management will result in poor LAN performance.

Since each item in the request/response path contributes to overall performance, it is desirable to minimize delays through each section. From the Ethernet hardware developer's perspective, the efficiency of the NOS and the cable throughput are fixed. The only areas available for improvement of the network hardware performance are optimization of the driver and the bus interface design. It is important to recognize that the hardware and driver are a small (but important) part of the total performance equation. In most

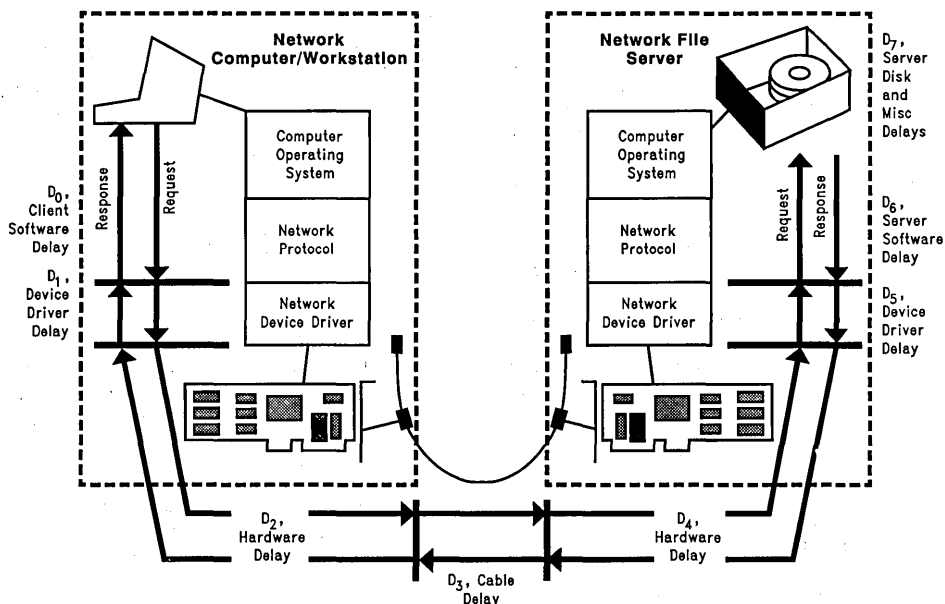

FIGURE 2. Representation of System Delays that Impact Performance

TL/F/11784-2

cases doubling or tripling performance of the network hardware will have a much smaller impact on total performance. (Whereas doubling or tripling the CPU performance could have a much greater affect.)

As can be seen in *Figure 2*, the total speed at which requests/responses can be handled is dictated by the serial path shown. For the analytically minded:

$$\text{Performance} = \frac{K_p}{\Sigma(\text{Request Delays})}$$

Basically, network performance is the reciprocal of the sum of the request delays for the measured transactions.  $K_p$  is a multiplier constant to convert to kbytes/sec.

A single request/acknowledge delay is the sum of the individual delays as shown in *Figure 2*.

$$\begin{aligned} \text{Request Delay} = & (D0 + D1) (2 K_{CPU1}) \\ & + (D5 + D6) (2 K_{CPU2}) \\ & + 2(D2 + D3 + D4) + D7 \end{aligned}$$

$D0$ ,  $D1$ ,  $D3$ ,  $D5$ ,  $D6$  are all software delays and thus are multiplied by the performance of the system processors, while  $D2$ ,  $D3$ ,  $D4$  are network hardware delays that are not affected by software performance (ideally).  $D7$  is the delay due to system hardware other than the network interface, such as a disk and controller.

### Measuring Performance

Generally, one would like to measure these delays and calculate the throughput of a particular network configuration. Most benchmarks can only evaluate the summation of these delays. This is done by measuring the actual data throughput, usually in kbytes/sec or in seconds for a particular task.

Now, of course every good marketer has his favorite benchmark, but the validity of a benchmark can be very deceiving. Most Ethernet vendors cite the Novell **PERFORMx** benchmark as a performance measure, this is valid but does not accurately model the request/response of a real network. Some testing labs have developed scripts that simulate user transactions in an attempt to create a more representative view of network speed, and these tend to be more valid. However, due to the ease of testing and general availability of the **PERFORM** program most comparisons utilize this program's measurements.

The perform benchmark tends to measure the throughput of the network interface, the protocol software, and the system CPU. The data being transferred is cached in the server's memory, so disk drive speed is not a factor. This means that the largest delay for a system is not taken into consideration.

Another important aspect of performance is the amount of time the server CPU is idle. The more CPU bandwidth that is available the greater the potential for the server to do other processing or to handle more information. This becomes important when the server is being used as a database engine or if multiple Ethernet cards are used concurrently. A server that is oversaturated will drop packets, and thus decrease performance because each of these packets will have to be retransmitted. Generally, CPU utilization indicates the potential for better performance rather than actual performance. In the NetWare world, the CPU utilization measure is made using the **MONITOR** program which is run on the server. A meaningful benchmark should contain both the throughput and the CPU utilization figures. For example,

a system with 100 kbyte/sec throughput with a 10% utilization (90% idle) should be better than a 100 kbytes/sec with a 90% utilization. When making comparisons between architectures, it is important to use the same equipment for each test since the benchmarks are also measuring the server's and workstations' performance. The network should have at least six workstations to ensure heavy Ethernet traffic.

### ARCHITECTURAL OVERVIEW

The architecture of an Ethernet card encompasses a hardware interface to the system as well as a software interface, which is really the packet buffer management that the hardware implements with the device driver software. This section will cover the hardware aspects first since this is very much the systems designer's decision. Secondly a description of various software interfaces is described, although in most cases this is actually defined by the integrated controller chosen for a particular design.

### Hardware Interfaces

Before discussing actual applications, it is useful to categorize Ethernet interfaces. Once done, this can be applied to various applications to determine the best fit for each application. A summary can be found in Table 1. The interfaces from the Ethernet subsystem to the host's system bus can be divided into roughly 5 categories as follows:

1. **I/O Mapped Slave:** In this design, the adapter interfaces to the system via a limited number of I/O ports, usually 16 bytes-64 bytes. The interface has dedicated RAM to buffer network data, usually 8k to 64 kbytes. A simple block diagram is shown in *Figure 3*. National's DP8390 core controllers have on-chip logic to ease implementation of this interface.

TLF/11784-3

**FIGURE 3. Diagram Showing Major Blocks of the I/O Mapped Architecture**

**Advantages:** A very simple interface, tends to be low cost. Does not occupy large address space (important for PC's with many peripherals competing for common address allocations). Places little performance requirements on the system bus, and so is ideal for systems that have poor bus bandwidth or long bus latencies.

**Disadvantages:** May be slightly lower in performance. Requires dedicated buffer RAM which can add to cost of the interface.

**2. Shared RAM Slave:** This architecture utilizes a RAM that is dual ported (usually a static RAM with an arbiter rather than an integrated dual port RAM) to enable the network interface and the main system to communicate through a common "window" of memory, as shown in *Figure 4*. The DP8390 has request/acknowledge logic to simplify implementation of this interface.

**FIGURE 4. Basic Block Diagram of the Shared Buffer RAM Design**

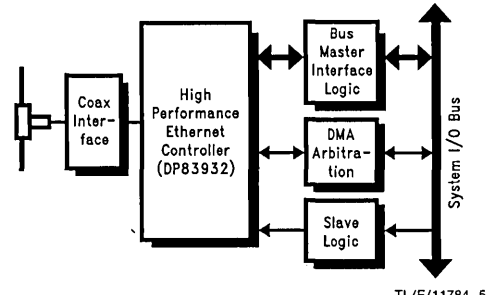

**Advantages:** A fairly simple interface that is slightly higher in performance than the I/O Slave since the data is directly accessible to the system via the buffer RAM.

**Disadvantages:** Tends to be more complex than the I/O interface, and thus more expensive. The additional cost is due to the logic required to dual port the buffer RAM which includes a couple of extra PALs, 4-6 extra octal buffers, and some added logic for software control. (However, as integrated or ASIC solutions become available this extra logic can be absorbed inexpensively making the solution cost equivalent to an I/O mapped design.) This architecture places slightly greater performance requirements on the system bus than the I/O Slave since the system is contending for the buffer RAM with the network interface.

The Shared RAM architecture is not the best choice when the host system has a limited addressing range and/or its memory cycles aren't significantly faster than its I/O cycles. In a PC-AT compatible application, the Shared RAM design typically has a 30% faster bus transfer speed, however when the effects of driver and Network Operating System (NOS) overhead are considered, the advantage of the Shared RAM design is reduced to 10% or less. In Micro Channel or EISA systems, the difference in I/O vs memory transfer rates is less, so the performance disparities would be reduced (assuming the network hardware does not present any other constraints).

**Note:** These relative numbers do not include disk access overhead, so the performance difference seen by a user will typically be lower.

**3. Simple Bus Master:** For the simple bus master interface, the network peripheral directly requests the system bus, and when granted, takes control of the bus and directly places packet data into system memory (*Figure 5*). The performance of this design is heavily dependent on the sophistication and speed of the DMA channel logic, and the bus itself. In the past, most Ethernet controllers did not have sufficient bus speed or buffer management to support this type of architecture, hence it's relatively new emergence has coincided with the introduction of high performance controllers such as the SONIC™ DP83932.

**FIGURE 5. Simple Bus Master Block Diagram**

In order to understand memory buffer structures, it is useful to compare the packet movement of a Shared Memory or I/O Interface (local memory) to that of the Bus Master design. In a local memory design (*Figure 6a*), the data is first buffered, then copied to the system memory. The Bus Master, on the other hand (*Figure 6b*), places the data directly into system memory. This latter approach is significantly faster because local memory designs require an extra read and write cycle to move the contents of the local buffer RAM into system memory. In theory, the Bus Master can eliminate additional data copies. Performance is reduced if the Bus Master cannot buffer directly to the NOS and a data copy has to be executed. The fact that local memory requires data buffering in two steps is not as significant to performance as the method of moving the data into system memory (i.e., DMA, I/O channel, etc.). Bus latency is one of the prime considerations when deciding to use a bus master approach. Newer generation controllers rely on a FIFO to buffer data until the bus becomes free for transfers. Depending on the computer, this delay can be longer than the maximum time allowed by the FIFO. When a FIFO overrun (or underrun) occurs, the packet must be retransmitted. In theory, the maximum bus latency tolerated by a controller can be calculated by the equation:

$$\text{Latency}_{\text{max}} = \frac{\text{Depth of FIFO (Bytes)}}{10 \text{ Mbits/S} \times 0.125 \text{ Byte/Bit}}$$

There are two classes of bus masters which for this document we will call a MAC (Media Access Control) Bus Master, and a Bus Master (for lack of better names). The distinction is that a MAC Bus Master becomes owner of the bus, but utilizes some form of system or external DMA controller to actually move the data. In other words the MAC Bus Master cannot generate addressing for the received or transmitted data. The Bus Master, on the other hand, utilizes a DMA controller that is built into the MAC. This DMA controller is capable of controlling data movement in a reasonably sophisticated way, and can place data into or take data from any desired location.

**Advantages.** Properly designed with enough intelligence in the packet buffering (i.e., not typically a MAC Bus Master), this implementation provides a very high performance data transfer throughput. If the DMA master is sophisticated enough, data can be placed directly into system memory, thus eliminating extraneous data copying by the driver software as is required by I/O mapped and Shared RAM designs.

(a) Shared Memory or I/O Architecture

(b) Bus Master Architecture

FIGURE 6. Comparison of Data Movement

**Disadvantages.** In order to achieve high performance, the DMA machine must be sufficiently sophisticated (not a MAC Bus Master). In many low performance bus systems, direct bus ownership is not supported. In other buses, such as ISA, the bus is not sophisticated enough to arbitrate between potential bus owners without tying up the CPU unnecessarily. In some high performance bus interfaces, the latency from bus request to bus grant can be very long and require on-card buffering of the data to avoid dropping packets.

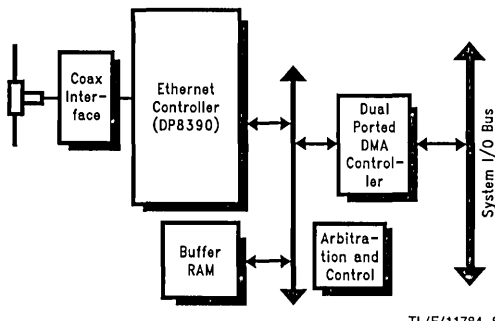

When comparing software driver performance, the efficiency of the driver plays a bigger role in Bus Master designs. This is because the Bus Master's hardware transfer is very efficient and the overhead of the driver is a bigger percentage of the data throughput. Typically in a PC (ISA bus) the bus master data transfer rate is 2-2.5 times that of an I/O based design. When software overheads are included, however, the Bus Master design typically achieves a performance increase over the I/O design. (Driver inefficiencies in reality can reduce this by about 5%.)

**Note:** These relative numbers do not include disk access overhead, so the performance difference seen by a user will typically be lower.

4. **Buffered Bus Master.** In this design the network packet data is DMA'd by a network controller through the on-card bus into a buffer RAM (Figure 7). The packet data is then transferred to the system by additional logic that DMA's the data across the system bus into main memory. The performance of this architecture is comparable to that of the standard bus master with a marginally higher use of CPU bandwidth.

**Advantages.** This architecture provides high performance close to the simple bus master design even in situations where there are extremely long bus latencies (i.e., EISA).

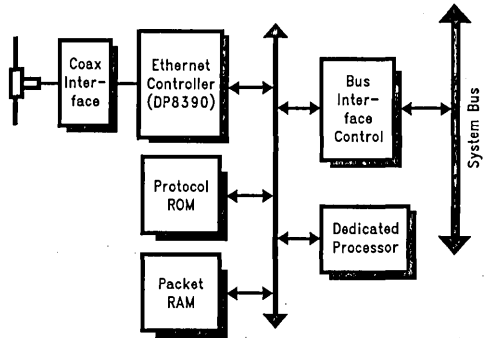

**Disadvantages.** When compared to the simple bus master interface, the cost of implementation is higher since this design requires additional buffer RAM and a complex system bus DMA channel in addition to the network interface's DMA channel. If the DMA interface is not sophisticated, the performance will be lower and the software driver will have to do additional processing.

TL/F/11784-8

FIGURE 7. Buffered Bus Master Block Diagram

5. **Intelligent Bus Master.** This design has a general purpose processor dedicated to the network interface for processing packet data (Figure 8). For low-end cards, the processor does not do protocol processing but only performs packet data manipulation and controls access between the system and the network interface. On high end designs, the dedicated network CPU does protocol processing which off-loads this task from the main system. The transfer of data to the system may be via an I/O, shared RAM, or bus master interface.

TL/F/11784-9

FIGURE 8. Intelligent Bus Master Block Diagram

**Advantages.** When using a processor with sufficient performance, this solution offers the highest performance of any of the solutions. This design also allows for the highest bus latencies, since on board RAM can store many packets. This architecture can off-load the server's CPU from processing the low level protocol tasks and can thus achieve very low server utilization relative to other technologies.

**Disadvantages.** Very costly in terms of hardware and component count. In order to achieve significant packet throughput advantages, the dedicated processor must be able to process packets at least as fast as the host CPU. In many cases, the low end cards are less efficient than simple bus master cards in terms of packet throughput.

In most practical examples, medium performance 16-bit processors are chosen and this choice tends to offer lower packet throughput than any of the other architectures. Typical CPU loading is roughly half that of a non-intelligent bus master.

**BUFFER MANAGEMENT ARCHITECTURES**

Just as the performance of a particular hardware implementation depends on how fast data is transferred to the system, the packet buffer management scheme helps determine how fast data can be transferred from the hardware to the Network Operating System. A great hardware design can be foiled by a poor software interface.

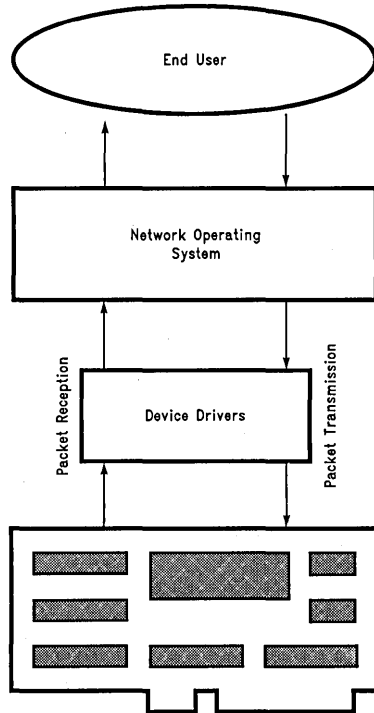

High performance software designs will reduce software complexity and directly provide the data to the NOS in a way that the NOS expects. There are cost/performance trade-offs in this interface as well, and so there are various buffering methods.

Before discussing the types of buffering that hardware may choose to implement, it is first useful to look at what operating systems expect for packet data. The goal is to minimize the device driver overhead, so a look at what information and in what form the NOS expects it is important.

Figure 9 shows a representation of how the user sends and receives data to/from the NOS. For sending packets, the NOS breaks up the data into smaller pieces so that they can fit within an Ethernet frame. The driver then takes this data and presents it to the hardware. On reception, the hardware gives data to the driver which in turn passes this data to the NOS. The NOS translates the data (if necessary) to a form acceptable to the user's application.

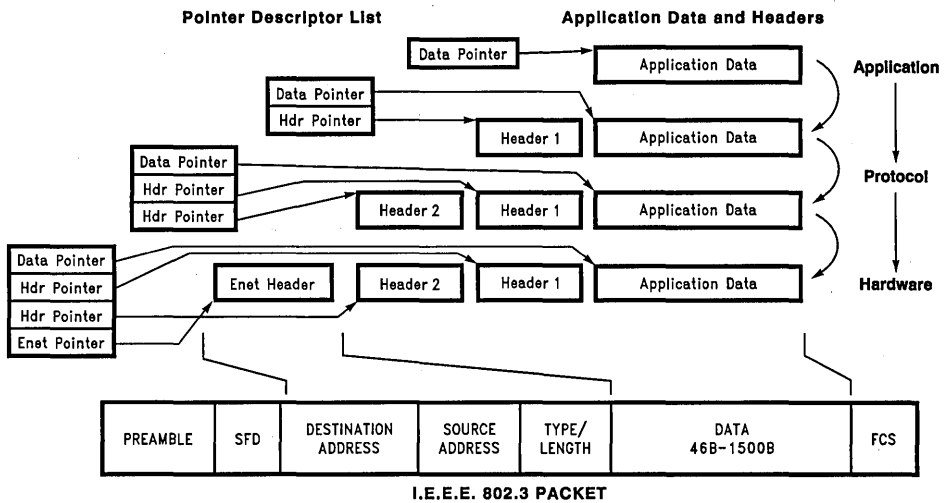

**Transmit Requirements**

The simpler part of the packet buffering scheme is the transmission of a packet. In this instance, the packet starts from the user's application, and the NOS prefixes network data, usually referred to as headers, to the application data as shown in Figure 10. These headers can contain protocol, routing, or application specific information. The most efficient method of "prefixing" is to create a pointer list which describes the data pieces' locations rather than copying all the data into a contiguous area. The driver receives this list from the NOS and then sends the information to the hardware. The network interface controller should be able to use this list with as little driver software manipulation as possible. The hardware and its associated driver must also be able to queue multiple requests since the network cable can only send one packet at a time.

TL/F/11784-10

FIGURE 9. User-Cable Data Movement through NOS to Driver to Hardware

TL/F/11784-11

FIGURE 10. Transmit Packet Creation

## Receive Requirements

One might assume that the receive packet handling should be very similar to the transmit, but there are a number of differences. First, unlike a transmit packet, the NOS, driver, and hardware have no idea when a packet may arrive, what kind of packet (i.e., IPX, TCP/IP, DECnet, etc.) it is going to receive, and how many packets may be received in a given time. While a packet to be transmitted is statically resident in memory until it is operated on, a packet being received must have sufficient memory allocated to it prior to reception. The amount of memory set aside must be equal to the maximum packet size since there is no way to predetermine a packet's length.

These unknowns require a different type of buffer management. Since a packet could be received at any moment, the driver or the hardware must allocate memory before the packet arrives. The system should provide enough memory to handle several packets at a time in case the packets are received faster than they can be processed. This memory allocation is accomplished in hardware by most architectures. A dedicated packet buffer RAM on the network card allows sufficient space to receive multiple packets (this capability is the reason that dedicated hardware RAM is used). All but the simple bus master architecture have a dedicated packet buffer.

In the simple bus master, the driver must allocate a dynamic pool of system memory, and so the structure of the receive portion of the driver depends more on the memory allocation scheme of the NOS than the network side. Thus for simple bus masters to be effective, they should implement a memory allocation/management scheme similar to that of the NOS to simplify data manipulation.

Another consideration is that ultimately the packet will be given to the host's operating system, so the hardware/driver should present the data in a compatible format. The NOS will fragment the packet to remove all of the headers and give the data to the receiving application in the form it accepts.

As can be seen in *Figure 11 a-c*, there are several possible schemes for dealing with received packets. In cases where only one packet type is being received, the hardware/software may be able to fragment the packet into its multiple headers as it is received and to place each header into a separate area for manipulation (called protocol fragmentation buffering). In some cases, this scheme is efficient since data copying can be eliminated (in theory). The down side for the NOS is that each layer must keep track of several pointers. When multiple protocols and packet types are involved, this type of scattering is difficult because the hardware will have to receive enough of the packet to determine

its type, and then either the hardware or software must find appropriate memory to place the fragments. This effort is required because different packet types have different header lengths and contents.

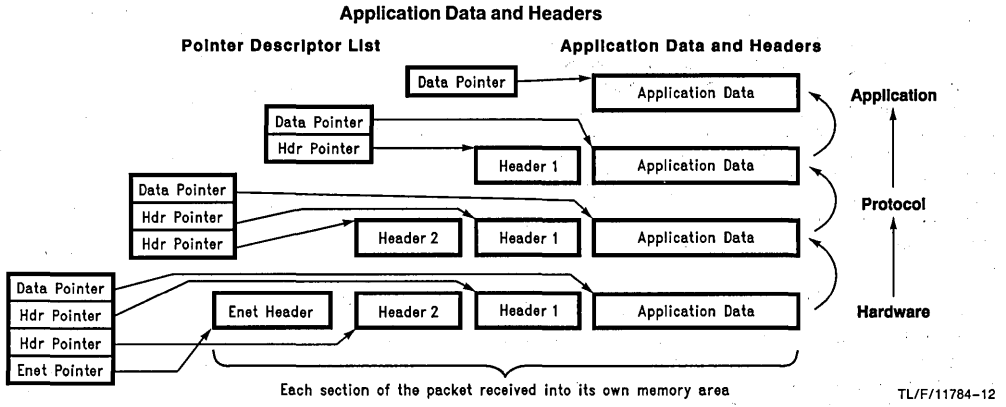

Another possible reception method is to fragment the packet into small buffers, usually 256 or 512 bytes. This will result in a large Ethernet packet being chopped into 3 pieces (*Figure 11b*). There are several advantages to this technique:

1. Operating system memory management uses these block sizes, so memory allocation is simplified by not having to allocate large contiguous memory blocks.
2. Most Ethernet packets are relatively small, usually <256 bytes. This type of memory scheme is more memory efficient than if a packet were contiguously buffered to a single area. This is because each memory area must be able to accommodate a full Ethernet packet 1518 bytes, and if a small 100 byte packet is received then the rest of the packet buffer will contain unused memory. (However these days operating systems with huge multi-megabytes of memory are common, and a few extra kbytes of packet buffers is typically not a big problem.)
3. In some schemes, the beginning of a new packet may be buffered directly at the end of the previous packet which causes additional fragmentation and hence more pointers (but is more memory efficient).

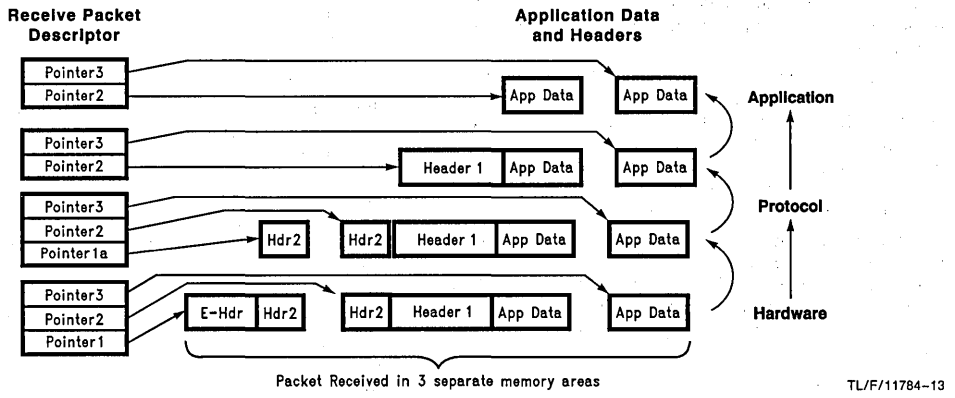

The problem with this second scheme is performance. When a packet is scattered as shown in *Figure 11b*, multiple pointers are required to keep track of the packet, this means that there is more software overhead associated with maintaining the pointers, and it is possible that some fields within the packet may be split between two buffers. Fortunately, this split is not likely to occur in the packet headers if >64 byte buffers are used, but the application data will be split, and may need to be copied to a contiguous buffer by the NOS prior to handing it off to the receiving application.

The problems with the two associated schemes can be overcome by having the hardware buffer the packet into a single contiguous memory area (*Figure 11c*). This allows the protocol software to have only one pointer to describe a packet. When a header is processed, the old pointer is thrown out, and the next header's pointer is easily created. The packet data arrives at the application in contiguous form. Multiple pointers to packet headers can easily be created if the software requires it. In multiple packet type applications, it is easier/cheaper for the software (as opposed to hardware) to determine the type of protocol/packet type for the received packet and manipulate the data based on this determination.

FIGURE 11

### Operating System Requirements

As has been described, the optimal buffering scheme for packets depends, in part, on the way the NOS interacts with the device driver and the hardware. At the device driver level, the NOS defines a programming interface for the exchange of packets between the hardware/driver and the NOS. The type of interface helps to determine the desired buffering scheme.

**Note:** Hardware architecture also affects this choice.

For non-embedded applications which use standard operating systems, the most prevalent transmit schemes provide the driver with a list of locations for the various portions of the packet. The driver/hardware then assembles the packet to prepare for transmission. Several schemes are used for receiving packets, but contiguous packet reception is the most popular. Packet scattering based on small memory block allocation is also quite common.

Most operating systems require a certain byte alignment on received packets to conform to their memory management schemes. For example, 32 bits OS's usually require double word alignment, while PC DOS (an 8-bit OS), most often demands byte alignment. In general, the transmit alignment is usually byte oriented because the header fragments generated may be an odd number of bytes.

### Hardware Packet Buffering Schemes

Keeping in mind the general characteristics outlined above, several hardware packet buffering techniques can be compared. The NOS requirements do not change based on the hardware architecture or the buffering scheme chosen, so when the hardware does not provide optimal algorithms, the device driver software is required to complete the job.

When the hardware packet buffering scheme minimizes bottlenecks (particularly software overhead), the theoretical performance of the driver/hardware set will increase. This section compares major buffering schemes and how they map into the NOS operations, hopefully revealing an indication of the better architectures.

The several schemes can be categorized as follows:

1. Simple DMA: Utilizing a simple start address and length, the system DMA performs all memory transfers.
2. Buffer Ring: A block of memory is setup as a recirculating ring where data at the top of the memory block automatically wraps to the bottom, and pointers track the used/open memory space.
3. Linked Lists: A number of descriptor structures that describe blocks of memory. Each block can contain either a part of a packet, a single packet, or multiple packets.
4. Protocol Translation: This scheme must be implemented on an intelligent card since the on board CPU performs driver tasks as well as protocol processing. The designer can customize the hardware using any combination of the three previous buffering schemes if the native CPU is not needed for protocol translation. This buffering scheme, due to it's unique programmability, will not be discussed separately.

### SIMPLE DMA BUFFERING

Typically this buffering architecture is used when the Ethernet Hardware is a simple MAC (Media Access Controller) Bus Master card that uses the system's DMA to provide a low cost solution. It is possible that the System DMA can be used in conjunction with a hardware scheme that includes a dedicated buffer RAM (like Shared RAM).

Reception tends to be a problem for the simple MAC bus master, so this is discussed first. Incoming packets are buffered in a small FIFO and a request is made for the system DMA controller to transfer the data. Simple bus master cards that do not use local memory must have access to the system bus before the FIFO fills, or the packet will be dropped. In addition, the host CPU must be able to allocate new blocks of memory as they are needed, which can be significant in terms of software overhead. For ISA based PC's, the DMA transfer rate is between 1.0-2.0 Mbytes/second which is not sufficient to keep up with the Ethernet data rate.

The transmit operation requires the DMA controller to transfer data from the host's memory to the controller's FIFOs (Figure 12). If the FIFOs are not large enough to buffer the maximum packet size, care must be taken to avoid a FIFO underrun because partial packets will be transmitted on the network. Once again, the host's CPU is responsible for all memory management.

TL/F/11784-15  
**FIGURE 12. System Memory Packet Reception**

### Buffer Ring DMA

For this architecture, the controller's memory manager utilizes a ring structure comprised of a series of contiguous fixed length buffers in a local RAM (Figure 13). The ring is typically divided into a transmit and receive section by the driver software. During reception, incoming data is buffered to the receive portion of the ring and then transferred to the system by the local DMA channel. The memory manager is responsible for three basic functions during reception: linking receive buffers for long packets, recovery of buffers when a packet is rejected, and recirculation of memory blocks that have been read by the host.

When transmitting data, the software driver must first assemble the packet in the transmit portion of the ring using DMA transfers. This information must include the destination address, the source address, the type/length of the packet, and the data itself. When transmission begins, the controller's local DMA channel transfers the data out of the ring and into the controller's FIFO. The controller sends out the data and appends a CRC field. The block of buffer memory used by the packet is then returned for reuse.

### Linked List Packet Handling

In a linked list structure, packets that are received or transmitted are placed in buffers that are linked by lists of pointers. The advantage to this approach, as mentioned earlier, is that it should eliminate unnecessary packet copying. The

software driver pre-allocates memory for receiving data and stores a list of pointers to available buffer pages in a Receive Resource Area (Figure 14). Another list of pointers (Resource Descriptor Area) is created when packets are received. Each pointer in this list corresponds to the starting address in memory of the received packet. Multiple packets can be stored in the same buffer area as long as their total length does not exceed the buffer page size.

The transmit buffer management scheme uses two areas in memory for transmitting packets (Figure 15). The Transmit Descriptor Area contains several fields that describe the packet to be transmitted and a pointer to the descriptor of the next packet to be transmitted. Quite often, operating systems store packet header information in one portion of memory and application data in another. Each of these fields is called a fragment.

The typical Ethernet packet contains multiple fragments, so the linked list buffering scheme provides pointers to each piece as well as a count of how many fragments are in the packet. In contrast, the buffer ring architecture would have required the driver to copy all of the fragments and the applications data into a contiguous area of local RAM prior to transmission. The buffer ring is a simple lower performance packet buffering scheme. The linked list structure adds some complexity, but will increase performance when properly tailored to the network operating system.

## SYSTEM APPLICATIONS

For a certain application, many architectures may prove adequate, but the *best* solution may not be obvious. The following section will discuss the general design tradeoffs to each approach as they apply to personal computers and office peripherals.

### PC/PC-AT Client Adapter

While many companies promote performance, most simple interfaces prove to be sufficient, therefore cost and compatibility are of greater importance. The I/O mapped design is by far the most prevalent architecture for PC client cards due to good packet throughput performance and low cost. I/O mapped cards also tend to be the easiest to install because the I/O space of PC's tends to be less crowded than the memory space.

Shared memory cards must map their local packet RAM into the PC's address space between 640k and 1M. In the DOS environment, this space is crowded with BIOS ROMs, EGA/VGA video RAM, and disk controller hardware. Depending on the machine, configuration address contention can result. Also, the PC-AT bus timing for dual ported RAMs is tricky and varies somewhat between clones, thus making compatibility a more difficult issue.

For bus mastering cards, arbitration is not well implemented on many PC-AT compatibles and is not available in the PC-XT. These types of cards seem to have the most trouble interfacing to PC-AT clones because they are sensitive to system timing and the addition of other add-in cards. An improperly designed card can interfere with DRAM refresh and thus cause catastrophic failure. Earlier Ethernet controllers are not suitable for this approach because the bus cycles are excessively slow, thus limiting CPU performance.

**Note:** PS/2's with a microchannel bus provide very good arbitration, so bus masters are much more suitable for this environment.

The other architectures previously mentioned tend to be too expensive for the minor performance gains that would be achieved.

**Performance.** Assuming that the I/O port design is the reference, then the relative performance of the shared RAM design offers between a 2%–7% packet throughput improvement. Faster 386 based machines tend to minimize any advantages when the NOS is taken into consideration. The bus master could offer up to 10% speed improvement, but when using older Ethernet controllers this improvement is less. The major advantage to this approach can be lower CPU utilization.

### PC (ISA Bus) Server Adapter

Until very recently, servers have been mostly high performance ISA Bus PC-ATs. Due to multiple users, the traffic on the server is much higher than the client, and so bottlenecks in packet transfer will be more noticeable. Servers may also have to support multiple network cards to allow for the internal bridging of networks. The weakest link in these systems tends to be the relatively slow ISA bus.

For ISA bus servers, I/O mapped, shared RAM, and bus master designs all have their advantages and disadvantages. The best overall solution could be the I/O mapped design in spite of its slightly lower performance; it is compatible to industry standards, lower cost, and offers reasonable performance. Multiple cards can easily be employed since this interface does not put a burden on the bus, nor tie up needed RAM space.

The Dual-Ported RAM design offers slightly better performance, and won't tie up the bus, but does use precious memory space. This solution may prove less suitable if several cards are required in the Server.

Simple bus masters can provide the best performance, but since multiple cards can tie up the PC-AT's ISA bus and prevent CPU and refresh from getting sufficient access to the bus, this could present a problem when multiple cards are placed on the bus. No standard exists for supporting arbitration among multiple bus masters. Some initial implementations will only allow installation of one card due to slow bus cycles.

**Performance.** Assuming that the I/O port design is the reference, then the relative performance of the shared RAM design offers between a 2%–7% packet throughput improvement. The bus master could offer up to 10% speed improvement.

### PS/2 and EISA Server Adapter

The 32-Bit 386/486 PS/2 and EISA machines require the best performance, and cost tends to be a secondary issue. In addition, both these buses have intelligent bus arbitration schemes for bus ownership. The major difference between the two is that the arbitration scheme for EISA has the potential for having a relatively large bus latency, whereas the Micro Channel bus latency tends to be lower. This difference affects the bus mastering approaches taken.

The I/O mapped scheme is not optimal since cost is less of an issue and performance is more important. The Dual Port RAM scheme is a better choice as bus transfer speeds can be optimized by using fast RAMs, but the cost of the associated RAMs and logic is more (4-32kx8 SRAM are typically used for on-card buffering).

A simple bus master can be a very good choice if the desired bus latency is accommodated and an intelligent buffering scheme is implemented. This architecture can cost the same as a shared memory design, but provide faster packet throughput. Also multiple cards can easily be accommodated.

For the best performance, a well implemented intelligent board which does on board protocol processing is the best choice. However, the cost is prohibitive, and while overall server CPU usage can be minimized, typical implementations do not offer the best overall throughput.

### PC Motherboard Applications

The goals in designing Ethernet connectivity onto PC motherboards differs from those of PC add-in cards. First, due to severe competition and a network oriented focus, add-in board designers tend to concentrate on both the cost and performance of an implementation. The primary concern for PC motherboard designers is CPU performance and compatibility to existing standards. The purpose of including Ethernet is to provide added value and a simple inexpensive connection. Board space and power consumption tend to be more critical on motherboards.

Applications on the motherboard fall into two design categories:

1. An adapter card design folded down onto the main system board.
2. A system bus interface (or local bus) directly connected to the CPU.

The best approach depends on whether the Ethernet's design goal is primarily cost or performance driven. The folded-down design offers compatibility with well established standards and thus the lowest risk. The system interface architecture offers better performance at the expense of complex system design considerations.

#### PC System I/O Bus Design

The easiest approach to embedded Ethernet is to simply graft an existing PC adapter's design onto the motherboard or daughter card. This places the controller in a less performance critical area of the overall system design (the I/O bus) and allows a migration path from a solution that is known to work. Since backward compatibility is achieved, investments in software and experience are preserved. This design can be applied across an entire line of PC's with no modification to the hardware or software.

The most common implementation would be to "fold" an ISA bus 16-bit Ethernet card design onto the motherboard and thus provide a common interface for both ISA and EISA. The growing popularity for ISA based adapters has led semiconductor suppliers to provide very highly integrated solutions for this environment. Unfortunately the same integration level is not yet available for EISA based 32-bit designs.

The only disadvantage to "folding down", an adapter card solution is slightly lower performance. Since the throughput of Ethernet is usually "cable limited" this approach is suitable for clients and most servers.

#### PC System Bus (CPU Bus)

In this implementation, the Ethernet controller is tightly coupled to the system CPU bus (386 or 486). This is illustrated

by the top shaded block in *Figure 16*. In a PC, the highest performance bus is the CPU system bus. Ethernet controllers designed to operate in this environment can provide a relatively clean interface with a low parts count. The bus master architecture makes the most sense for this bus due to the simplicity of the interface.

The CPU system bus tends to be the most critical aspect of a PC's overall performance. Adding peripherals to this bus has generally been avoided because I/O functions can reduce bus efficiency. Embedded cache memories on some CPU's help to lessen this burden, but system performance will be affected. Another concern is that this bus was not designed to support the large fanout required for driving multiple I/O devices.

Interfacing to the CPU's bus presents many challenging design problems. The characteristics of this bus are determined by both the CPU and the memory controller. Changes in CPU type and frequency will cause the interface to vary for each PC model in a product line. The controller's operating frequency must be closely matched to that of the CPU to avoid timing problems. This can create problems for modular PC's that offer CPU upgradeability.

Table I summarizes the discussion on PC-Ethernet architectures. It should be noted that the ratings assume that each implementation is a good efficient design. For example, a simple bus master is an excellent architecture only for applications where it meets with the requirements of the bus; this may not always be true. Some qualitative performance references are given, but these should not be taken as valid for every case.

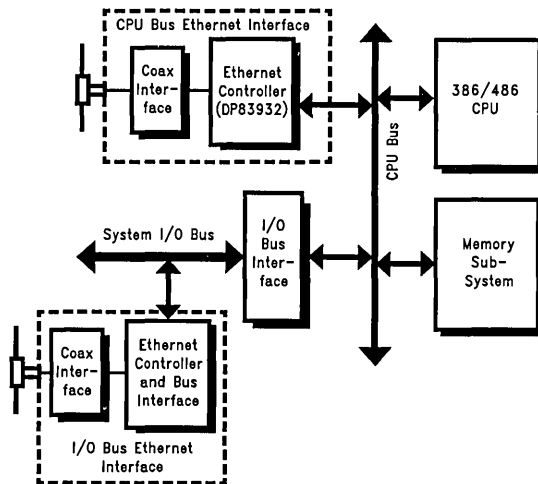

FIGURE 16. Two Choices for Ethernet on a PC Motherboard

TL/F/11784-19

TABLE I. Suitability of Architecture for PC Applications

Architecture (Note 1)	I/O Mapped	Dual Port RAM	Simple Bus Master	Buffered Bus Master	Intelligent
PC, PC AT (ISA), PS/2 (Client) (Note 2)	Excellent	Good	Fair	Poor	Poor
PC AT (ISA Bus) (Server) (Note 2)	Good	Good	Fair	Poor	Fair
PS/2 (Server) (Note 2)	Fair	Good	Excellent	Fair	Excellent
PC AT (EISA) (Client/Server)	Fair	Good	Excellent	Good	Good
PC Motherboard (System Bus) (Note 3)	Good	Good	Good	Poor	Poor

**Note 1:** The rating from best to worst: Excellent, Good, Fair, Poor.

**Note 2:** These applications assume that the Ethernet interface is supplied on an adapter card.

**Note 3:** This application places the Ethernet interface on the PC AT motherboard (system planar) interfaced to the system CPU bus. If the Ethernet interface is placed on the motherboard connected to an I/O bus the architectural choice is represented by the bus (like ISA).

### CONCLUSION

The correct choice of an Ethernet controller must be a careful balance of all of the design goals. In the majority of cases, the throughput of 16-bit Ethernet controllers is more than sufficient (with the exception of servers). For 386 or greater based PC's, throughput is limited by the network operating system and the 10 Mbit/sec. data rate of Ethernet. The decision to use a 32-bit controller should be based on the need for available CPU bandwidth, and to a much lesser extent, throughput.

# Writing Drivers for the DP8390 NIC Family of Ethernet Controllers

National Semiconductor  
Application Note 874

AN-874

## INTRODUCTION

This document provides detailed information for writing drivers for the NIC Family of Ethernet Controllers; DP8390 NIC, DP83901 SNIC™, DP83902 ST-NIC™, and DP83905 AT/LANTIC™. It describes the basic components of the drivers: (1) hardware initialization, (2) initiating transmissions, and (3) servicing receive and transmit interrupts. It includes specific examples of actual network drivers (DriverInitialize, DriverSend, and DriverISR). **We recommend that you become familiar with the individual part Data-sheets.**

## HARDWARE INITIALIZATION

The initialization procedure supplies configuration parameters for the NIC Controllers to operate in the current system. This involves the CPU loading the proper values into the configuration and address registers and enabling the NIC Controllers onto the network. The following shows a list of parameters that must be initialized before the NIC Controllers become operational.

- data bus width (8 or 16 bits)
- physical address
- types of interrupts that may be serviced
- size of the Receive Buffer Ring
- FIFO threshold
- types of packets that may be received

An example of an initialization routine for a typical 8-bit system is exemplified in DriverInitialize. Note that the DATA CONFIGURATION register must be initialized before all other registers are initialized (except the COMMAND register). Note also the sequencing to enable the DP83902 and DP83905 onto the network.

## PACKET TRANSMISSION

The transmit driver is generally partitioned into two parts. The first part (DriverSend) initiates a transmission whenever the upper level software passes a packet to the driver. If the driver is unable to transmit the packet immediately (i.e., the transmitter is busy), the supplied packet is queued in a transmit-pending buffer. After initiating or queuing up the packet, DriverSend returns.

DriverSend operates in conjunction with an interrupt service routine (DriverISR). After completing the transmission, the NIC Controllers interrupt the CPU to signal the end of the transmission and indicate status information in the TRANSMIT STATUS register.

## RECEIVE DRIVER

The responsibility of the receive driver is to transfer data from the Receive Buffer Ring to the host's memory. Ideally, this process is done as fast as possible to eliminate any bottlenecks that may be incurred by the driver. The NIC Controllers facilitate removing data from the Ring by providing a Remote DMA channel to transfer data from the Ring to an I/O port which is readable by the host system. It also

maintains two pointers to track packets in the Ring: BOUNDARY and CURRENT. These registers respectively point to the last unread packet in the Ring and the next vacant location in memory to receive another packet. Generally, the receive driver removes the next packet pointed to by BOUNDARY, then increments BOUNDARY to the succeeding packet indicated by the Next Page Pointer in the 4-byte NIC Controllers receive header. This process continues until all packets have been removed from the Ring.

The NIC Controllers automate packet removal with the "send packet" command. When this command is issued, the NIC Controllers automatically load the DMA start address with BOUNDARY, load the DMA byte count from the 4-byte receive header, then begin transferring data. At the end of the DMA, the NIC Controllers update BOUNDARY with the Next Page Pointer from the receive header. To remove all packets from the Ring, the receive driver simply issues the "send packet" command until the BOUNDARY and CURRENT registers are equal.

Because of the asynchronous nature of reception, the receive driver must be interrupt driven. Typically, packet reception is given high priority since delaying packet removal may overflow the Receive Buffer Ring. If several packets in the ring have been queued, all packets should be removed in one process (i.e., a software loop which empties the Ring). In heavy traffic conditions, local memory can fill up quickly so it is important that the Ring be large enough to handle these situations.

To find out how many packets are lost due to Ring overflows or network errors, the NIC Controllers have three statistical registers to monitor the network; FRAME ALIGNMENT ERROR tally, CRC ERROR tally, and FRAMES LOST tally. These registers are useful in initially determining the size of the Ring and how many packets are lost due to network related errors (CRC errors and/or frame alignment errors).

## EXAMPLE DRIVERS

The following transmit and receive drivers are written in assembly for fast execution. The transmit driver is partitioned into two parts, DriverSend and DriverISR, while the receive driver resides entirely within DriverISR. This section gives an overview of DriverISR, followed by a description on how receive and transmit interrupts interact with DriverISR.

### Interrupt Service Routine (DriverISR)

DriverISR is concerned with interrupts originating from receptions, transmissions, and errored transmissions. Errored receptions are ignored since these are usually collision fragments and are of no use to the upper layer software. DriverISR (Figure 2) consists of (1) a packet transmitted routine and (2) a packet received routine. The basic functions of the routines are as follows:

Packet Transmitted Routine: checks the status of all transmissions and transmits the next packets in the transmit-pending queue.

1

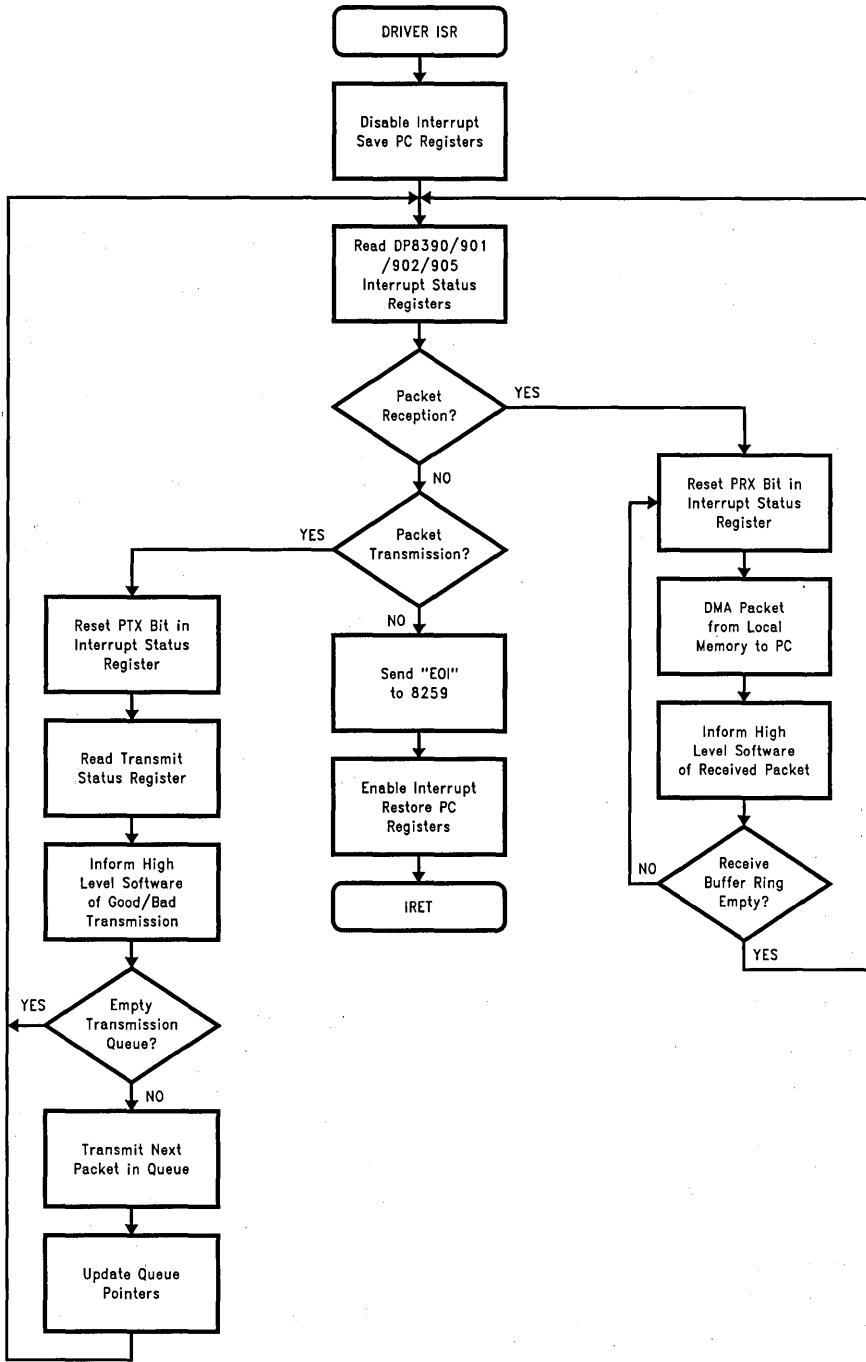

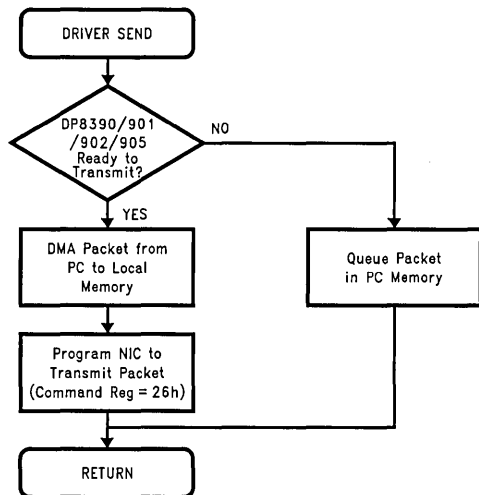

FIGURE 2. Interrupt Service Routine

Packet Received Routine: removes all packets in the receive buffer ring by using the "send packet" command of the NIC Controllers.

### Transmit Driver

The transmit drivers consist of two parts. The first part, DriverSend (Figure 3), initiates transmission when called by the upper layer software. DriverSend checks if the NIC Controllers are ready to transmit by reading the COMMAND register (TXP bit is zero). If ready, the DriverSend using the DP8390's Remote DMA channel, transfers from the PC's memory to local memory, then issues the transmit command and returns. Otherwise, if the NIC Controllers are busy (TXP bits equal one) DriverSend queues the packet in the transmit-pending queue, then returns.

TL/F/11785-3

FIGURE 3. Driver Send Routine

After a transmission is completed, DriverISR services the interrupt from the NIC Controllers and (1) reports status information by reading the TRANSMIT STATUS register and (2) transmits the next packet in the transmit-pending queue,

if any. Thus, for a transmit interrupt, DriverISR executes the following steps:

1. Reset PTX bit in INTERRUPT STATUS register.
2. Check for good transmission by reading the TRANSMIT STATUS Register.
3. If there are more packets in the transmit-pending queue, transmit the next packet; otherwise go to 4.
4. Read INTERRUPT STATUS register for any pending interrupts.

### Receiver Driver

Since the receiver driver must be interrupt driven, it resides completely within the DriverISR. When the receive interrupt occurs, one or more packets may be buffered into the Ring by the NIC Controllers. The DriverISR removes packets from the Ring and then passes them up to the host. Using the "send packet" command, packets are removed until the Ring is empty, that is, when CURRENT and BOUNDARY registers are equal. The sequence of the receive packet routine is shown below.

1. Reset the PRX bit in the INTERRUPT STATUS register.
2. Remove the next packet in the receive buffer using the "send packet" command.
3. Check to see if the receive buffer ring is empty: BOUNDARY register = CURRENT PAGE register
4. If the Ring is not empty, go to 1; otherwise read INTERRUPT STATUS register for any more pending interrupts.

### OTHER SOFTWARE CONSIDERATIONS

The NIC Ethernet Controllers require some special software considerations to operate in all network environments. In particular, the handling of overflow of the receive buffer ring must be handled EXACTLY as described in the data sheet and Design Tips.

The most efficient manner to remove packets from the transmit-pending queue is to use Driver Send to initiate transmission of the very first packet in the queue; then upon completion, use the DriverISR to transmit the remaining packets. Using this method, the DriverISR examines the queue, transmits the next available packet, then exits. The DriverISR transmits the next packet after the NIC Controllers issue the next transmit interrupt.

# DP83905EB-AT AT/LANTIC™ Evaluation Board

National Semiconductor  
Application Note 875  
Rick Willardson

## 1.0 OVERVIEW

The DP83905EB-AT AT/LANTIC Demonstration board provides system designers with complete 16-bit 10BASE-T, 10BASE2 and 10BASE5 Ethernet Solutions in a half-size, jumperless, ISA adapter card. The board uses only four ICs and can be configured as either a shared memory or an I/O port adapter card. All of the bus interface logic is implemented in the DP83905, AT Local Area Network Twisted Pair Interface Controller (AT/LANTIC). The AT/LANTIC uses an E<sup>2</sup>PROM to store the board's IEEE node address and its own configuration information. It uses two 8k x 8 SRAMs for buffering packets to and from the network.

The DP83905 has a built in Manchester Encoder/Decoder and Twisted Pair Transceiver. This allows the AT/LANTIC to transmit and receive packets on a 10BASE-T network with the addition of only a filter and some discrete components. An AUI interface on the AT/LANTIC can also be used to run a 10BASE5 or 10BASE2 network with the addition of two 1:1 pulse transformers, a DC-DC Converter and the DP8392 Coaxial Transceiver Interface (CTI). Refer to the schematic at the end of this Application Note.

## 2.0 ARCHITECTURAL FEATURES

- Designed with the DP8390 Network Interface Controller, NIC
- Complete Ethernet solution with only 4 ICs
- Board options are configurable in software
- Half-size PC-AT® adapter card
- 2 Modes for ISA interface—Shared Memory or I/O Port (NE2000<sup>plus</sup>™ compatible)
- 10BASE-T, 10BASE2 or 10BASE5 connectivity
- Serial EEPROM stores IEEE address and AT/LANTIC configuration while using less power than a typical bipolar PROM
- Surface mount technology on most parts
- Boot PROM socket to allow diskless boot from NetWare™, LANManager and other network operating systems
- Able to select one of eight interrupts

TL/F/11786-1

### 3.0 BOARD DESIGN AND LAYOUT

Figure 2 shows the part placement and power plane layout for the DP83905EB-AT Demonstration Board. The design is straight forward because all of the bus interface logic, including the 24 mA ISA bus drivers, is internal to the AT/LANTIC. The Twisted Pair interface is simple as the TPI transceiver is also internal to the AT/LANTIC. Thin Ethernet (10BASE2) is achieved with the addition of a DP8392CV CTI device and a DC-DC converter.

#### 3.1 ISA Bus Interface

All of the ISA Bus interconnects of the AT/LANTIC can be directly routed to the ISA Bus connector. Changing the physical placement of the AT/LANTIC may make these traces easier to route, but in order to keep the Twisted Pair Interface traces as short as possible, the AT/LANTIC should be placed as close as possible to the card's metal bracket. This makes the routing of the ISA Bus traces longer and hence noisier. To filter low frequency noise (kHz range) on the bus a 22  $\mu$ F decoupling capacitor was placed near the bus connector between power and ground.

The Boot PROM address lines also come directly from the ISA Bus connector. The reason for this is that the AT/LANTIC's Memory Support Address Bus does not buffer address bit A0 which is needed by the boot PROM (the AT/LANTIC only does word aligned transfers when in 16-bit mode). Boot PROM addresses must come directly off the ISA Bus where byte or word aligned transfers may be used by software. The physical location of the PROM is not critical.

#### 3.2 Memory Support Bus Interface

The Memory Support Interface is that part of the design which is used by the AT/LANTIC's Local DMA and Auto-Configuration. This includes the SRAMs and the E<sup>2</sup>PROM.

Figure 1 shows how both SRAMs and the E<sup>2</sup>PROM are connected to the Memory Support Bus of the AT/LANTIC. The AT/LANTIC uses the SRAM (8k x 16) for buffering transmit and receive packets and it uses the E<sup>2</sup>PROM to store the IEEE Node Address, a checksum, a board type, Configuration Registers A, B and C and codes which determine the data width in which the board is to run. Primarily the E<sup>2</sup>PROM is used on start up; once the AT/LANTIC reads the configuration data and the IEEE node address out of the E<sup>2</sup>PROM, this information is stored in the AT/LANTIC and made accessible by software.

In order to change the boot configuration of the board, the current configuration is changed in software and the AT/LANTIC downloads the new configuration to the E<sup>2</sup>PROM. The new configuration will be stored so that when the board is powered up again, the new configuration will be loaded. (See Section 4.0—older designs required hardware jumpers to do this). The E<sup>2</sup>PROM that the AT/LANTIC uses (NM93C06) is a serial device. The AT/LANTIC uses its MSD0–2 pins for Serial Data Out, Serial Data In and Clock to the E<sup>2</sup>PROM when reading or writing it.

The two RAMs provide 16 kbytes of memory for the AT/LANTIC to use for buffering received packets and for the system to use for buffering transmit packets. In Shared RAM mode the RAM logically resides in system memory, but it must still be connected to the AT/LANTIC's Memory Support Bus. The AT/LANTIC buffers the data and address from the ISA Bus, decodes the address and drives chip select and the read or write strobe to the RAM. Note that the board was designed to accommodate either DIP or SOP SRAMs.

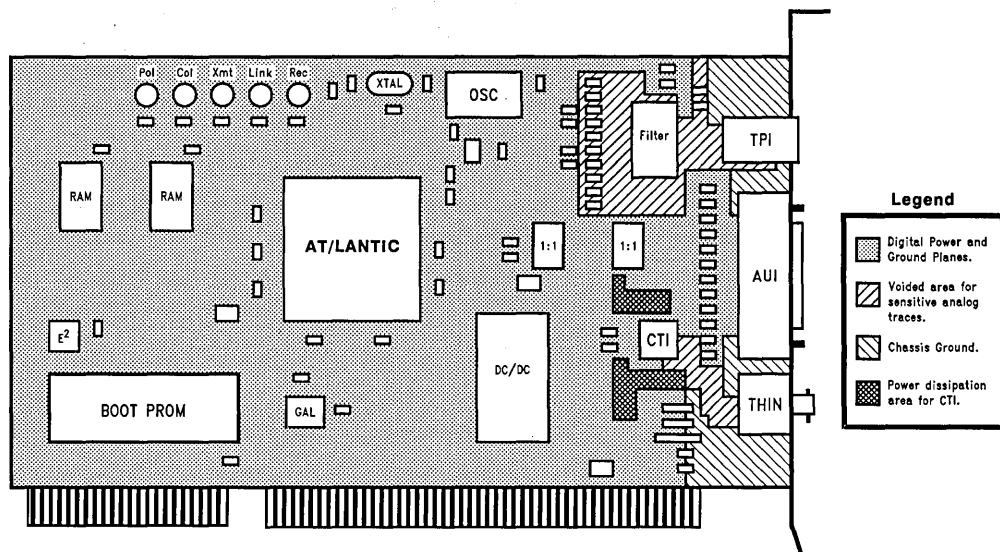

FIGURE 2. DP83905EB-AT Board Layout and Component Placement

TL/F/11786-2

### 3.3 AT/LANTIC

Some design and layout considerations were made with respect to the DP83905. These are described in the following three sections.

#### 3.3.1 Crystal and Oscillator Design

The AT/LANTIC has been designed to operate with either a crystal or an oscillator module. The DP83905EB-AT comes assembled with the crystal option. If an oscillator module is used, the crystal and the load capacitors C1 and C2 must be removed from the board. If the capacitors are not removed, they will create excessive loading on the clock which may stop the card from working. When mounting an oscillator, it should be raised slightly off the board so that it is not touching the metal pads for the capacitors C1 and C2 (some oscillator modules have built-in insulating raisers).

There are two layout considerations with respect to the clock. First, the traces for the clock should be short and the crystal or oscillator should be placed close to the AT/LANTIC (see *Figure 2*). Second, if a standard size crystal is being used and it must lie flat on the PC board, the power planes should be voided in that area. Note that on the DP83905EB-AT a low-profile crystal is being used that is not laying down. In this situation, it is not critical that the power planes be removed.

#### 3.3.2 Decoupling for the AT/LANTIC

The AT/LANTIC, like any other VLSI device, is composed of multiple functional/logic blocks. In some cases, these blocks run off of separate power rails internal to the part. Some of these blocks (such as the Twisted Pair Transceiver) can be quite susceptible to noise. Not only can the input signals couple noise from the board and environment, but output signals can transmit noise to the environment. Also, since the separate power pins are all connected to the same 5V supply in the PC, other noisy power signals can affect power supplies that need to be kept noise free. By separately decoupling the supply pins to the AT/LANTIC, the internal supplies are reasonably isolated from each other. Instead of placing decoupling capacitors near the AT/LANTIC, place the decoupling capacitors directly to the power pins. Each of the seven blocks within the AT/LANTIC should be decoupled by at least one 0.01  $\mu\text{F}$  capacitor. Thus, each of the power rails in the chip has independent decoupling. This minimizes EMI and reduces power supply noise.

Another area of concern is the AT/LANTIC's ISA bus interface. This section is driving the ISA bus with 24 mA bus drivers. Not only is the current high, but the rise and fall times of the bus signals are fast. By decoupling the ISA interface supply, noise produced by these drivers is reduced.

Decoupling of noise from the PC bus is achieved using 0.01  $\mu\text{F}$  and 22  $\mu\text{F}$  capacitors (used to filter out lower frequency noise in the order of a few kHz). One 22  $\mu\text{F}$  is placed near the media end of the board and the other near the ISA bus connector.

#### 3.3.3 PLL Power Supply Noise

The VCO (Voltage Controlled Oscillator) block of the receive PLL (Phase-Lock Loop) within the AT/LANTIC is sensitive to noise in the frequency range of 10 kHz to 400 kHz. As little as 100 mV of noise in this range can cause the PLL

to lose lock on an incoming packet. In order to improve the performance of the PLL, a single pole filter should be used on the PLL power supply pin. This is shown below in *Figure 3*.

TL/F/11786-3

FIGURE 3. PLL  $V_{CC}$  Noise Filter

#### 3.4 Twisted Pair Interface (TPI)

This section refers to the layout diagram in *Figure 2*, of this Application Note.

The Twisted Pair Interface of the DP83905EB-AT is simple: the only components needed external to the AT/LANTIC are the pre-emphasis resistors, some capacitors, a transformer/filter module and, of course, the RJ45 modular connector. Resistors R19-22 (refer to the schematic at the end of this application note) provide the preemphasis for the TXO $\pm$  output as described in the AT/LANTIC datasheet. R23 damps the TXO $\pm$  output undershoot. Resistors R24 and R25 terminate the receive Twisted Pair line. C9, C43-C45 filter out the common mode noise in the transformer/filter. C46 and C47 filter out the high frequency noise harmonics on the TXO $\pm$  output. All these components together with the transformer/filter module should be placed as close to the AT/LANTIC's twisted pair interface pins as possible. The traces should be kept straight and should not run near any other traces. The traces on the cable side of the transformer/filter module to the RJ45 connector should be kept short and straight too. Additionally, make sure that all differential traces are tracked in parallel so they are equal-length and will pick up the same amount of common mode noise.

The entire area under all of these signals should be voided of signal traces and power planes, as these could couple noise into the Tx/Rx signals. This is shown in *Figure 2*. This part of the circuit is very critical and will affect FCC test results directly. Precaution should be taken during layout to ensure that noise is reduced as much as possible.

#### 3.5 Attachment Unit Interface (AUI)

The DP83905EB-AT can be used with an external Medium Attachment Unit (MAU) so that connectivity to 10BASE5 or another medium can be achieved. This interface is via the 15-pin D-type connector and is a direct interface to the AT/LANTIC's ENDEC. The AT/LANTIC's ENDEC requires two 270 $\Omega$  pull-down resistors on the transmit outputs and 78 $\Omega$  terminations on the receive and collision inputs. Also, the RX, TX and CD lines must be AC coupled using a standard 1:1 pulse transformer. This is the only design requirement for the AUI interface: it is needed to isolate the AT/LANTIC from DC fault conditions. Although these differential signals are not as noise sensitive as the Twisted Pair inputs, care should still be taken when laying out this section of the board. It is not necessary to void the power planes under them.

### 3.6 Coaxial Transceiver Interface (CTI)

This section refers to the layout diagram in *Figure 2* of this application note.

The Coax Transceiver Interface (DP8392CV) should be placed very close to the BNC connector. This will allow the TXO/RXI trace to be short and straight. The area under this trace should be voided of all other signals and power planes (as shown in *Figure 2*) in order to meet the IEEE 802.3 input capacitance requirement. The BNC connector on the demonstration board is a standard part, however, "quiet" connectors are readily available to reduce noise for performance and FCC qualification. The CTI requires an area of copper on the top of the board for heat dissipation. This is also shown in *Figure 2* and is documented in the DP8392CV datasheet. The ground shield of the BNC connector (and of the coax cable) is resistively and capacitively decoupled to chassis ground. There is a chassis ground strip on each layer of the board running from the top to the bottom of the PC board. This is connected to the chassis of the PC through the 15-pin AUI connector's body metal. Chassis ground is then capacitively decoupled to digital ground. The chassis ground trace along the front of the board forms a "shield" so that noise is not emitted into or received from the environment.

In order to provide a jumperless solution, a 1:1 transformer is required between the CTI and the 15-pin AUI connector. This provides 500V isolation between the CTI and the DTE ground as required by the IEEE 802.3 specification.

#### 3.6.1 DC-DC Converter Solution

The DP83905EB-AT has been designed to use a standard DC-DC converter which operates from a 12V supply and meets the specifications of the DP8392CV. When the AT/LANTIC is programmed for Thin Ethernet, the THIN output is driven high to turn on the DC-DC converter. For Thick Ethernet and Twisted Pair (10BASE5/T) the AT/LANTIC drives the THIN output low, turning off the DC-DC converter.

Table I shows the possible settings for bits PHYS1 and PHYS0, the Physical Layer Interface selection bits in Configuration Register B. When programmed as [0 1] the THIN output of the AT/LANTIC will go high which will turn on the DC-DC converter. When programmed to any other combination the THIN output will go low, turning the DC-DC converter off.

TABLE I. Physical Medium Selection

PHYS1-0	Media
0 0	10BASE-T
0 1	10BASE2
1 0	AUI (10BASE5)
1 1	TPI (RSL)

#### 3.7 Interrupt Scheme

The DP83905EB-AT will support the selection of one of eight host interrupts. (Encoded mode.)

To program the AT/LANTIC to use the encoded mode interrupt scheme, set the INTMODE bit in Configuration Register C HIGH (logic 1)—see Section 4.3 for details. INT3 is the active interrupt output and INTO, 1, 2 are programmable outputs containing the values in bits 3-5 of configuration register A.

The DP83905EB-AT connects the AT/LANTIC's INTO-3 pins to the inputs of a 16V8 GAL. The GAL maps the INTO-2 inputs to the host's interrupts, as shown in *Figure 4* and Table II. This interrupt scheme is Novell NE2000plus compatible. The INT3 pin from the AT/LANTIC strobes true when an interrupt is generated by the AT/LANTIC's internal circuitry. The selected interrupt is output on the GAL (strokes LOW) for the duration of the INT3 strobe.

This means that the interrupt outputs are intended for use in an edge triggered interrupt environment. They will not function correctly in a machine with level triggered interrupts—interrupts may be missed.

By definition the ISA bus uses edge triggered interrupts, however, in an EISA machine, interrupts can be system selected to be either edge or level triggered.

```

IRQ3.OE = !INT3 & !INT2 & !INT1 & !INT0;
IRQ3 = 0;
IRQ4.OE = !INT3 & !INT2 & !INT1 & INTO;

IRQ15 = 0;

```

FIGURE 4. GAL Contents

TABLE II. Interrupt Selection

INT 2, 1, 0	Interrupt Level
0 0 0	IRQ 3
0 0 1	IRQ 4
0 1 0	IRQ 5
0 1 1	IRQ 9
1 0 0	IRQ 10
1 0 1	IRQ 11
1 1 0	IRQ 12
1 1 1	IRQ 15

#### 3.8 Status LEDs

Five LEDs are located at the top of the board to indicate network status. The LEDs from left to right are: POLARITY (POL), COLLISION (COL), TRANSMIT (XMT), LINK (LNK) and RECEIVE (REC).

The POL LED is lit when the TPI module detects seven consecutive link pulses or three consecutive receive packets with reversed polarity.

The COL LED is lit for approximately 50 ms whenever a collision is detected.

The XMT LED is lit for approximately 50 ms whenever the AT/LANTIC controller transmits data.

In TPI mode, the LNK LED is lit while link pulses are being received. This indicates that the twisted-pair connection is active.

The REC LED is lit for approximately 50 ms whenever received data is detected.

### 3.9 Bed-of-Nails Testing

The DP83905EB-AT supports in-circuit testing to ensure that the board has been assembled correctly with working parts. The schematic for the board shows each of these points (TPxx) as test points. Physically, they are holes on the board or surface mount pads. Every node on the board that does not include a through hole part has an associated test point. The AT bus signals are also brought out to test points. This allows a bed-of-nails tester to probe every node of the board.

### 4.0 CONFIGURATION OPTIONS

Please refer to the AT/LANTIC hardware and software design guides for a more detailed explanation of this section.

The DP83905EB-AT does not require jumpers because all the configuration options for the board can be programmed by software. The serial E<sup>2</sup>PROM can also be written to by the AT/LANTIC, allowing the configuration to be changed and saved. The memory map of the E<sup>2</sup>PROM is shown in Table III.

TABLE III. E<sup>2</sup>PROM Contents

	D15-D8	D7-D0
0FH	73H	Config. Reg. C
0EH	Config. Reg. B	Config. Reg. A
0DH	Not used	Not used
0CH	Not used	Not used
0BH	Not used	Not used
0AH	Not used	Not used
09H	Not used	Not used
08H	42H	42H
07H	57H	57H
06H	Not used	Not used
05H	Not used	Not used
04H	Not used	Not used
03H	Checksum	Board Type
02H	E'Net Address 5	E'Net Address 4
01H	E'Net Address 3	E'Net Address 2
00H	E'Net Address 1	E'Net Address 0

The fields in the E<sup>2</sup>PROM are defined as:

**CONFIG REG. A**—Stores base I/O Address and Interrupt number that the board is currently using. The AT/LANTIC has write access to this location. See bit description in Section 4.1.

**CONFIG REG. B**—Stores Physical Layer Interface and programmable bus options. The AT/LANTIC has write access to this location. See bit description in Section 4.2.

**CONFIG REG. C**—Stores Boot PROM address and other hardware specific configuration options. The AT/LANTIC cannot write to this location. See bit description in Section 4.3.

**42H**—This location (08H) must contain 42H (ASCII "B"). When DWID is low, the software will read this location in the PROM Store of the AT/LANTIC and determine that the board is in an 8-bit slot. The AT/LANTIC cannot write to this location.

**57H**—This location (07H) must contain 57H (ASCII "W"). When DWID is high, the software will read this location in the PROM Store of the AT/LANTIC and determine that the board is in a 16-bit slot. The AT/LANTIC cannot write to this location.

**CHECKSUM**—This location is only used in Shared RAM mode. The checksum is used to verify the Ethernet Address and the board type. The two's complement addition of the last eight bytes (03H-00H) must equal FFH, otherwise there is an error. The value of the checksum is determined from this. The AT/LANTIC cannot write to this location.

**BOARD TYPE**—This location is only used in Shared RAM mode. The Board Type indicator tells the network driver what hardware is being used. The AT/LANTIC cannot write to this location. When the board is configured to operate in WD8013EBT compatible Shared RAM mode, the Board Type should be 05H.

**ETHERNET ADDRESS**—The last six bytes of the E<sup>2</sup>PROM contain the Ethernet Address which is issued by the IEEE. These bytes must be programmed uniquely prior to fitting the device onto the board, as the AT/LANTIC is unable to write to these locations.

#### 4.1 Configuration Register A

Please refer to the AT/LANTIC datasheet for a detailed description of the bits in Configuration Register A. The following descriptions show the bit definitions and their default settings.

**IOAD2-0 (D2-D0)**—The Base I/O Address for the DP83905EB-AT is programmed by these three bits. When programmed to [0 0 1], the AT/LANTIC will power up in software mode and not respond to any I/O Address. However, it will monitor the parallel port (278H) for four consecutive writes. On the fourth write to 278H, bus data will be loaded into Configuration Register A, setting the I/O address for the board. This is done so that the board will not conflict with other I/O slaves in the PC. The method the AT/LANTIC uses for monitoring the parallel port and activating configuration load is unique; no other device/software is likely to perform four consecutive writes to this location. Note that the DP83905EB-AT is shipped in this mode. When run the first time, the base I/O address must be changed using the ATLES software package.

**INT2-0 (D5-D3)**—Based on Configuration Register C, these three bits select which interrupt line is directly driven or which decode is used for coded interrupts. The DP83905EB-AT comes programmed to drive coded interrupt 3. [INT2-0 = 0 0 0].

**FREAD (D6)**—This enables the Fast Read option of the AT/LANTIC's Remote DMA Read operation. The DP83905EB-AT is shipped with the FREAD function disabled. [FREAD = 0].

**MEMIO (D7)**—Selects either I/O Port mode or Shared RAM mode. The DP83905EB-AT comes configured to run in I/O Port mode. [MEMIO = 0].

#### 4.2 Configuration Register B

Please refer to the AT/LANTIC Datasheet for a detailed description of the bits in Configuration Register B. The following descriptions show the bit definitions and their default settings.

**PHYS1-0 (D1-D0)**—The Physical Layer Interface bits select the type of physical layer being used on the board. This could be 10BASE-T, 10BASE2, AUI (10BASE5) or Reduced Squelch Twisted Pair. The DP83905EB-AT comes configured to use 10BASE2. [PHYS1,0 = 0 1].

**GDLNK (D2)**—This bit enables link test pulse generation and integrity checking when using twisted pair. It can also be read to indicate status. Link pulse generation and checking is disabled by writing a 1 to this bit. The DP83905EB-AT is shipped with link testing enabled.

**IO16CON (D3)**—One of two methods of generating  $\overline{IO16}$  is chosen using this bit. In normal operation,  $\overline{IO16}$  is driven off of the address decode.  $\overline{IO16}$  can be configured to be driven from the slave read or write strobe by this bit. The DP83905EB-AT, as shipped, will generate  $\overline{IO16}$  from address decode. [IO16CON = 0].

**CHRDY (D4)**—The way the AT/LANTIC drives  $\overline{IOCHRDY}$  can be selected by programming this bit. When low, the AT/LANTIC will drive  $\overline{IOCHRDY}$  after a slave strobe is asserted. When high, the AT/LANTIC will drive  $\overline{IOCHRDY}$  on BALE being asserted; this may be required when being used with some AT bus chipsets that sample  $\overline{IOCHRDY}$  early. The DP83905EB-AT, as shipped, will drive  $\overline{IOCHRDY}$  after slave strobe is asserted.

**BE (D5)**—This bit can be read by software to determine if there was a Bus Error. A bus error will occur if the AT/LANTIC attempts to insert wait states into a system access and the system terminates the cycle without inserting wait states.

**BPWR (D6)**—This bit protects Boot PROM write cycles. When high, the AT/LANTIC can generate write cycles to the Boot PROM. This feature is intended for use with writeable Boot storage devices. The DP83905-AT is not shipped with a Boot PROM, so this is programmed low.

**EELoad (D7)**—The EELoad bit enables/disables the AT/LANTIC from writing the configuration information into the E2PROM. This bit must be set before running the E2PROM load algorithm documented in the AT/LANTIC datasheet.

#### 4.3 Configuration Register C

Please refer to the AT/LANTIC Datasheet for a detailed description of all the bits in Configuration Register C. The following descriptions show the bit definitions and their default settings.

**BPS3-0 (D3-D0)**—These four bits select the memory address and size of the Boot PROM. If BPS3-0 is equal to [0 0 0 X], the Boot PROM is disabled. The DP83905EB-AT comes configured to operate without the boot PROM.

**COMP**—When this bit is programmed high, the AT/LANTIC's memory uses the full 64 kbytes of RAM. When low, the memory map is compatible with either the NE2000*plus* or the WD8013EBT (16 kbytes of RAM). The DP83905EB-AT is configured to run in compatible mode.

**INTMODE**—This bit selects which mode the AT/LANTIC's interrupt will run. When low, direct drive interrupts are used. When high, coded interrupts are used. The DP83905 is configured to use coded interrupts.

**CLKSEL**—When low, the NIC core of the AT/LANTIC is clocked by the 20 MHz clock on the X1 input. When high, an external clock other than 20 MHz can be used to clock BSCK. The DP83905EB-AT is configured to run on the internal 20 MHz clock.

**SOFEN**—This bit enables the software to update configuration registers A and B. When high, the configuration registers are not accessible by software. The DP83905EB-AT is configured to allow software to update the configuration registers.

#### 5.0 FUNCTIONAL OPERATION

The DP83905EB-AT takes advantage of the AT/LANTIC's ability to function in either Shared RAM mode or I/O Port mode. When in Shared RAM mode, the AT/LANTIC's bus interface is configured such that the local RAM on the board is mapped into system memory as well as the AT/LANTIC's memory. This allows the driver to have direct access to the AT/LANTIC's local memory. In I/O Port mode, the local RAM on the board is only mapped in the AT/LANTIC's address space. This permits the AT/LANTIC to have sole ownership of the RAM. The network driver has access to the RAM through a data latch, which is in I/O space.

In both architectures, the AT/LANTIC uses the local RAM to buffer both transmit and receive packets. During transmissions, the driver will write Ethernet packets into a designated block in the RAM, typically called the Transmit Buffer. In most cases, the transmit buffer is large enough for only one packet, and although they can be, packets are not queued for transmission. When the entire packet is written to memory and the AT/LANTIC is programmed to perform a transmission, the AT/LANTIC will begin reading the packet and storing it in blocks of bytes or words into its FIFO. From the FIFO, the data is serialized, encoded and transmitted to the network.

In a like manner, the AT/LANTIC uses the local RAM to store packets as they are received from the network. The AT/LANTIC's Receive Buffer is organized as a ring (or FIFO) so that multiple packets can be buffered and at the same time the network driver can read packets that have already been received. As packets are received into the AT/LANTIC's FIFO from the network, the AT/LANTIC's DMA puts the packet data into the local RAM. After packets have been buffered by the AT/LANTIC, the network driver will read the packets out of the buffer ring. Sections 5.1 and 5.2 describe how the AT/LANTIC operates in each of its bus modes. Sections 5.3 and 5.4 briefly describe the transmit and receive operations.

##### 5.1 Shared RAM Mode

With the AT/LANTIC configured to operate in Shared RAM Mode, the DP83905EB-AT is hardware compatible with a WD8013EBT card. Changes to the EEPROM contents are needed for the WD8013EBT drivers to run.

While operating in Shared RAM mode, the local RAM on the DP83905EB-AT can be mapped into system memory at one of several different locations. The upper and lower address decode and memory width can be selected by the Shared Memory Control Registers of the AT/LANTIC. The depth of the memory can be selected in Configuration Register C by setting the compatible (COMP) bit. This will configure the RAM to be either 16 kbytes (compatible with the NE2000*plus* and WD8013EBT) or 64 kbytes. The local buffer RAM is then accessible to both the AT/LANTIC and the ISA bus. An arbiter, internal to the AT/LANTIC, will determine which device currently has access to the RAM. The AT/LANTIC will only access the RAM during local DMA burst cycles for transmit and receive operations, however, it is critical that the AT/LANTIC is granted the bus within a short time after requesting it. For this reason, the arbiter will grant access to the internal NIC core in the event that both the AT/LANTIC and the host request the local bus at the same time. This arbitration is transparent to both the hardware and the network driver.

### 5.2 I/O Port Mode

If the AT/LANTIC is configured for I/O Port Mode, the DP83905EB-AT will be hardware compatible with an NE2000*plus* card. The NE2000*plus* network drivers will then run on the DP83905EB-AT.

In I/O Port mode, the AT/LANTIC is configured to use the Remote DMA function of the NIC core. In this mode of operation, the local RAM of the DP83905EB-AT is accessible only by the AT/LANTIC. In order for the driver to read any packets from the buffer ring or write any packets into the transmit buffer, the AT/LANTIC must be programmed to perform a remote DMA cycle. To execute a Remote DMA, the bus interface logic of the AT/LANTIC performs a simple handshake between the ISA bus and the NIC core through a D-type data latch (internal to the AT/LANTIC). For a remote DMA read, the AT/LANTIC will read a byte/word of data from the local memory and write it to the data latch. At the same time an I/O read cycle is executed by the host and the data is read from the latch. The handshake logic will wait state the ISA bus if the data is not ready when the read strobe becomes active. In a like manner, the AT/LANTIC will read data from the latch and write it to the local RAM during a remote DMA write.

As in Shared RAM mode, the AT/LANTIC's registers are accessible in I/O space. There is the addition of a hardware RESET port which can be driven by reading and writing to I/O location BASE + 18H, where BASE is the I/O base address chosen in Configuration Register A. The registers, data latches and reset port occupy 16 bytes of I/O space. Unlike Shared RAM mode, the Ethernet Address PROM is not located in I/O space. It is accessible only by the AT/LANTIC, so a remote DMA read is used to obtain its contents. In both I/O mode and Shared RAM mode, the Ethernet Address PROM is not a physical device, but a dynamic copy of the Ethernet address and other information (from the E<sup>2</sup>PROM) held in the AT/LANTIC.

### 5.3 Transmit

The DP83905EB-AT can transmit and receive Ethernet packets on the three basic types of media available today. A twisted pair transceiver internal to the AT/LANTIC allows easy connectivity to a 10BASE-T network. The transceiver

provides link integrity checking, polarity detection and correction and pre-emphasis of the transmit output. The AT/LANTIC can also be configured to use its AUI interface for connection to a MAU (10BASE2/5/F/T) or on board 10BASE2 transceiver.

To transmit a packet, there are three basic steps that need to be taken. Please refer to *Figure 1* of this Application Note. First, the packet that is to be transmitted is loaded into the AT/LANTIC's buffer RAM by the host. The packet must consist of a destination address, a source address, length and data. If the data is less than 48 bytes, it must be padded with arbitrary data so that the entire packet is 64 bytes as required by the IEEE 802.3 standard. (This is not a requirement of the AT/LANTIC.) Next, once the packet is in RAM, the host programs the local DMA registers with the location and length of the packet to be transmitted. Lastly, the host issues the transmit command to the AT/LANTIC and the AT/LANTIC will start transmitting the packet.

The first activity the AT/LANTIC does is a prefetch to load the FIFO with data. Next, the NIC core of the AT/LANTIC will start sending preamble in NRZ format to the ENDEC. The ENDEC, in turn, encodes the data with the transmit clock in Manchester format and drives a differential transmit pair to either the internal twisted pair transceiver or to the AUI port of the AT/LANTIC. The twisted pair transceiver then drives the TXO outputs while pre-emphasizing the signal to eliminate inter-symbol jitter. If 10BASE2 is being used, the DP8392CV receives the differential transmit data from the AT/LANTIC and drives the coax line with a single-ended signal. Both transceivers will monitor the network for collisions.

In the event that there is a collision, the transceiver will drive a 10 MHz signal on the Collision Detect differential pair. The ENDEC will then drive a collision signal to the NIC core so that the Ethernet MAC control section of the NIC will implement the collision backoff algorithm and attempt re-transmission.

After the preamble and start-of-frame delimiter have been transmitted, the AT/LANTIC will serialize bytes from the FIFO and transmit them in the manner described above. When the FIFO empties to a pre-set threshold, the AT/LANTIC will fetch more data from the local RAM using its local DMA function. As the data is being transmitted, a Cyclic Redundancy Check (CRC) is continuously being calculated. After all the data has been transmitted, the 4 byte CRC value is transmitted. This allows receiving stations to check the received packet for data integrity.

### 5.4 Receive

Receiving a packet is almost the exact opposite of transmitting a packet. The functional blocks discussed above remain the same, however there are some differences which will be discussed. The transceiver will sit idle until a valid signal is received on the media, indicating the start of a packet. This causes the transceiver's RX squelch to turn off. Both the twisted pair transceiver (internal to the AT/LANTIC) and the DP8392CV CTI have squelch circuitry which filter out noise on the network, however, they are implemented differently. The TPI transceiver checks an incoming signal for both amplitude and frequency (sometimes referred to as smart squelch).

The CTI only checks for valid amplitude. Once the CTI has turned its RX squelch off it starts driving the receive differential pair of the AUI. The ENDEC (internal to the AT/LANTIC) recovers a 10 MHz clock and receive data in NRZ format from the receive pair with its analog PLL. The NRZ data is clocked into the NIC core, de-serialized, and loaded into the FIFO. When the number of bytes in the FIFO reaches the programmed threshold, the AT/LANTIC requests the local bus and writes the received data into the receive buffer memory using its local DMA. After the packet is received, the AT/LANTIC writes four bytes of status information into the buffer and interrupts the host to inform it that the packet can be removed by software.

## 6.0 CONCLUSION

The DP83905EB-AT Demonstration board provides system developers with an easy to understand and use example of how to design an industry standard Ethernet adapter card. The DP83905EB-AT design can readily be adapted for PC® motherboard designs too.

By using the DP83905 AT/LANTIC, jumperless Ethernet boards can be made extremely cost effective and simple to design and use.

### Parts List for DP83905EB-AT

#### Capacitors

C1	27 pF	10% Ceramic, SMT 0805
C2	27 pF	10% Ceramic, SMT 0805

# The Operation of the FIFO in the DP8390, DP83901, DP83902 and DP83905

National Semiconductor  
Application Note 886  
Bonnie Wilson  
Bill Lee

## 1.0 INTRODUCTION

To accommodate the different rates at which data comes from (or goes to) the network and goes to (or comes from) the system memory, the NIC contains a 16-byte FIFO for buffering data between the bus and the media. The FIFO threshold is programmable, allowing filling (or emptying) the FIFO with different burst lengths. When the FIFO has filled to its programmed threshold, the local DMA channel transfers these bytes or words into local memory. It is crucial that the local DMA is given access to the bus within a minimum bus latency time, otherwise a FIFO underrun (or overrun) occurs. During transmission the DMA writes data into the FIFO and the Transmit Serializer reads data from the FIFO and transmits it. During reception the Receive Deserializer writes data into the FIFO and the DMA reads data from the FIFO.

## 2.0 FIFO THRESHOLD

The DMA transfers between the FIFO and memory occur in bursts beginning when the FIFO threshold is reached. The threshold takes on different meanings during transmission and reception. During reception the FIFO threshold refers to the number of bytes in the FIFO. During transmission the FIFO threshold refers to the number of empty bytes in the FIFO: the size of the FIFO (16) - # bytes in FIFO. Bits FT0 and FT1 in the Data Configuration Register set the FIFO threshold to 2 bytes, 4 bytes, 8 bytes, or 12 bytes (1 word, 2 words, 4 words, or 6 words).

The threshold for the first burst is different than subsequent thresholds as discussed in detail in Sections 3.0 and 4.0. The values in Tables I and II are derived from the timing diagrams in Section 6.0. The first threshold refers to the state of the FIFO at point B in the timing diagrams, and the threshold refers to the state of the FIFO at point D. The discussion below refers to the threshold, not the first threshold.

The FIFO logic operates differently in reception and transmission. During reception in byte mode, a threshold is indicated when approximately the  $n + 14$ th bit has entered the FIFO; thus, with an 8-byte threshold, the NIC issues Bus Request (BREQ) when the FIFO contains 9 bytes and 6 bits. For reception in word mode, BREQ is generated when approximately  $n + 22$  bits have entered the FIFO; thus with a 2-word threshold, BREQ is issued when the 54th bit has entered the FIFO. Refer to Table I for the exact receive thresholds for each case.

During transmission in byte mode, a threshold is indicated when approximately the  $n + 12$ th bit has entered the FIFO; thus with an 8-byte threshold, the NIC issues BREQ when the FIFO contains 9 bytes and 4 bits. For transmission in word mode, BREQ is generated when approximately  $n + 29$  bits have entered the FIFO. Thus, with a 4-word threshold (equivalent to an 8-byte threshold), BREQ is issued when the 96th bit has entered the FIFO. Refer to Table II for the exact transmit thresholds for each case.

TABLE I. Receive Packet Thresholds

Receive Packet Cases	First Threshold	Threshold
Word Mode, 1 Word Threshold	4 Words, 11 bits	2 Words, 5 bits
Word Mode, 2 Word Threshold	4 Words, 10 bits	3 Words, 6 bits
Word Mode, 4 Word Threshold	5 Words, 7 bits	5 Words, 5 bits
Word Mode, 6 Word Threshold	6 Words, 8 bits	6 Words, 6 bits
Byte Mode, 2 Byte Threshold	9 Bytes, 2 bits	3 Bytes, 4 bits
Byte Mode, 4 Byte Threshold # 1	9 Bytes, 2 bits	5 Bytes, 6 bits
Byte Mode, 4 Byte Threshold # 2	9 Bytes, 6 bits	5 Bytes, 6 bits
Byte Mode, 8 Byte Threshold	10 Bytes	9 Bytes, 6 bits
Byte Mode, 12 Byte Threshold	13 Bytes, 7 bits	13 Bytes, 5 bits

TABLE II. Transmit Packet Thresholds

Transmit Packet Cases	First Threshold	Threshold
Word Mode, 1 Word Threshold	6 Words	3 Words, 12 bits
Word Mode, 2 Word Threshold	4 Words, 3 bits	3 Words, 13 bits
Word Mode, 4 Word Threshold	5 Words, 13 bits	5 Words, 13 bits
Word Mode, 6 Word Threshold	7 Words, 13 bits	7 Words, 13 bits
Byte Mode, 2 Byte Threshold	12 Words, 1 bit	(See Timing Diagram, Figure 14)
Byte Mode, 4 Byte Threshold	12 Bytes, 1 bit	5 Bytes, 5 bits
Byte Mode, 8 Byte Threshold	9 Bytes, 6 bits	9 Bytes, 4 bits
Byte Mode, 12 Byte Threshold	13 Bytes, 6 bits	13 Bytes, 4 bits

### 3.0 FIFO OPERATION DURING RECEIVE

At the beginning of reception, the NIC stores the entire Address field of each incoming packet in the FIFO to determine whether the packet matches its Physical Address Registers or maps to one of its Multicast Registers. Therefore, the first local DMA transfer does not occur until after 8 bytes (4 words) have accumulated in the FIFO, regardless of the value of the threshold. This affects the bus latencies at 2 byte, 4 byte, 1 word, and 2 word thresholds during the first receive BREQ. Thus the threshold for the first burst that is loaded into memory differs from the remaining threshold values. Refer to Table I for the exact threshold values.

### 4.0 FIFO OPERATION DURING TRANSMIT

Before transmitting, the NIC performs a prefetch from memory to load the FIFO. The number of bytes prefetched is the programmed FIFO threshold, except for 1 byte, 1 word, and 2 word thresholds which prefetch 4 bytes, 2 words, and 4 words respectively. The next BREQ is not issued until after the NIC actually begins transmitting data, i.e., after Preamble and SFD. The threshold for the first burst that is loaded from memory following the prefetched data often differs from the remaining threshold values. Refer to Table II for the exact threshold values.

### 5.0 FIFO UNDERRUNS AND OVERRUNS

To assure that there is no overwriting of data, the FIFO logic flags an overrun if it becomes full before bus acknowledge is returned. To assure that there is no lost data, the FIFO flags an underrun if it becomes empty before bus acknowledge is returned. There are two causes which produce overruns and underruns:

1. The bus latency is so long that the FIFO has filled (or emptied) before the local DMA has serviced the FIFO.
2. The bus latency or bus data rate has slowed the throughput of the local DMA to a point where it is slower than the network data rate (10 Mb/s). This second condition is also dependent upon DMA clock and data width (byte wide or word wide).

The worst case condition ultimately limits the overall bus latency that the NIC can tolerate.

### 6.0 TIMING DIAGRAMS

The following pages contain detailed timing diagrams and descriptions of every possible receive and transmit mode transfer. The descriptions are of 2, 4, 8, and 12 byte transfers (on an 8-bit Novell board) and 1, 2, 4, and 6 word transfers (on a 16-bit Novell board). For each transfer, the bus clock runs at 20.0 MHz. Tables III and IV summarize the information found in the receive and transmit transfer diagrams respectively.

**TABLE III. Receive Packet Transfers**

Receive Packet Cases	After SFD to BREQ Asserted (Point A to B)	BREQ Asserted to MWR Deasserted (Point B to C)	MWR Deasserted to BREQ Asserted (Point C to D)	BREQ Asserted to MWR Deasserted (Point D to E)
Word Mode 1 Word Threshold	75 ± 4 bits Shifted In	7 Words Removed 52 bits Shifted In	22 bits Shifted In	2 Words Removed 12 bits Shifted In
Word Mode 2 Word Threshold	74 ± 2 bits Shifted In	4 Words Removed 16 bits Shifted In	28 bits Shifted In	2 Words Removed 6 bits Shifted In
Word Mode 4 Word Threshold	87 ± 2 bits Shifted In	4 Words Removed 9 bits Shifted In	53 bits Shifted In	4 Words Removed 9 bits Shifted In
Word Mode 6 Word Threshold	104 ± 2 bits Shifted In	6 Words Removed 14 bits Shifted In	80 bits Shifted In	6 Words Removed 14 bits Shifted In
Byte Mode 2 Byte Threshold	74 ± 2 bits Shifted In	18 Bytes Removed 86 bits Shifted In	12 bits Shifted In	2 Bytes Removed 6 bits Shifted In

RECEIVE PACKET

FIGURE 1. Receive Packet—Word Mode, 1 Word Threshold

TL/F/11819-1

After the preamble and the Start of Frame Delimiter (SFD) (Point A), the FIFO shifts in  $75 \pm 4$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 7 words into memory while shifting in 52 bits of data until MWR is deasserted (Point C). BREQ is asserted

when there are 2 words and 5 bits in the FIFO (Point D). Two words are removed from the FIFO and stored in memory, while 12 bits are shifted into the FIFO until MWR is deasserted (Point E). D and E are repeated until the packet is complete.

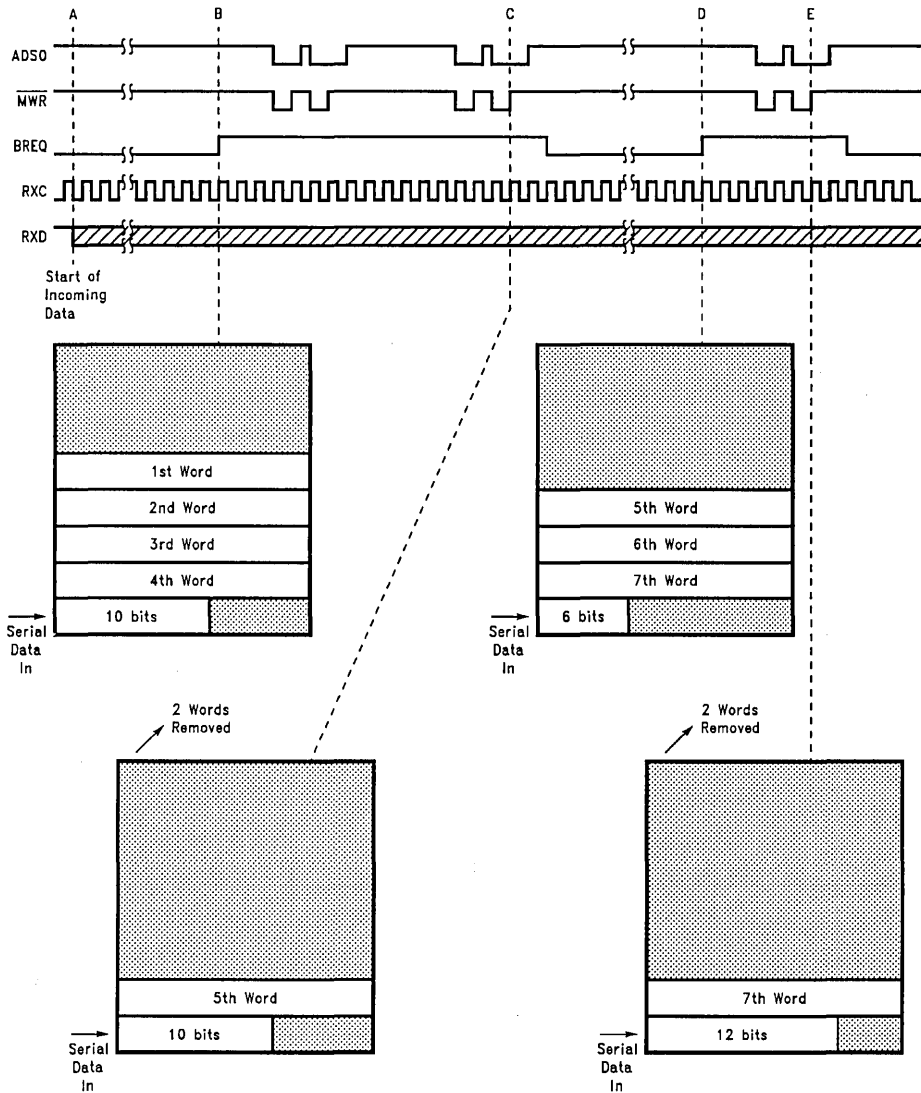

FIGURE 2. Receive Packet—Word Mode, 2 Word Threshold

TL/F/11819-2

After the preamble and the SFD (Point A), the FIFO shifts in  $74 \pm 2$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 2 bursts of 2 words each into memory while shifting in 16 bits of data until

$\overline{MWR}$  is deasserted (Point C). BREQ is asserted when there are 3 words and 6 bits in the FIFO (Point D). Two words are removed from the FIFO and stored in memory, while 6 bits are shifted into the FIFO until  $\overline{MWR}$  is deasserted (Point E). D and E are repeated until the packet is complete.

**FIGURE 3. Receive Packet—Word Mode, 4 Word Threshold**

TL/F/11819-3

After the preamble and the SFD (Point A), the FIFO shifts in  $87 \pm 2$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 1 burst of 4 words into memory while shifting in 9 bits of data until MWR is

deasserted (Point C). BREQ is asserted when there are 5 words and 5 bits in the FIFO (Point D). Again, 4 words are removed from the FIFO and stored in memory, while 9 bits are shifted into the FIFO until MWR is deasserted (Point E). D and E are repeated until the packet is complete.

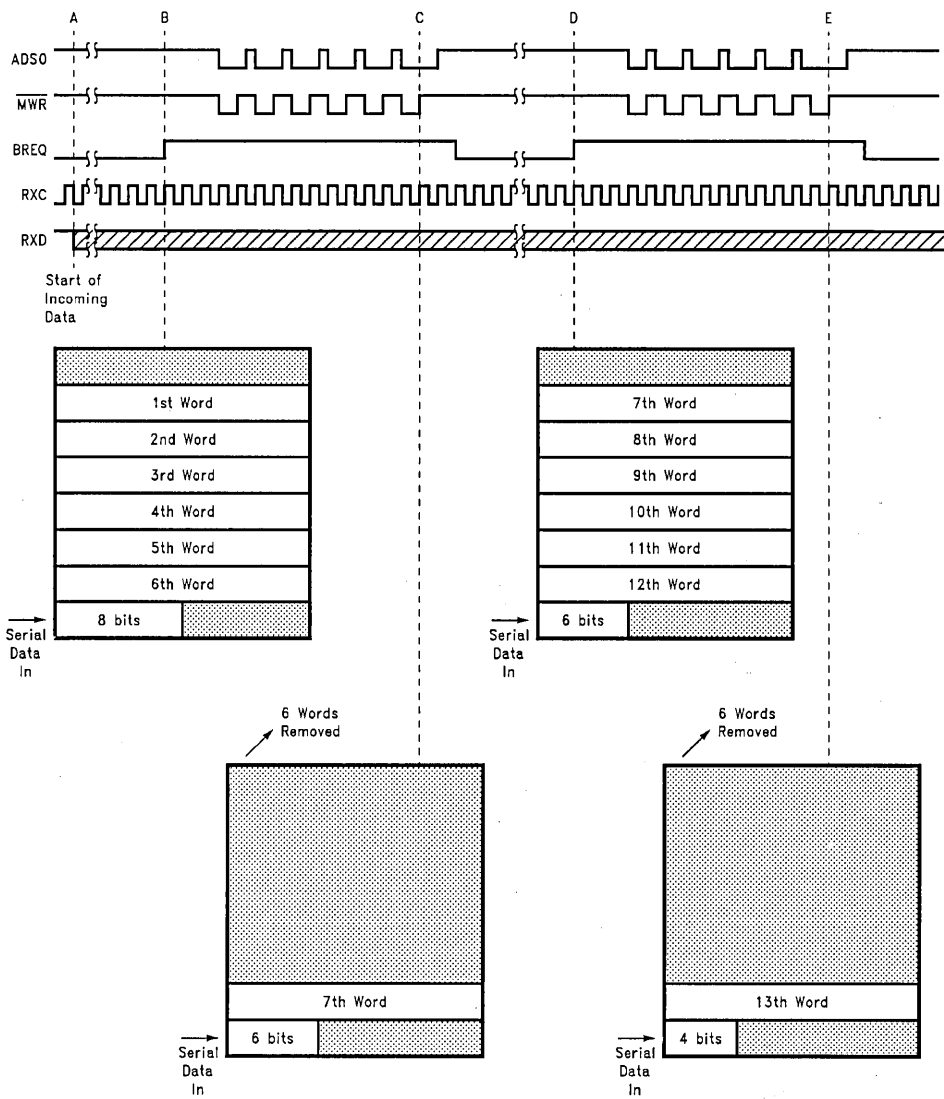

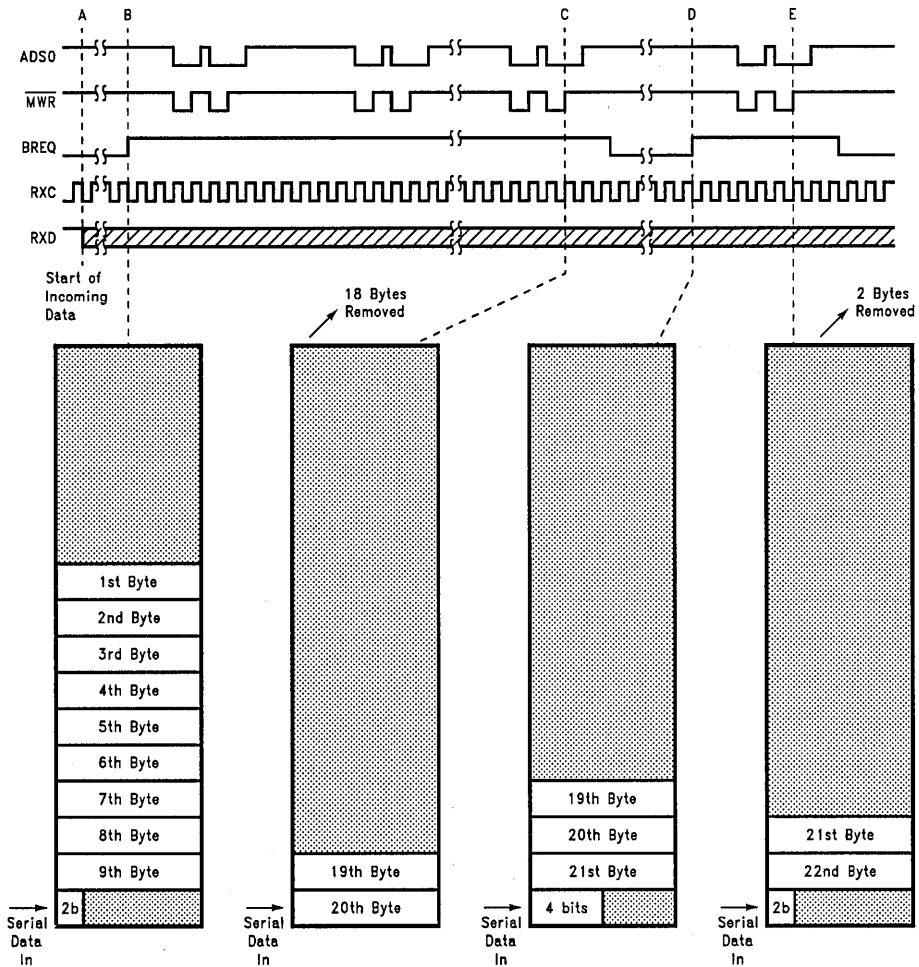

FIGURE 4. Receive Packet—Word Mode, 6 Word Threshold

TL/F/11819-4

After the preamble and the SFD (Point A), the FIFO shifts in  $104 \pm 2$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 1 burst of 6 words into memory while shifting in 14 bits of data until  $\overline{MWR}$  is

deasserted (Point C). BREQ is asserted when there are 6 words and 6 bits in the FIFO (Point D). Again, 6 words are removed from the FIFO and stored in memory, while 14 bits are shifted into the FIFO until  $\overline{MWR}$  is deasserted (Point E). D and E are repeated until the packet is complete.

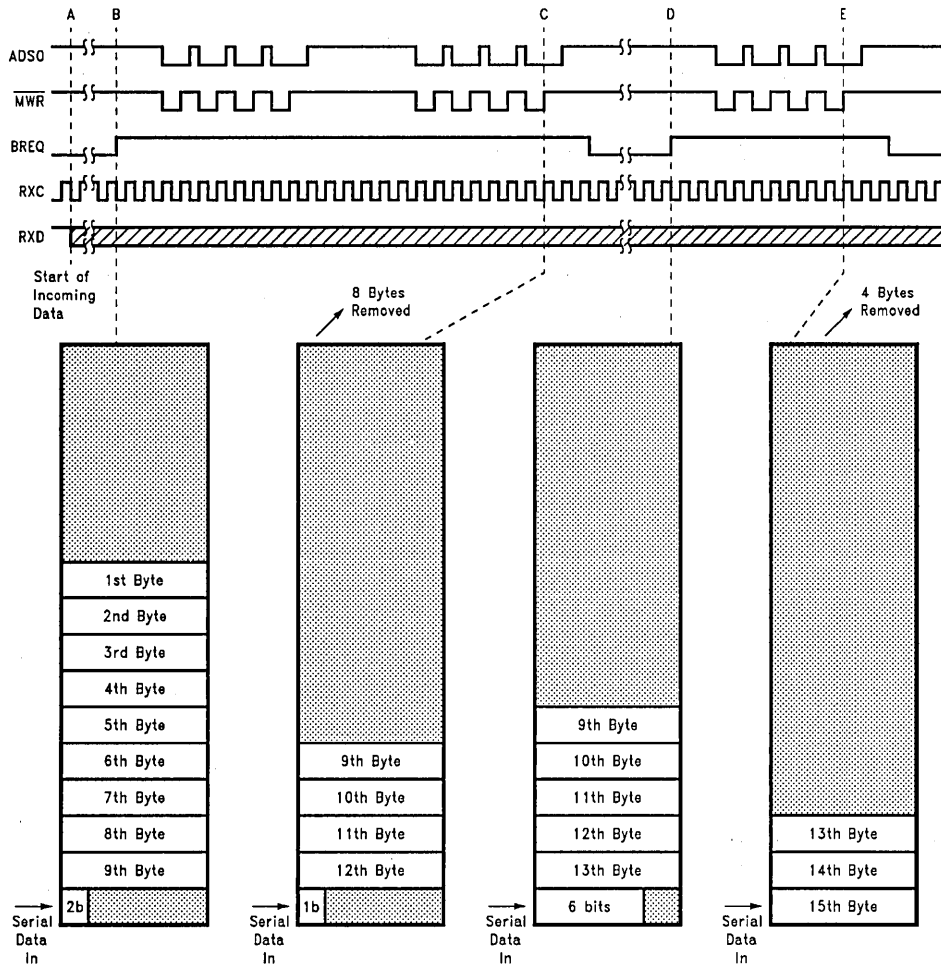

**FIGURE 5. Receive Packet—Byte Mode, 2 Byte Threshold**

TL/F/11819-5

After the preamble and the SFD (Point A), the FIFO shifts in  $74 \pm 2$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 9 bursts of 2 bytes each into memory while shifting in 86 bits of data until  $\overline{MWR}$

is deasserted (Point C). BREQ is asserted when there are 12 bytes and 4 bits in the FIFO (Point D). Two bytes are removed from the FIFO and stored in memory, while 6 bits are shifted into the FIFO until  $\overline{MWR}$  is deasserted (Point E). D and E are repeated until the packet is complete.

TL/F/11819-6

**FIGURE 6. Receive Packet—Byte Mode, 4 Byte Threshold—First Situation**

After the preamble and the SFD (Point A), the FIFO shifts in  $74 \pm 1$  bit of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 2 bursts of 4 bytes each into memory while shifting in 23 bits of data until

$\overline{\text{MWR}}$  is deasserted (Point C). BREQ is asserted when there are 5 bytes and 6 bits in the FIFO (Point D). Four bytes are removed from the FIFO and stored in memory, while 10 bits are shifted into the FIFO until  $\overline{\text{MWR}}$  is deasserted (Point E). D and E are repeated until the packet is complete.

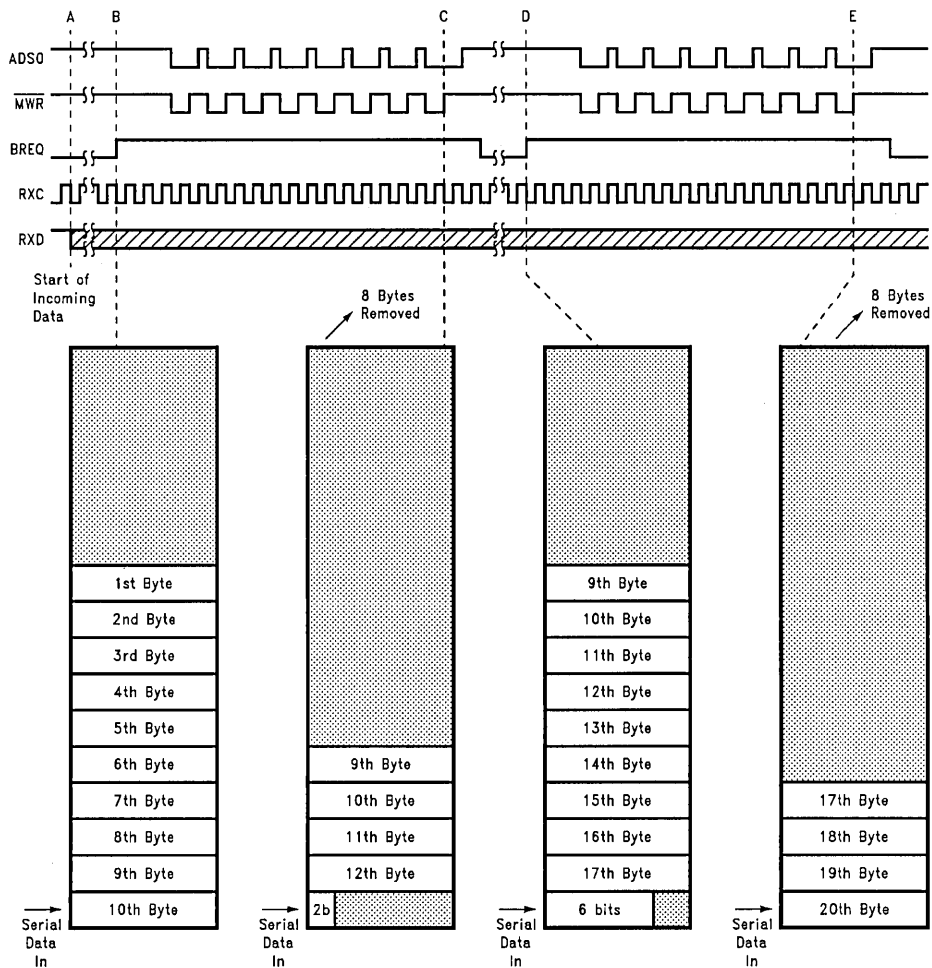

TL/F/11819-7

**FIGURE 7. Receive Packet—Byte Mode, 4 Byte Threshold—Second Situation**

After the preamble and the SFD (Point A), the FIFO shifts in  $78 \pm 1$  bit of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 3 bursts of 4 bytes each into memory while shifting in 38 bits of data until

$\overline{MWR}$  is deasserted (Point C). BREQ is asserted when there are 5 bytes and 6 bits in the FIFO (Point D). Four bytes are removed from the FIFO and stored in memory, while 10 bits are shifted into the FIFO until  $\overline{MWR}$  is deasserted (Point E). D and E are repeated until the packet is complete.

**FIGURE 8. Receive Packet—Byte Mode, 8 Byte Threshold**

TL/F/11819-8

After the preamble and the SFD (Point A), the FIFO shifts in  $80 \pm 2$  bits of data (depending on the location of the SFD with respect to  $t_1$  of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 1 burst of 8 bytes into memory while shifting in 18 bits of data until MWR is

deasserted (Point C). BREQ is asserted when there are 9 bytes and 6 bits in the FIFO (Point D). Again, 8 bytes are removed from the FIFO and stored in memory, while 10 bits are shifted into the FIFO until MWR is deasserted (Point E). D and E are repeated until the packet is complete.

TL/F/11819-9

**FIGURE 9. Receive Packet—Byte Mode, 12 Byte Threshold**

After the preamble and the SFD (Point A), the FIFO shifts in  $111 \pm 2$  bits of data (depending on the location of the SFD with respect to t1 of the DMA sequence) before BREQ is asserted (Point B). The FIFO transfers 1 burst of 12 bytes into memory while shifting in 26 bits of data until MWR is

deasserted (Point C). BREQ is asserted when there are 13 bytes and 5 bits in the FIFO (Point D). Again, 12 bytes are removed from the FIFO and stored in memory, while 26 bits are shifted into the FIFO until MWR is deasserted (Point E). D and E are repeated until the packet is complete.

TRANSMIT PACKET

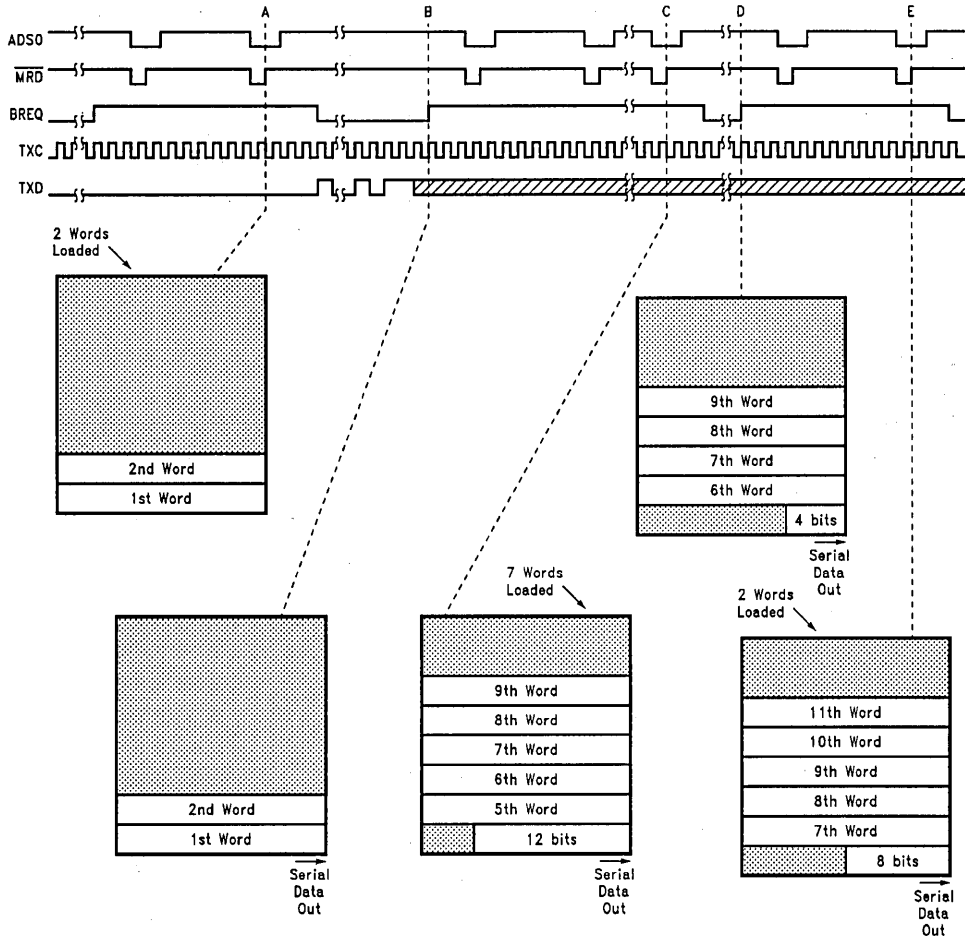

FIGURE 10. Transmit Packet—Word Mode, 1 Word Threshold

TL/F/11819-10

The FIFO prefetches 2 words from memory (point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO, and BREQ is asserted (Point B). During this burst, 7 words are loaded into the FIFO from

memory while 52 bits are shifted out until  $\overline{MRD}$  is deasserted (Point C). The next BREQ comes when there are 4 words and 4 bits in the FIFO (Point D). Two words are loaded into the FIFO from memory while 12 bits are shifted out (Point E). D and E are repeated until the packet is complete.

FIGURE 11. Transmit Packet—Word Mode, 2 Word Threshold

TL/F/11819-11

The FIFO prefetches 2 bursts of 2 words each from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 3 bits are shifted out, BREQ is asserted (Point B). During this burst, 2 words are loaded into the FIFO from memory while 6 bits

are shifted out until MRD is deasserted (Point C). The next BREQ comes when there are 4 words and 3 bits in the FIFO (Point D). Again, 2 words are loaded into the FIFO from memory while 6 bits are shifted out (Point E). D and E are repeated until the packet is complete.

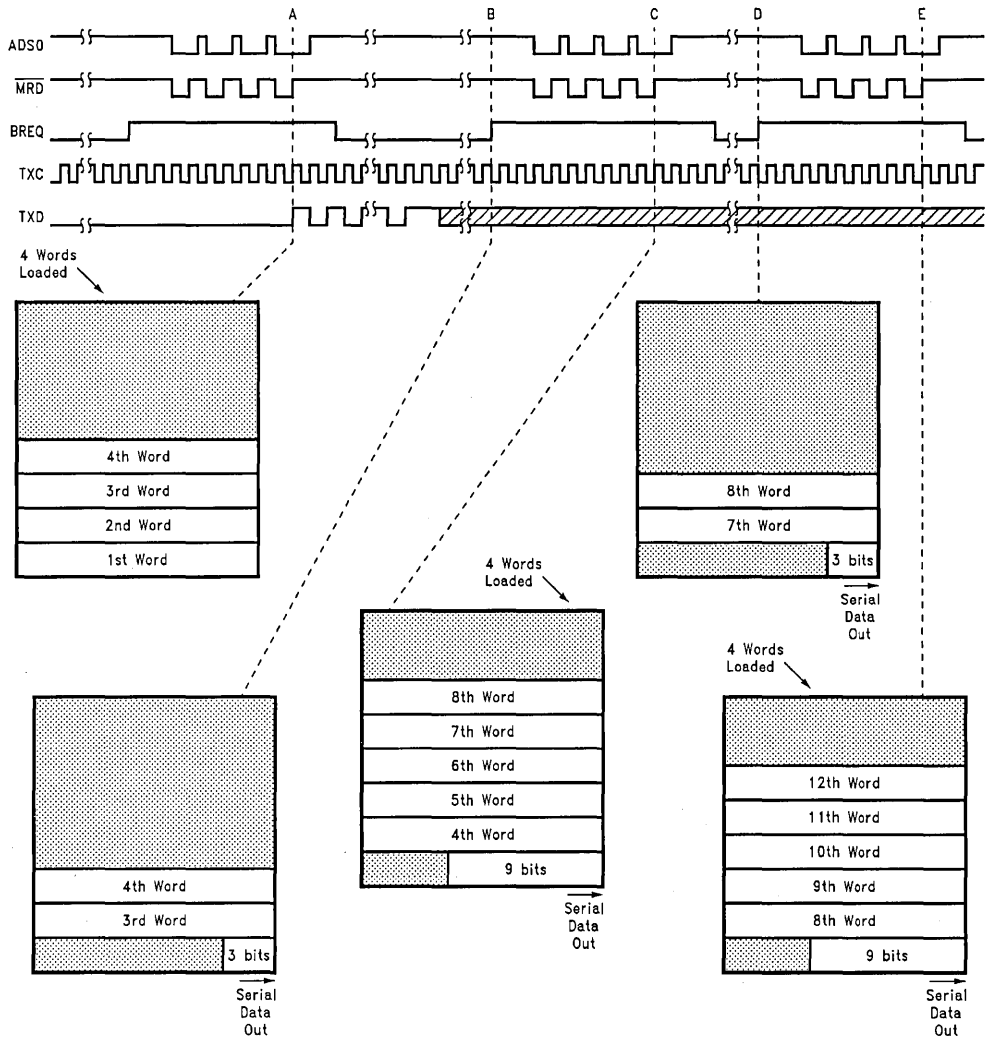

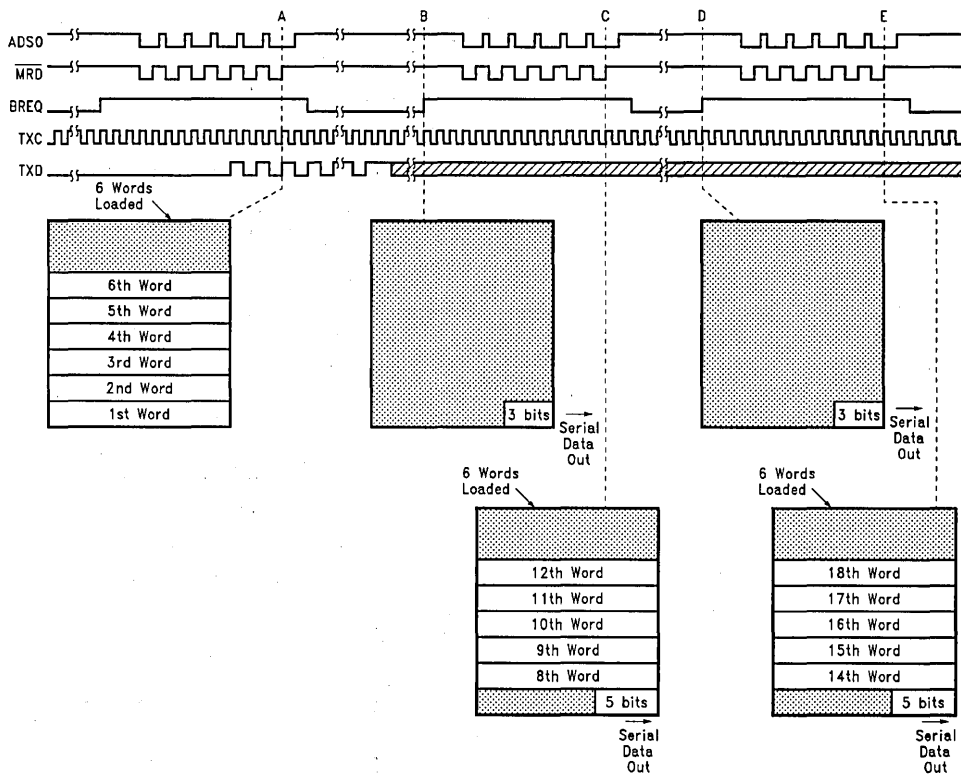

FIGURE 12. Transmit Packet—Word Mode, 4 Word Threshold

TL/F/11819-12

The FIFO prefetches 4 words from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 29 bits are shifted out, BREQ is asserted (Point B). During this burst, 4 words are loaded into the FIFO from memory while 9 bits are shifted out until

MRD is deasserted (Point C). The next bus request comes when there are 2 words and 3 bits in the FIFO (Point D). Again, 4 words are loaded into the FIFO from memory while 9 bits are shifted out (Point E). D and E are repeated until the packet is complete.

TL/F/11819-13

**FIGURE 13. Transmit Packet—Word Mode, 6 Word Threshold**

The FIFO prefetches 6 words from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 93 bits are shifted out, BREQ is asserted (Point B). During this burst, 6 words are loaded into the FIFO from memory while 14 bits are shifted out until MRD is deasserted (Point C). The next bus request comes when there are 3 bits in the FIFO (Point D). Again, 6 words

are loaded into the FIFO from memory while 14 bits are shifted out (Point E). D and E are repeated until the packet is complete.

**Note:** At Point B, the 7th word is latched in approximately 10 ns before its first bit is clocked out. Occasionally, 94 bits will be shifted out before the first BREQ. In this case, the first bit of the 7th word and every 8th word from then on will be corrupted. Since no error occurs, this mode should not be used.

FIGURE 14. Transmit Packet—Byte Mode, 2 Byte Threshold

TL/F/11819-14

The FIFO prefetches 2 bursts of 2 bytes each from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 1 bit is shifted out, BREQ is asserted (Point B). Eleven bursts of two bytes each are loaded into the FIFO from memory while 106 bits

are shifted out (Point C). At this point the bursts become one byte instead of two bytes (Point D). The FIFO loads 1 byte from memory while 7 bits are shifted out (Point E). D and E are repeated until the packet is complete.

**Note:** BREQ remains asserted until the entire packet is transmitted.

TL/F/11819-15

FIGURE 15. Transmit Packet—Byte Mode, 4 Byte Threshold

The FIFO prefetches 4 bytes from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 1 bit is shifted out, BREQ is asserted (Point B). Four bursts of 4, 4, 4, and 3 bytes, respectively, are loaded into the FIFO from memory while 49 bytes are shifted out until MRD is deasserted (Point C).

The next bus request comes when there are 10 bytes and 3 bits in the FIFO (Point D). Four bytes are loaded into the FIFO from memory while 10 bytes are shifted out (Point E). D and E are repeated until the packet is complete.

**Note:** Some samples prefetches two bursts of 4 bytes each, and only 2 bursts of 4 bytes each were loaded into the FIFO between Points B and C. Both the cases sometimes had bursts of 3 bytes after point D, continuing until the packet is completed. A pattern could not be developed. This does not corrupt any bits and no error occurs.

FIGURE 16. Transmit Packet—Byte Mode, 8 Byte Threshold

TL/F/11819-16

The FIFO prefetches 8 bytes from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 22 bits are shifted out, BREQ is asserted (Point B). During this burst, 8 bytes are loaded into the FIFO from memory while 18 bits are shifted out until

MRD is deasserted (Point C). The next bus request comes when there are 6 bytes and 4 bits in the FIFO (Point D). Again, 8 bytes are loaded into the FIFO from memory while 18 bits are shifted out (Point E). D and E are repeated until the packet is complete.

TL/F/11819-17

FIGURE 17. Transmit Packet—Byte Mode, 12 Byte Threshold

The FIFO prefetches 12 bytes from memory (Point A). The preamble starts during these prefetches. After the preamble and the Start of Frame Delimiter are transmitted, data is shifted out of the FIFO. After 78 bits are shifted out, BREQ is asserted (Point B). During this burst, 12 bytes are loaded into the FIFO from memory while 26 bits are shifted out until

MRD is deasserted (Point C). The next bus request comes when there are 2 bytes and 4 bits in the FIFO (Point D). Again, 12 bytes are loaded into the FIFO from memory while 26 bits are shifted out (Point E). D and E are repeated until the packet is complete.

# AT/LANTIC™ Software Developer's Guide

National Semiconductor  
Application Note 887  
David Milne

## INTRODUCTION

This document is designed to aid the development of software for the AT/LANTIC device. It is recommended that the AT/LANTIC data sheet be read before and then in conjunction with this description.

A brief introduction to the two Adapter architectures is given below.

## Table of Contents

### 1.0 INTRODUCTION TO THE AT/LANTIC DEVICE

#### 2.0 CONFIGURING THE AT/LANTIC

- 2.1 Changing and Saving a Configuration
- 2.2 Enabling a "New" Adapter
- 2.3 Programming Configuration Register C

#### 3.0 INITIALIZING THE AT/LANTIC

- 3.1 Hardware Reset
- 3.2 Get Bus Size/ID Bytes
- 3.3 Initializing the Registers
- 3.4 Checking the Cable
- 3.5 Checking the Interrupt
- 3.6 Checking the Boot ROM

#### 4.0 TRANSFERRING INFORMATION

- 4.1 I/O Mode Transfers
  - 4.1.1 DMA Write Sequence
  - 4.1.2 DMA Read Sequence
- 4.2 Shared Memory Transfers

#### 5.0 TRANSMISSION SEQUENCE

- 5.1 Register Sequence

#### 6.0 RECEPTION SEQUENCE

- 6.1 The Buffer Ring
- 6.2 Removing a Packet
- 6.3 Dealing with Overflows

### 1.0 INTRODUCTION TO THE AT/LANTIC

The AT Local Area Network Twisted Pair Interface Controller provides a simple method of interfacing any ISA (Industry Standard Architecture) bus based systems to an Ethernet Network. This device can emulate one of the most popular Ethernet Adapter architectures—Novell's NE2000 adapter.

The configuration information describing the devices architecture, address, interrupt etc. can either be loaded from switches or from an EEPROM. Use of the EEPROM method allows the device to be configured solely by software thus providing a more user friendly Ethernet adapter.

TL/F/11820-1

FIGURE 1. NE2000 Emulation Mode

The NE2000 mode utilizes a Data Port register through which all transfers to/from the buffer RAM take place. Any transfer requires the buffer RAM address, transfer size and direction to be programmed into registers before the transfer can be initiated.

This mode of operation is often referred to as I/O Mode.

TL/F/11820-2

FIGURE 2. Shared Memory Mode

In Shared Memory mode the buffer RAM is mapped into system memory. This allows any data in the buffer RAM to be directly transferred across the ISA bus.

The AT/LANTIC requires a 20H byte space in the PC's I/O Port map, this area contains all of the AT/LANTIC's registers. The contents of this register block depend on the mode the AT/LANTIC is operating in. One common factor is the NIC core register section which contains 16 registers. The location of the register block is given by "I/O address" (also referred to as I/O base). Figures 3 and 4 show the contents of the register block for either mode.

The AT/LANTIC can access a RAM area of up to 64 kbytes, however the standard is to only use 16 kbytes of this area.

1

The method of accessing this RAM area is described in Section 4.0 of this document. The AT/LANTIC's memory map depends on the mode of the device. *Figures 5 and 6* show the full 64 kbyte memory map for each mode (each mode with the chip in compatible mode utilizing only 16 kbytes for the RAM Buffer).

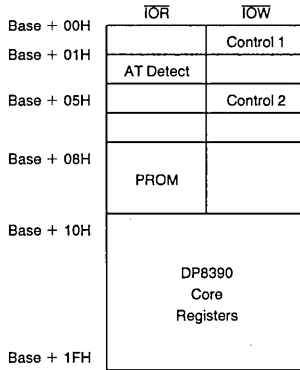

FIGURE 3. Shared Memory Mode I/O Map

FIGURE 4. I/O Port Mode Register I/O Map

FIGURE 5. Shared Memory Mode Memory Map

FIGURE 6. I/O Port Mode Memory Map

## 2.0 CONFIGURING THE AT/LANTIC

The AT/LANTIC controller is designed such that it is fully software configurable. The configuration information is held in three registers A, B and C as described in the data sheet under Section 5.1. As an added safety feature configuration registers A and B are hidden, so that they cannot be accidentally overwritten. Register C is only accessed during a RESET and can not be directly accessed by software.

Register A controls the I/O address, interrupt and mode of the AT/LANTIC device. Register B controls the cable type selection and certain flags altering some interface timings to the ISA bus (refer to Section 4.1 "Bus Error Condition").

### 2.1 Changing and Saving a Configuration

#### CHANGING THE CONFIGURATION

Registers A and B can be read directly at I/O address offset 0AH and 0BH respectively. To write to these registers a read access must be immediately followed by a write access. Interrupts should be disabled during the write sequence to ensure it is not corrupted. These registers can only be accessed when the NIC command register is set to page 0, refer to AT/LANTIC data sheet Section 5.3.

As register A can change the address location of the AT/LANTIC registers (and hence of reg. B) then a software update of both registers A and B should first change register B and then register A. This allows the same base I/O address to be used for both register updates.

#### THE GDLNK BIT

Special care should be taken when configuring the GDLNK bit of register B. If this bit is set to 1 then the link integrity checking (TPI mode) is disabled. If link integrity checking has not been disabled (10BT standard) then this bit reads 1 for good link and 0 for link broken. If the AT/LANTIC is in TPI mode with a good link and reg. B is read then the GDLNK bit is shown to be 1, if this was written directly back to reg. B then link integrity checking is disabled. Thus it is necessary to mask out the GDLNK bit when writing to reg. B unless the disabling of link integrity checking is required.

#### SAVING A CONFIGURATION

The AT/LANTIC has a feature allowing the required configuration to be saved to an EEPROM such that on power up the configuration registers are automatically loaded with the correct values. There is a special algorithm which writes the configuration to the EEPROM, this is described in the pseudo code below. This algorithm does not change the registers directly, i.e. the new state only appears on the next power up.

```

CONFIGURATION_SAVE ()
{
//Interrupts are disabled to ensure the
// sequence is not corrupted.
    Disable interrupts;

// Set EELOAD bit in register B.
    value = READ (Config_Reg_B);
    value = value & (~GDLNK);
    value = value | EELOAD;
    WRITE (Config_Reg_B, value);

// Output the configuration info.
    READ(Config_Reg_B);
    WRITE(Config_Reg_B, config_for_A);
    WRITE(Config_Reg_B, config_for_B);
    WRITE(Config_Reg_B, config_for_C);

// Wait for EELOAD bit to go low.
    while(value && EELOAD)
    {
        value = READ(Config_Reg_B);
        WAIT();
    }
    Enable Interrupts;
}

```

## 2.2 Enabling a "New" Adapter

It is possible to place the AT/LANTIC controller in a "disabled" state in which it shall not respond at any I/O base location. This is a particularly useful mode for software configurability as it allows the auto selection of an available configuration before the AT/LANTIC based adapter is enabled. Hence potential conflicts of Interrupt and I/O base address can be avoided.

The method of enabling the AT/LANTIC from this "disabled" state consists of writing a byte four consecutive times to port 278H, during which time interrupts should be disabled to ensure the sequence is not corrupted. The lower 3 bits of this byte inform the AT/LANTIC of which address it should enable to. More information on the mapping of these three bits to I/O base locations can be found in the AT/LANTIC data sheet under Section 5.1.

The port 278H is normally a PC's secondary printer port. Using the "four writes" sequence ensures that an adapter is not accidentally enabled if the port is in use. If the port is active when the adapter is to be enabled then it is possible to corrupt a print sequence, to avoid this the code should check if the port is active and if so wait until the port is free. The printer uses port 278H as a data port and port 279H as a control port, reference should be made to the PC's technical manual for an explanation of these registers and how the port operates.

Once the AT/LANTIC is enabled configuration register A may contain old information in bits 3-7. Register A bit 7 is the MEMIO (architecture) bit, the offset of the configuration registers varies depending on the state of this bit. Thus the software has to detect which architecture mode the AT/LANTIC has appeared in before bits 3-7 of reg. A and all of reg. B can be overwritten with the new configuration information.

## DETECTING AT/LANTIC MODE

The AT/LANTIC can appear in either the I/O port mode or the Shared Memory mode. As the I/O address is known then the mode of operation can be found by checking the data at the address of register A, i.e., check offset 0AH for I/O mode and offset 1AH for Shared Memory mode. The recommended method of detecting the architecture of an AT/LANTIC at a known I/O base is given in the pseudo code below.

```

FIND_MODE()
{
// Check if in I/O mode
    config_a = READ(IO_BASE + 0AH);
// Check MEMIO is low i.e. I/O mode.
    if((config_a & 80H) == 0)
    {
// Check IOAD bits match the I/O base addr.
        if((config_a & 7) relates to IO_BASE)
            return(IO_MODE_DETECTED);
    }
// Check if in Shared Memory mode.
    config_a = READ(IO_BASE + 1AH);
// Check MEMIO is high i.e. S/M mode.
    if((config_a & 80H) == 1)
    {
// Check IOAD bits match the I/O base addr.
        if((config_a & 7) relates to IO_BASE)
            return(SHARED_MEM_DETECTED);
    }
// No AT/LANTIC mode detected.
return(NO_MODE_DETECTED);
}

```

## 2.3 Programming Configuration Register C

Configuration register C can not be accessed directly by software. Details on what configuration register C controls can be found in the AT/LANTIC data sheet Section 5.1. The upper four 4 bits of register C are fixed depending on the design of the adapter card, the lower four bits vary depending on the boot ROM option selected. It is necessary to know the boot ROM option selected so that register C is correctly updated by the "Configuration\_Save" routine (as given under Section 2.1). As register C can not be read some mechanism is required to detect the boot ROM option in use. The recommended method is to place a signature text string in the boot ROM at a fixed location. This string would contain information on the size of ROM in question. The code should then scan the RAM space for this signature string. If found, then the location and size of the boot ROM is known and the value required for register C can be calculated. As register C can not be written to directly, the only method of updating it is to use the "Configuration—Save" routine.

It should be noted that any change to the value of register C is not active until the AT/LANTIC has been reset (normally a power off/on of a PC) and the new contents of the EEPROM have been loaded into the registers.

### 3.0 INITIALIZING THE AT/LANTIC

The following section deals with all of the functions necessary to initialize and partly test the AT/LANTIC device. It is recommended that the code follows the order of each of the sub-sections.

#### 3.1 Hardware Reset

The first step in the initialization sequence is to provide a reset pulse to the NIC core of the AT/LANTIC device. The method of providing this signal depends on the architecture selected for the AT/LANTIC.

#### I/O MODE RESET SEQUENCE

In this mode a portion of the I/O address map acts as a reset port, offsets 18H to 1FH, any of these offsets can be used as the reset port. To activate a reset the port should be read from and then written to (with any value). Following this a delay of 1.6 ms is required to make sure the reset has completed.

#### SHARED MEMORY RESET SEQUENCE

This mode contains two control registers (refer to Section 5.2 of the AT/LANTIC data sheet). The MSB of control register 1 is the RESET flag. To activate the reset this bit should be toggled high then low. Again a delay of 1.6 ms is required to allow the reset to complete.

#### PLACING THE AT/LANTIC IN STOP MODE

Following the hardware reset it is necessary to place the NIC core of the AT/LANTIC in the STOP mode, which performs a software reset. This is done by setting the STOP and RS2 bits of the NIC command register (refer to the AT/LANTIC data sheet Section 5.3 for more information on the NIC core registers), PS0 and PS1 are cleared to ensure that the NIC core is in "page 0". (The NIC core registers are split into 3 pages of 16 registers, the bits PS0 and PS1 in the command register define which page the NIC is currently operating in.) The code should wait until the software reset is indicated as complete (when the RST bit of the Interrupt Status register is set to a 1).

#### 3.2 Get Bus Size/ID Bytes

This section deals with detecting the size of the slot an adapter has been inserted into and checking ID byte values are correct for the mode of operation selected. The two AT/LANTIC modes are quite different in their approach to this problem and shall be discussed separately.

#### I/O MODE

The I/O mode architecture maps PROM data into RAM space locations 00H to 1FH. The contents of this RAM space are given in *Figure 7*. Offset 1EH contains a word value which depends on the size of slot in which the adapter currently resides. If the value equals 5757H, then the slot is 16-bit, if the value equals 4242H, then the slot is 8-bit. If the value does not equal either of the previous values, then the adapter is not correctly functional in NE2000 emulation mode, i.e., these bytes also act as ID bytes. An example of the DMA read operation required to get the word from offset 1EH is described in Section 4.1.2 of this document. The initial transfer requires the Data Configuration Register (DCR) to be programmed for 8-bit operation, and the PC to perform two byte wide reads of the Data Port. Once the data has been transferred the DCR and PC transfers can be set for the correct bus width.

#### SHARED MEMORY MODE

The shared memory mode contains a register which holds information on the size of slot occupied by the adapter. The LSB of this register, the AT detect register (refer to AT/LANTIC data sheet Section 5.2) is set to 1 for 16-bit mode and 0 for 8-bit mode.

Correct emulation of the Ethercard Plus16 requires an ID byte. In this mode the registers at offsets 08H to 0FH (see *Figure 8*) contain first the Ethernet address then an ID byte followed by a checksum byte.

For the AT/LANTIC shared memory mode the ID byte at offset 0EH should contain value 05H. The two complement sum of all of the eight bytes should equal FFH. If this is not the case, then the adapter is not correctly operating in Ethercard Plus16 emulation mode.

00H	ETHERNET ADDR. 0
01H	ETHERNET ADDR. 1
02H	ETHERNET ADDR. 2
03H	ETHERNET ADDR. 3
04H	ETHERNET ADDR. 4
05H	ETHERNET ADDR. 5
06H	(BOARD ID BYTE)
07H	(CHECKSUM)
1EH	42H or 57H
1FH	42H or 57H

	Board ID Byte
0FH	Checksum

FIGURE 8. S/M Mode PROM Loaded Registers

#### 3.3 Initializing the Registers

When initializing an adapter for Shared Memory mode it is necessary to set up two control registers before initializing the NIC core registers, the following step is ignored for I/O Port mode.

#### SHARED MEMORY ADDRESS INITIALIZATION

In shared memory mode the Buffer RAM is mapped into the PC address space. Two control registers define where in the PC memory map this RAM shall appear, refer to Section 5.2 of the AT/LANTIC data sheet. Address bits A13–A18 of the selected memory address should be programmed into bits 0–5 of control register one. Address bits A19–A23 should

be programmed into bits 0–4 of control register two. The MEMW bit of control register 2 defines if the memory is 8 kwords or 8 kbytes in size. This bit should be defined during this initialization. It may also be necessary to initialize the MEME bit of control register 1, this depends on the method of controlling the buffer RAM—refer to Section 4.2.

- e.g. D0000H, 16 kbytes memory.
- Control reg. 1 is 28H,
- Control reg. 2 is 41H.

**NIC CORE REGISTER INITIALIZATION**

The following register initialization sequence is mandatory for both I/O Port and Shared Memory modes. All of the registers discussed are explained in detail under Section 5.3 of the AT/LANTIC data sheet.

1. Put the AT/LANTIC in STOP mode. Refer to Section 3.1 on putting the AT/LANTIC in STOP mode.
2. Initialize Data Configuration Register (DCR), WTS (transfer width) dependent on the result of the previous section, LS set, ARM is dependent on the method chosen to control the receive buffer ring (refer to Section 6.0). The FIFO threshold is typically set to 8 bytes/4 words i.e., FT1 is set. (When in Shared Memory mode the WTS bit can always be set if 16 kbytes of RAM are being used.)
3. Clear Remote Byte count registers.
4. Initialize Receive Configuration Register (RCR), this register determines which packets are accepted by the AT/LANTIC and buffered into RAM. The options available are save errored packets, runt packets, multicast packets, broadcast packets, physical address match packets and all physical address packets (promiscuous mode). Setting the register to 00H allows only physical address match packets. Further discussion on setting the physical and multicast addresses is given later in this section.
5. Place the NIC in loopback mode 1 or 2 by setting bits LB0 or LB1 in the Transmit Configuration Register. Loopback is described in the data sheet under Section 6.5.
6. Initialize the Receive Buffer Ring, Boundary Pointer (BNDRY), Page Start (PSTART), Page Stop (PSTOP), Transmit Page Start (TPSR).

The values for these registers are discussed at the end of this section.

7. Clear the Interrupt Status Register (ISR), by writing FFH to it.
8. Initialize Interrupt Mask Register (IMR), this register controls which sources of interrupt are allowed or disallowed. It would be normal to set PRXE (packet received), PTXE (packet transmitted), PTXEE (packet transmission error) and OVWE (overflow) in the register.
9. Program the Command Register for page 1 (set bits PS0, RD2 and STP) and initialize the physical, multicast and CURR registers as described later in this section.
10. Put the NIC in to START mode, set the START bit and clear the STOP, PS0 and PS1 bits in the Command Register. The receive is still not active as the NIC core is in loopback mode.

11. Remove the AT/LANTIC from loopback mode by initializing the Transmit Configuration Register (TCR) to its correct value, typically 00H.

The AT/LANTIC is now ready to receive and transmit packets.

**SETTING UP THE BUFFER RING**

The values to be programmed in to the buffer ring pointers PSTART, PSTOP, CURR, BNDRY and TPSR depend on the mode of operation of the AT/LANTIC. There are several possible modes NE2000 and Ethercard Plus16 emulation modes which use 16k of Buffer RAM and a non-compatible mode which allows up to 64k of Buffer RAM. The size of transfers in question also alter the size of the Buffer Ring.

The buffer RAM is split into "pages" each containing 256 bytes. The standard is to have a transmit buffer followed by the receive buffer ring. It is recommended that two transmit buffers be utilized as this improves performance. One packet can be loaded into the RAM while another is being transmitted on the network. Each transmit buffer requires 6 "pages" for a full Ethernet packet (some protocols may not require a maximum Ethernet packet). The Transmit Page Start Register (TPSR) should point to the buffer being transmitted for the whole duration of a transmission, i.e., when the alternate buffer is being loaded during a transmission the TPSR should not be altered. The receive buffer ring follows the transmit buffer. The Page Start register (PSTART) is set to the page following the transmit buffer(s). The Page Stop (PSTOP) register is set to the end of the buffer RAM plus one page (the size of buffer RAM is determined by the bus width/memory width.)

**FIGURE 9. Buffer RAM Layout**

In NE2000 emulation mode the buffer RAM resides at locations 4000H to 8000H (refer to Figure 6). The Ethercard Plus16 buffer RAM resides at 0000H to 4000H (refer to Figure 5). These examples are for 16-bit modes.

There are two possible methods of controlling the receive buffer ring a software method and an automated method called "send packet". These are discussed in more detail in Section 6.0 of this document.

Initializing CURR and BNDRY for

- (i) the software method,
- CURR = PSTART + 1
- BNDRY = PSTART
- Next\_PKT = PSTART + 1

(ii) the "send packet" method,  
 CURR = BNDRY = Next\_PKT = PSTART  
 ("Next\_PKT" is a software declared variable further described in Section 6.0).

#### SETTING THE PHYSICAL ADDRESS REGISTERS

During initialization, the NIC core physical address registers are loaded with the adapters Ethernet address (refer to Section 5.3 of the AT/LANTIC data sheet). Each adapter contains a unique six byte address for identification on a network. The Ethernet address is held in a PROM store in the AT/LANTIC, the method of retrieving the information depends on its present architecture mode. In shared memory mode the Ethernet address is held at register offsets 08H to 0DH, see *Figure 3*. These values can then be written to the NIC physical address registers. In I/O mode the address is held in the first three words of the RAM thus a Remote DMA read is required to retrieve the information, refer to Section 4.1.2.

#### SETTING THE MULTICAST REGISTERS

To allow a network station to receive packets destination addresses other than the stations physical node address, it is necessary to store a list of these destination addresses. A group of addresses to be received are referred to as multicast addresses. This device can not hold all of the addresses, thus the AT/LANTIC contains 8 multicast address registers (MAR0-7) which decode the addresses to be received. These multicast registers provide filtering of multicast addresses hashed by the CRC logic. All destination addresses are fed through the CRC logic and as the last bit of the destination address enters the CRC, the 6 MSB's of the CRC generator are latched. These six bits are then used to index a unique filter bit (FB0-63) in the multicast address registers. When a software developer wishes to accept a specific multicast address the above sequence should be followed to determine which filter bit in the multicast registers should be set. Several bits can be set to accept several multicast addresses. A pseudo code example of the routine required for this is given below.

```
// Hexadecimal equivalent of the NIC's CRC
// equn.
define CRC_POLYNOMIAL 04C11DB6H

// The multicast address is held in a 6 byte
// array.
unsigned char mult_addr[6];
crc = FFFFFFFFH;

// The following loops create the 32-bit CRC
// value.

// Loop through each byte of the address.
for(i=0; i<6; i++)
{
// Loop through each bit of that byte.
for(bit=0; bit<8; bit++)
```

```
{
  carry=(crc31)^(mult_addr[i] &
    (1<<bit)) > bit);
  crc <= 1; if (carry)
    crc = ((crc^CRC_POLYNOMIAL) | carry);
}
}

// Extract the 6 MSB's from the CRC value,
// this six bit value is used to index a
// unique filter bit.
index >= 26;
index &= 3FH;
// Find the multicast register number and
// bit of that register to set.
register_no = crc > 3;
register_bit = 1 < (crc & 7);

// Calculate the new register value.
value = READ(MAR[register_no]) |
register_bit;

// Set the Multicast Address Register (MAR)
// value.
WRITE (MAR[register_no], value);

3.4 Checking the Cable

There are four possible media types that can be selected
with the AT/LANTIC device. Both the TPI(10BT) and
TPI(non spec.) modes simply use the GDLNK bit of configura-
tion register B to indicate the cable status. The test for a
good "Thin" Ethernet cable is more involved and a pseudo
code description of what is required is given below. Thick
Ethernet cable can be checked by performing level 3 loop-
back as described in Section 6.5 of the AT/LANTIC data
sheet. However this test can only be guaranteed if per-
formed on a non-active network, i.e. no information is being
passed on the network during the test.

// Assume already initialized.

thin_cable_check()
{
// Set up a cable check packet for
// transmission. The destination addr.
// should equal the source address to avoid
// other stations receiving this pkt. The
// data field is of the developers choice.
  packet = set_up_cable_pkt();
  length = size of (packet);
```

```

// Set the transmit byte count registers.
WRITE(TBCRO, length_LSB);
WRITE(TBCR1, length_MSB);

// Clear the Interrupt Status Register.
WRITE(INTSTATUS, FFH);

// Issue the transmit command.
WRITE(CMND, (RD2 | STA | TXP));

// Poll the interrupt status register until
// the packet is indicated as transmitted
// or there is a timeout.
while(time_in_loop < 1 second)
{
    STATUS = READ(INTSTATUS);

    if(STATUS & (ISR_TXE | ISR_PTX))
        break;

    update--time--in--loop();
    Short_Delay();
}

// If the routine timed out the tx failed.
if(time_in_loop > 1 second)
    return(NO_CABLE);

// Read the Transmit Status Register.
TSR_value = READ(TSR);

// Check if there were excessive collisions.
if(TSR_value & ABT)
    return(UNTERMINATED);

// If there was 1 to 15 collisions the cable
// is good.
if(TSR_value & COL)
    return(CABLE_OK);

// Check for other transmission failures
// only after collision check because if a
// collision occurred it can set some of
// the following bits in error.
if(TSR_value & (CDH | CRS | FU));
    return(NO_CABLE);

// If this point is reached the tx passed.
return(CABLE_OK);
}

```

More detail on the Interrupt Status Register (ISR) and the Transmit Status Register (TSR) bits can be found in the AT/LANTIC data sheet under Section 5.3.

### 3.5 Checking the Interrupt

When an interrupt is detected an interrupt handler is called. This handler should then investigate the cause of the interrupt and act accordingly. In the case of the AT/LANTIC there is an Interrupt Status Register which provides information on the cause of the interrupt. It is necessary for the handler to be installed before this test is carried out.

The following pseudo code routine checks interrupt operation by assuming that when the interrupt handler is called and the ISR is found to have its PTX bit set then a "packet\_transmitted" flag is incremented/set.

```

// Assume Initialized and ISR installed.
Interrupt_check()
{
    // Clear the 'packet_transmitted' flag.
    packet_transmitted = 0;

    // Clear the Interrupt Status Register.
    WRITE(INTSTATUS, FFH);

    // Set the transmit byte count zero.
    WRITE(TBCRO, 0);
    WRITE(TBCR1, 0);

    // Issue the transmit command.
    WRITE(CMND, (RD2 | STA | TXP));

    // This transmission is used to generate an
    // interrupt.

    // Loop until ISR is called and
    // packet_transmitted flag is set
    // or there is a time out.
    while(time_in_loop < 1 second)
    {
        if(packet_transmitted)
            return(Interrupt_OK);

        update_time_in_loop();
    }
    return(Interrupt_FAILED);
}

```

### 3.6 Checking the Boot ROM

If a boot ROM has been identified as belonging to the adapter under going diagnostics then it is possible to check that its data has not been corrupted. The sum of all of the ROM bytes should equal 0. The size of the ROM (in 1/2 k segments) is held at byte offset 03H, offsets 00H and 01H should hold values 55H and AAH respectively.

#### 4.0 TRANSFERRING INFORMATION

Before transmission of a packet or processing of a reception, it is necessary to store or retrieve data from the buffer RAM. The two architecture modes available on the AT/LANTIC have different methods of accessing the buffer RAM.

##### 4.1 I/O Mode Transfers

When in I/O mode the NIC core of the AT/LANTIC transfers data to or from the buffer RAM using one of its DMA channels. The software programs the start address of the RAM segment to be transferred, the size of transfer and the direction of the transfer. The DMA controller passes data between the data transfer port and the buffer RAM, byte or word at a time. The system always writes or reads data via this port. The Data Transfer Port is mapped from I/O base offset 10H to 17H (any of these registers act as the Data Transfer Port). It is important that no other value be written to the command register during a DMA.

##### BUS ERROR CONDITION

On some implementations of the ISA bus it is possible for an error condition to arise during a DMA transfer. This is flagged by a "BE" (Bus Error) bit in configuration register B being set (writing a one to this bit resets it). The AT/LANTIC provides two differing methods for correcting this condition, these are implemented by setting either the "IO16CON" bit or the "CHRDY" bit in configuration register B. For a more detailed discussion on the cause of the error and the remedies available reference should be made to the AT/LANTIC data sheet Section 6.7 ("16-Bit I/O Cycles with CHRDY Fix").

It is recommended that a check for this error condition be carried out before an adapter is enabled on a network. This can be done by performing a DMA, checking if the "BE" bit has been set and if so implementing one of the fixes. It is also possible to perform the check at the end of every DMA (as the error may not happen during all DMA sequences).

##### 4.1.1 DMA WRITE SEQUENCE

The DMA write sequence is typically used to load up a packet to be transmitted in to the transmit buffer, as in the example below.

```

...
// Create a transmit packet and hold a
// pointer to its address in the PC RAM.
packet = set_up_xmt_pkt();

Disable Interrupts;

// Write out the Buffer RAM address for the
// xmt packet to the Remote DMA addr.
// registers. This is either TPSR1 or TPSR2.
WRITE(RSAR0, TPSR_LSB);
WRITE(RSAR1, TPSR_MSB);

// Write out the size of the packet to the
// Remote DMA BYTE count registers.
length = SIZEOF(packet);
WRITE(RBCR0, length_LSB);
WRITE(RBCR1, length_MSB);

```

```

// Issue the Remote DMA write command.
WRITE(CMND, (RDL | STA));

// Loop until all bytes/words transferred.
address = packet;
for(loop through the transmit pkt)
{
value = contents of address;
WRITE(DATA_PORT, value);
increment address pointer;
}

// It is necessary to wait until the last
// transfer is flagged as being placed into
// memory. An access to the command
// register before the DMA has completed may
// corrupt the last transfer and lead to
// serious system errors.
while(time_in_loop < 1 second)
{
status = READ(INTSTATUS);

if(status & ISR_RDC)
return(TRANSFER_OK);

update_time_in_loop();

Short_Delay();
}

Enable Interrupts;

return(TRANSFER_FAILED);
...

```

##### 4.1.2 DMA READ SEQUENCE

The DMA read sequence is typically used for removing packets from the receive buffer ring. However the example below reads the Ethernet address from Buffer RAM (as would be required during initialization).

```

...
// Read the Ethernet address and place it at
// PC RAM space pointed to by 'addr'.

Disable Interrupts;

// Set the Remote read start address to 0.
WRITE(RSAR0, 0);
WRITE(RSAR1, 0);

```

```

// Set the Remote DMA BYTE count to 6.
WRITE(RBCRO, 6);
WRITE(RBCRL, 0);

// Issue the Remote DMA read command.
WRITE(CMND, (RDO | STA));

// Read 3 words or 6 bytes depending on bus
// width.
for(loop 3 or 6 times)
{
  contents of addr = READ(DATA_PORT);
  increment address;
}

Enable Interrupts;

return(TRANSFER_COMPLETED);
...

```

The above examples often refer to the Command and Interrupt Status registers and their associated bits. More details on these registers can be found in the AT/LANTIC data sheet Section 5.3.

The size of access to the data port is dependent on the width of the bus detected during the initialization sequence. However, it should be noted that in 16-bit mode the length of transfer is programmed in bytes even if the transfers to/from the data port are to be word wide.

There are some assembly language commands that greatly simplify the transfer loop to the data port.

e.g., for the Intel 286 Processor.

```

set cx to byte count;
set es:di to pc RAM destination;
set dx to DATA_PORT;
set direction flag;
rep insw/outsw

```

#### 4.2 Shared Memory Transfers

When in Shared Memory mode the buffer RAM is mapped into a portion of the PC RAM space. Access to the buffer uses the same method as access to any portion of the PC address space. The location at which the buffer RAM appears is controlled by two Shared Memory Control Registers. These registers also set the size and width of transfer as well as enabling or disabling the RAM buffer. The buffer RAM can be set to 16 kbytes or 8 kbytes in size (as determined by the adapter hardware) and the CPU transfer width can be 8-bit or 16-bit wide (as determined in Section 3.2). These settings are controlled by two register bits, the MEMW bit of control register 2 controls the width of memory i.e., 8 kbytes/16 kbytes and the 8-bit/16-bit of control reg. 2 controls whether the transfer is 8-bit or 16-bit wide. If the transfers are to be 16-bit wide then the 8-bit/16-bit should be set only for the duration of the transfer. It is also possible to disable the buffer RAM when there is no transfer in progress by using the MEME bit of control register 1. This allows more than one adapter to utilize the same RAM location in the PC memory map. It should be noted that if multiple adapters are to use the same RAM location then all the adapters must disable the RAM when transfers are not in

progress. If only one adapter is allowed to use the RAM location then the memory can be enabled at initialization.

If the software being developed has to be fully compatible with the Ethercard Plus16 architecture then the control registers cannot be assumed to be readable. Thus when toggling the MEME and 8-bit/16-bit during a transfer it is necessary to either re-calculate the value of the address bits in the register or recall some store of the initialized value.

#### EXAMPLE TRANSFER

This example is for 16 bit wide transfers with memory only enabled for the duration of the transfer.

```

// 'Cntrl1' and 'Cntrl2' are stored at
// initialization.

// Enable the buffer memory.
WRITE(CNTRL1, (cntrl1 | MEME));
// Enable 16-bit wide transfers.
WRITE(CNTRL2, (cntrl2 | 8/16));

// Memory transfer.
MEMCOPY(PCaddr, BufferAddr, size);

// Disable the buffer memory.
WRITE(CNTRL1, cntrl1);
// Disable 16-bit wide transfers.
WRITE(CNTRL2, cntrl2);

```

There are some assembly language commands that provide a simple and efficient means of doing the "memcpy()" function in the above example.

e.g., for the Intel 286 Processor.

```

set cx to byte count;
set es:di to pc RAM destination;
set ds:si to pc RAM source;
set direction flag;
rep movsw

```

#### 4.3 The Boot ROM

The AT/LANTIC provides support for both standard boot ROMs and FLASH PROMS. Configuration register C controls the location at which the ROM is enabled, access to the ROM is then the same as access to any area of PC RAM.

The use of a FLASH prom allows software to directly update a boot ROM with the latest driver software for an adapter, thus eliminating the need to replace a ROM for each new release of software. It is necessary to set the BPWR bit of configuration register B when a FLASH prom is to be updated. Write cycles to the ROM area are only allowed when this bit is set. After this bit is set the software should follow the algorithm to program the FLASH prom (as given in the PROM's data sheet).

#### 5.0 TRANSMISSION SEQUENCE

When a transmission is required, it is necessary to select a free transmit buffer to place the packet information into (assuming there is more than one transmit buffer in the buffer RAM). The packet should then be transferred, as described in Section 4.0, to this location. A check is then required to see if a packet is presently being sent out onto the network. If a transmission is in progress then the address and size of

this new packet should be held in a "store" until the transmission completes. If a transmission is in progress then this packet can be sent directly out on to the network. This requires the Transmit Page Start Register and the Transmit Byte Count Registers to be programmed with the address and length of the packet respectively. Following this the transmit command can be issued to the Command Register. It is important to remember that the TPSR cannot be altered during a transmission.

#### ISSUING A TRANSMIT

```

...
// No transmission in progress. The new
// packet is held at transmit buffer
// address XMT_BUFFERx
    WRITE(TPSR XMT_BUFFERx_MSB);
// Set the byte size of the packet, held in
// 'length'.
    WRITE(RBCR0, length_LSB);
    WRITE(RBCR1, length_MSB);

// Issue the transmit command.
    WRITE(CMND, (RD2 | STA | TXP));

```

#### 5.1 Transmission Status Checking

Once a transmission has completed the AT/LANTIC will return an interrupt. It is the task of the Interrupt Service Routine (ISR) to determine whether the transmission was successful or not and deal with it accordingly. If the transmission completed successfully, a check should be made to see if more transmissions are required, the details of which may be held in the "store" described in the above paragraph.

When called the ISR should check the Interrupt Status Register. If the PTX bit is set then this indicates that the packet

was transferred without error and the transmission can be flagged as successful. If the TXE bit is set, then an error has occurred and more information is required. This extra information is provided by the Transmit Status Register (TSR) from which the relevant error flags and statistics counters can be updated before the transmission can be flagged as completed with error. If collisions occurred during transmission then the COL bit of the TSR is set and the number of collisions that occurred is held in the Number of Collisions Register (NCR). The software can use this register to keep statistics on the amount of collisions occurring on a network.

### 6.0 RECEPTION SEQUENCE

#### 6.1 The Buffer Ring

As packets are received they are placed in to the buffer ring and as they are processed they are removed from the ring. At initialization an area of memory is allocated to act as the receive buffer ring and the AT/LANTIC's buffer management scheme controls the operation of the memory.

Four pointers are used to control the ring; the page start (PSTART) and page stop (PSTOP) pointers to determine the size of the buffer ring, the current page (CURR) pointer to determine where the next packet will be written to from the network and the boundary (BNDRY) pointer to show where the next packet to be read and processed lies. As packets are received, the boundary pointer follows the current page pointer around the ring. During operation the page start and page stop registers remain unchanged.

The receive buffer ring is divided into 256 byte buffers (called "pages") and these are linked together as required by the received packets. Since all AT/LANTIC registers are byte wide the ring pointers refer to the page (256 byte) boundaries, see *Figure 10*.

FIGURE 10. The Receive Buffer Ring

TL/F/11820-3

On a valid reception the packet is placed in the ring at the page pointed to by CURR plus a 4 byte offset (see *Figure 11*). The packet is transferred to the ring through the AT/LANTIC which links the page buffers as necessary until the complete packet is received. The first and last buffers (PSTART and PSTOP) are linked just as the first and second buffers would be. At the end of a reception, the status from the Receive Status Register (RSR), a pointer to the next packet and the byte count of the current packet are written into the 4 byte offset (see *Figure 12*).

**6.2 Removing a Packet**

Once packets are in the receive buffer ring they must be processed. The AT/LANTIC supports two differing adapter

architectures which have their own method of accessing the buffer memory, these are discussed in Section 4.0 of this document. As packets are removed from the buffer ring, the boundary (BNDRY) pointer must be updated. The BNDRY follows CURR around the ring (see *Figure 13*).

If the current local DMA address (the place where a newly received packet is being stored) ever reaches BNDRY then the ring is full and any more receptions cannot be achieved until some processing has been done on the ring. This condition is known as overflow. More details on this condition and how to overcome it are given in Section 6.3.

**FIGURE 11. Receiving a Packet**

TL/F/11820-4

**FIGURE 12. Receive Packet Header**

TL/F/11820-5

TL/F/11820-6

FIGURE 13. Removing a Packet

When the CURR and BNDRY pointers are equal, the buffer ring can either be full or empty. To ensure that the software never misinterprets this condition the BNDRY pointer can be kept one less than the CURR pointer when the ring is empty, and only equal to CURR when the ring is full, as shown below.

1. Use a variable (Next\_pkt) to indicate where the next packet will be removed from the buffer ring.

2. At initialization set (see Section 3.3):

```
BNDRY = PSTART
```

```
CURR = PSTART + 1
```

```
Next_pkt = PSTART + 1
```

3. After each packet is removed from the ring, use the next packet pointer in the header information (the second byte of the header), HNXTPKT and set:

```
Next_pkt = HNXTPKT
```

```
BNDRY = HNXTPKT
```

```
if (BNDRY < PSTART)
```

```
  BNDRY = PSTOP - 1
```

### THE SEND PACKET COMMAND

When in I/O mode the Remote DMA channel can be automatically initialized to transfer a single packet from the receive buffer ring. The transfer is initiated by issuing a "send packet" command, setting bits RD1, RD0 and STA in the command register. The DMA will be initialized to the value of the BNDRY pointer and the Remote Byte Count registers will be initialized to the values found in the buffer header of each received packet. After the data has been transferred, the BNDRY pointer is advanced and the Remote DMA is then prepared to receive the next packet.

This method does not require the manual updating of registers as discussed in Steps 1-3, however it does limit the software to accessing a packet just once.

The receive sequence is initiated by an interrupt generated by the AT/LANTIC when data is ready to be removed from the ring or an overflow has occurred. The Interrupt Service Routine should then interrogate the Interrupt Status Register which flags a PRX bit when a packet is ready to be removed or OVW if the buffer ring is full. When this PRX bit is set then a receive subroutine following the above sequence should be called, if the OVW bit is set the overflow routine discussed in Section 6.3 should be called.

The receive buffer "ring" is a linear section of RAM forced into a ring by linking the end (PSTOP) and beginning (PSTART) of the buffer. Some of the received packets shall overlap or "wraparound" this link in the buffer, i.e. the start of the packet is held up to PSTOP and the rest is held from PSTART. This condition is automatically dealt with when in I/O mode however Shared Memory mode requires more care. In Shared Memory mode a "wraparound" packet has to be transferred in its two sections, i.e., the section up to PSTOP and the section from PSTART.

A pseudo code example of the sequence is given below.

### RECEIVE ROUTINE

```
Receive_subroutine()
```

```
{
// This routine loops until all the packets
// currently held in the buffer ring are
// removed.
  while(Next_pkt != CURR)
  {
```

```

// Get the 4 byte header from the packet
// pointed to by Next_pkt, the method of
// removing the data depends on the mode of
// the AT/LANTIC.
    status = read_status();
// If in shared memory mode then check if
// the packet wraps around the PSTOP
// pointer.
    if(in_shared_memory_mode)
    {
        if (status.length + Next_pkt > PSTOP)
        {
            transfer_up_to_PSTOPO;
            transfer_from_PSTART();
        }
        else
            transfer_all_at_once();
    }
    else
// I/O mode automatically carries out
// wraparound.
        transfer_all_once();
// Set the Next_pkt pointer to equal the
// next packet pointer in the status bytes.
    Next_pkt = status.next_packet;
// Update the boundary pointer.
    BNDRY = Next_pkt - 1;
    if(BNDRY < PSTART)
        BNDRY = PSTOP - 1;

    WRITE(BNDRY);
} // end of while loop.
}

```

### 6.3 Dealing with Overflows

In heavily loaded networks it is possible for the receive buffer ring to be filled with packets that still require processing, i.e., the CURR pointer reaches the BNDRY pointer. If this situation occurs then the AT/LANTIC suspends further receptions and posts an overflow (OVW) interrupt.

In the event of an overflow condition occurring it is necessary to follow the routine given below. If this routine is not adhered to then the AT/LANTIC may act in an unpredictable manner. A flow chart of the routine is given in *Figure 8*.

**Note:** It is necessary to define a variable in the driver, which will be called "Resend".

1. Read and store the value of the TXP bit in the AT/LANTIC Controller's Command Register.
2. Issue the STOP command to the AT/LANTIC Controller. This is accomplished by setting the STP and RD2 bits in the AT/LANTIC Controller's Command Register.
3. Wait for at least 1.6 ms. Since the AT/LANTIC Controller will complete any transmission or reception that is in

progress, it is necessary to time out for the maximum possible duration of an Ethernet transmission or reception. By waiting 1.6 ms this is achieved with some guard band added. Previously, it was recommend that the RST bit of the Interrupt Status Register be polled to insure that the pending transmission or reception is completed. This bit is not a reliable indicator and subsequently should be ignored.

4. Clear the AT/LANTIC Controller's Remote Byte Count registers (RBCRO and RBCR1).
5. Read the stored value of the TXP bit from step 1, above.

If this value is a 0, set the "Resend" variable to a 0 and jump to step 6.

If this value is a 1, read the AT/LANTIC Controller's Interrupt Status Register. If either the Packet Transmitted bit (PTX) or Transmit Error bit (TXE) is set to a 1, set the "Resend" variable to a 0 and jump to step 6. If neither of these bits is set, place a 1 in the "Resend" variable and jump to step 6.

This step determines if there was a transmission in progress when the stop command was issued in step 2. If there was a transmission in progress, the AT/LANTIC Controller's ISR is read to determine whether or not the packet was transmitted by the AT/LANTIC Controller. If neither the PTX nor TXE bit was set, then the packet will essentially be lost. If a packet was "lost" then a transmit command can be reissued to the AT/LANTIC Controller once the overflow routine is completed (as in step 11). Also, it is possible for the AT/LANTIC Controller to deter indefinitely, when it is stopped on a busy network. Step 5 also alleviates this problem. Step 5 is essential and should not be omitted from the overflow routine, in order for the AT/LANTIC Controller to operate correctly.

6. Place the AT/LANTIC Controller in either mode 1 or mode 2 loopback. This can be accomplished by setting bits D2 and D1, of the Transmit Configuration Register, to "0,1" or "1,0", respectively. Further explanation of loopback can be found in the AT/LANTIC data sheet under Section 6.5.
7. Issue the START command to the AT/LANTIC Controller. This can be accomplished by setting the START and RD2 bits in the Command Register. This is necessary to activate the AT/LANTIC Controller's Remote DMA channel.
8. Remove one or more packets from the receive buffer ring.
9. Reset the overwrite warning (OVW, overflow) bit in the Interrupt Status Register.
10. Take the AT/LANTIC Controller out of loopback. This is done by writing the Transmit Configuration Register with the value it contains during normal operation. (Bits D2 and D1 should both be programmed to 0.)
11. If the "Resend" variable is set to a 1, reset the "Resend" variable and reissue the transmit command. This is done by the TXP bit in the Command Register. If the "Resend" variable is 0, nothing needs to be done.

**Note:** If Remote DMA is not being used, the AT/LANTIC Controller does not need to be started before packets can be removed from the receive buffer ring. Hence, step 8 could be done before step 7, eliminating or reducing the time spent polling in step 5.

**Note:** When the AT/LANTIC Controller is in STOP mode, the Missed Packet Tally counter is disabled.

# I/O Channel Ready Considerations for the DP83902EB-AT

National Semiconductor  
Application Note 892

## INTRODUCTION

Some PC-AT® compatible systems that use bus interface chip sets with modified timing characteristics such as some Chips & Technologies or VLSI technologies chip sets have different timing requirements that require modification to 16-bit I/O mapped designs to operate properly. 8-bit I/O mapped designs do not require this modification.

This paper describes the timing issues associated with the DP83902EB-AT and methods of fixing these timing incompatibilities.

## OVERVIEW

The timing inconsistency is the time of assertion and deassertion of the IOCHRDY bus signal. IOCHRDY floats active (ready) when not driven by an I/O card. Normally, an I/O card should drive IOCHRDY low (not ready) to insert wait states only after the address and I/O read or write signal are asserted. However, on some PC-AT buses, during a 16-bit I/O operation the bus controller actually samples the IOCHRDY signal before the I/O read or write signal is asserted. To correct the early sampling of IOCHRDY by the bus controller, the I/O card can drive IOCHRDY based only on an address decode, thus allowing IOCHRDY to be asserted earlier and in the proper state when it is sampled by the bus controller.

Remote read cycles are executed by National Semiconductor's DP83902 ST-NIC™, Network Interface Controller with integrated twisted pair, during packet reception. A remote read cycle will be used to illustrate how the early sampling of IOCHRDY is compensated. Also, the PAL® equations needed to generate IOCHRDY and the necessary modifications to account for the early sampling of IOCHRDY for the DP83902EB-AT will be described.

```
NRDYEN = !( !NSTNICB & !NIOR & !SA4 & NACK
            # !NSTNICB & !NIOW & !SA4 & NACK
            # !NSTNICB & !PRQ & !NIOR & SA4 & !SA3
            # !NSTNICB & !PRQ & !NIOW & SA4 & !SA3 );
enable NIOCHRDY = !NRDYEN;
```

```
NIOCHRDY = (0);
```

FIGURE 1. "Normal" IOCHRDY PAL Equations for DP83902EB-AT

## REMOTE READ CYCLE

The ST-NIC receives data from the network and transfers the data to the local buffer memory using the local DMA channel. The ST-NIC then executes a remote DMA read to transfer the received data from the buffer memory to the host memory through the I/O port latch.

Referring to *Figure 2*, the remote read cycle functions as follows:

1. The ST-NIC reads a word from local buffer memory asserting  $\overline{MRD}$  and writes the word into the I/O port latch asserting  $\overline{PWR}$ .
2. The ST-NIC asserts the request line (PRQ) to inform the host a word is in the I/O port latch.
3. The host reads the I/O port asserting  $\overline{IOR}$ . IOCHRDY is asserted if  $\overline{IOR}$  occurs before PRQ to extend the assertion time of  $\overline{IOR}$ , effectively wait-stating the host so that the host-I/O handshake can occur.
4.  $\overline{RACK}$  is asserted to signal to the ST-NIC that the host has read the word from the I/O port latch.

Steps 1–4 are repeated until all words are transferred.

## "NORMAL" IOCHRDY TIMING DURING A REMOTE READ CYCLE

The "normal" IOCHRDY PAL equations are shown in *Figure 1* and the complete PAL equations for U2 in the DP83902EB-AT are shown in AN-752 in the 1992 Local Area Network Databook. The corresponding timing diagram is shown in *Figure 2*. Referring to *Figure 1* and AN-752, whenever NRDYEN is true, IOCHRDY is driven, otherwise it will be held TRI-STATE®. The first two terms in the NRDYEN function are for a slave read and write, respectively. The next two terms are for remote read and write, respectively. There are 7 unique variables in the function NRDYEN. Namely, NSTNICB, NIOR, NIOW, NACK, PRQ, SA4 and SA3. A brief explanation of each follows.

NSTNICB—(SA9–SA5) chip select the I/O card. This is the base address of the I/O card.

NIOR—( $\overline{\text{IOR}}$ ) the I/O read command signal.

NIO $\overline{\text{W}}$ —( $\overline{\text{IOW}}$ ) the I/O write command signal.

NACK—( $\overline{\text{ACK}}$ ) Used during slave read/write cycles to indicate a successful register (byte) transfer.

PRQ—Used during remote read/write cycles to inform the host that the NIC has written a word in the I/O port latch.

SA4 and SA3—Address signals from the I/O bus. The states of these signals determine if the address on the I/O bus is for the I/O port latch or the NIC registers.

The on board IOCHR $\overline{\text{D}}$ Y signal will only be driven to wait state the host until the NIC writes to the I/O port latch and asserts PRQ.

The remote word transfer is complete after the  $\overline{\text{RACK}}$  signal is asserted indicating the host has read the word from the I/O port latch.

**MODIFIED IOCHR $\overline{\text{D}}$ Y TIMING DURING A REMOTE READ CYCLE**

The modified IOCHR $\overline{\text{D}}$ Y PAL equations shown in *Figure 4* implement both the "normal" IOCHR $\overline{\text{D}}$ Y timing and the modified IOCHR $\overline{\text{D}}$ Y timing. These equations replace the section of the U2 PAL equations in AN-752 shown in *Figure 1*. The modified IOCHR $\overline{\text{D}}$ Y schematic and timing diagram are shown in *Figures 3* and *5* respectively.

NIOCHR and NIOCHR.OE (enable NIOCHR) together are for slave read and remote read. Also, NIOCHW and NIOCHW.OE (enable NIOCHW) together are for slave write and remote write. These signals (NIOCHR and NIOCHW) together produce the "normal" IOCHR $\overline{\text{D}}$ Y signal.

NIOCHC and NIOCHC.OE (enable NIOCHC) together modify the IOCHR $\overline{\text{D}}$ Y timing. In the modified IOCHR $\overline{\text{D}}$ Y timing, IOCHR $\overline{\text{D}}$ Y is driven when the I/O card address is decoded, thus driving IOCHR $\overline{\text{D}}$ Y before it is sampled by the host.

By driving IOCHR $\overline{\text{D}}$ Y on an address decode the possibility exists that it may be driven on a memory access instead of an I/O access. IOCHR $\overline{\text{D}}$ Y must be held TRI-STATE if the host issues a memory access command signal (MEMR or MEMW) because if these signals become active after an address decode to the I/O card this means that the address was a memory address and not an I/O address. Thus, the address was not intended for the I/O card and driving IOCHR $\overline{\text{D}}$ Y may cause contention with the memory.

PRQ is held TRI-STATE until the ST-NIC's Data Configuration Register (DCR) is programmed. A pull-up resistor is needed to guarantee PRQ is asserted while its TRI-STATE to prevent IOCHR $\overline{\text{D}}$ Y from "getting stuck" low and effectively locking up the host.

Driving IOCHR $\overline{\text{D}}$ Y early must be an option since this has been seen to cause problems on some PC's, but fixes problems on others. The variable CLONEN is a jumper used to switch the IOCHR $\overline{\text{D}}$ Y signal characteristics to "normal" or modified timing. The inverted SYSCLK (System Clock) and BALE (Bus Address Latch Enable) signals are AT bus signals and are used to assert CLONEN when the bus address is valid, which is indicated by BALE. CLONEN is asserted when BALE is asserted and deasserted after BALE is deasserted and the next SYSCLK rising edge occurs, allowing enough time for the I/O command signal to occur. At this point, the modified IOCHR $\overline{\text{D}}$ Y timing is TRI-STATE and the "normal" IOCHR $\overline{\text{D}}$ Y timing is enabled.

EN16 is used to determine if the data transfer is 8 or 16 bits. The modified IOCHR $\overline{\text{D}}$ Y is necessary only during 16-bit I/O accesses because the early sampling of IOCHR $\overline{\text{D}}$ Y only occurs during 16-bit I/O accesses.

To incorporate the IOCHR $\overline{\text{D}}$ Y modification in the DP83902EB-AT, replace the section of the U2 PAL equations shown in *Figure 1* with the PAL equations of *Figure 4* and add a 74F74 D flip-flop and a jumper to the evaluation board to hard-wire CLONEN to U2.

### INTRODUCTION

The AT/LANTIC Ethernet controller provides a simple method of interfacing a PC ISA (Industry Standard Architecture) bus based system to Ethernet. The AT/LANTIC controller emulates a popular adapter card for PC compatibles: the Novell® NE2000 *Plus* card. The AT/LANTIC also implements a shared memory mode that provides added flexibility and performance. The high level of integration ensures a small and cost-effective solution. In order to use a network interface, driver software is required that is specific to the network interface and the network operating system. Since the AT/LANTIC is compatible with the most popular adapter cards, driver support is second to none.

### ABOUT THIS GUIDE

This guide is written for hardware design engineers wishing to develop an Ethernet interface using AT/LANTIC. The guide is written in two sections. The first part is a step-by-step examination of the design process. The second section provides reference material with additional detailed information.

**1.0 DP83905 ETHERNET INTERFACE DESIGN**

**1.1 Design Decisions and Implementation Details**

This section of the AT/LANTIC guide is intended to ask the designer to choose which options are best for each application, whether it is an adapter card, a motherboard or some other embedded design. (Note that Application Note AN-844 "DP83905EB-AT AT/LANTIC™ Demonstration Board" shows detailed schematics of an AT/LANTIC solution.)

**1.1.1 ISA Bus Connection**

The AT/LANTIC supports both 8- and 16-bit ISA bus configurations. An 8-bit interface is cheaper than 16-bit (less board space and only one SRAM), but has lower performance. There are three options for connecting the bus interface as described:

1. For an 8-bit interface, pins SD8-15, SBHE, LA17-23, MWR, MRD, M16, and I016 should be left unconnected, and DWID should be tied low.
2. For a 16-bit interface, DWID should be tied high.
3. For a 16-bit adapter card that can be used in 8- and 16-bit slots, DWID should be connected to pin D29 of the ISA bus. In a 16 bit slot this is +5V. In an 8-bit slot, this is unconnected, and a pull-down within AT/LANTIC will ensure that 8-bit mode is selected.

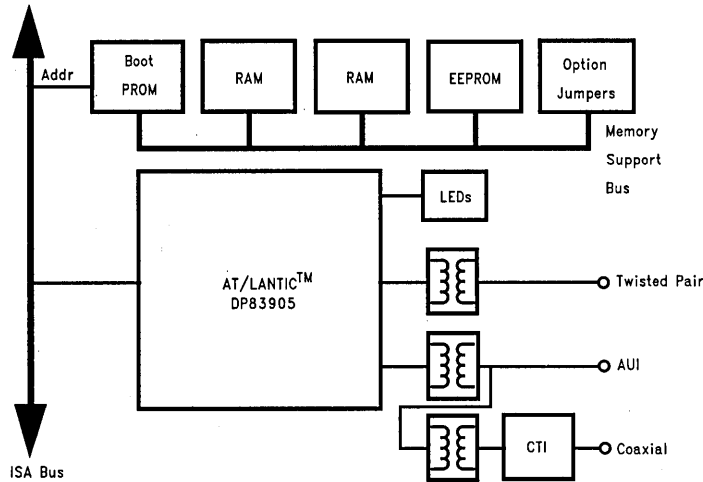

**1.1.2. Interrupts**

The AT/LANTIC has 4 dedicated interrupt output pins. This allows the user to select the required interrupt without changing jumpers on the board. In some applications, the choice of 4 interrupts may not be sufficient. The AT/LANTIC allows you to use an external decoder to expand the choice to 8 interrupts.

For 4 interrupts, connect each of the pins INT0-3 directly to the interrupt signals. We strongly recommend using the following scheme to promote software compatibility across AT/LANTIC platforms:

AT/LANTIC	PC
INT0	IRQ3
INT1	IRQ4
INT2	IRQ5
INT3	IRQ9

Configuration register C bit 5 "INTMOD" should be set to "0" (see Section 1.1.9).

**FIGURE 1. Simplified Block Diagram of AT/LANTIC Application**

TL/F/11850-1

For 8 interrupts, an external decoder is required. This decoder must have the following properties:

INT0-2 selects which 1 of the 8 outputs is driven. This output follows the logic level of INT3. The 7 unselected outputs must remain high impedance.

The decoder outputs are connected to 8 ISA interrupts. We recommend using the following scheme to promote software compatibility across AT/LANTIC platforms:

AT/LANTIC			PC
INT2	INT1	INT0	
0	0	0	IRQ3
0	0	1	IRQ4
0	1	0	IRQ5
0	1	1	IRQ9
1	0	0	IRQ10
1	0	1	IRQ11
1	1	0	IRQ12
1	1	1	IRQ15

Configuration register C bit 5 "INTMOD" should be set to "1" (see Section 1.1.9). The 8 interrupt mode interface can be implemented in a single GAL as shown in Figure 2.

FIGURE 2. GAL/PAL Circuit Diagram

The PAL or GAL equations should be:

- IRQ3 = INT3;
- IRQ4 = INT3;
- IRQ5 = INT3;
- IRQ9 = INT3;
- IRQ10 = INT3;
- IRQ11 = INT3;
- IRQ12 = INT3;
- IRQ15 = INT3;
- IRQ3.oe = /INT2 & /INT1 & /INT0;
- IRQ4.oe = /INT2 & /INT1 & INT0;
- IRQ5.oe = /INT2 & INT1 & /INT0;
- IRQ9.oe = /INT2 & INT1 & INT0;
- IRQ10.oe = INT2 & /INT1 & /INT0;
- IRQ11.oe = INT2 & /INT1 & INT0;
- IRQ12.oe = INT2 & INT1 & /INT0;
- IRQ15.oe = INT2 & INT1 & INT0;

### 1.1.3. Buffer RAM

The standard RAM sizes for 8- and 16-bit cards are 8k and 16k respectively, using one or two 8k x 8 RAMs. The AT/LANTIC will also support the use of 32k x 8 RAMs giving 4 times the standard RAM capacity. Using additional memory can provide a performance boost in server applications.

Note that the use of 32k x 8 RAMs will make the design INCOMPATIBLE with NE2000.

For 8k x 8 RAMS, MSA1-13 are used. Configuration register C bit 4 "COMP" should be set to "0".

For 32k x 8 RAMS, MSA1-15 are used. Configuration register C bit 4 "COMP" should be set to "1".

When making an 8-bit-only interface, only one RAM is required, connected to MSD0-7. For a standard ISA bus configuration, 100 ns RAMs, or faster, should be used. Details of how to calculate RAM speeds are given in Section 2.5.

### 1.1.4 Crystal/Oscillators

#### 1.1.4.1 20 MHz Clock

AT/LANTIC requires a 20 MHz ±0.01% clock. Both crystal and oscillator solutions are supported. In general, a crystal solution is cheaper, however if a suitable clock is already available on your board, it could be used.

To use a crystal, use the following circuit.

FIGURE 3. Crystal Circuit

The value of the capacitors should be 26 pF minus the printed circuit board trace capacitance. (Typical trace and pin capacitance is about 4 pF).

1. Note that the following rules should be applied:
2. The signal traces should be short.
3. The ground return path to the capacitors should be short, and should connect to the AT/LANTIC OGND pin.
4. There should not be other signal traces through the region of the crystal.
5. It may help to place a ground plane under the crystal.
6. The crystal should conform to the following specifications:

- AT cut parallel resonant crystal
- Series resistance ≤ 25Ω
- Specified load capacitance ≤ 20 pF
- Accuracy 0.005% (50 ppm)
- Typical load 50 μW-75 μW

7. Do not connect X1 or X2 to anything else.

Alternately, an oscillator may be used. If used the oscillator output should be connected directly to X1. X2 should be left unconnected. The clock should be better than 40:60 duty cycle, and should have a good quality waveform.

#### 1.1.4.2 BSCLK

The AT/LANTIC core can be clocked either by the 20 MHz clock, or by a separate clock input "BSCLK". The maximum clock rate is 20 MHz, so the 20 MHz clock is usually used.

To use the 20 MHz clock, connect the BSCLK pin to 0V, and set Configuration register C bit 6 "CLKSEL" to "0". To use another clock source, connect the clock source to the BSCLK pin, and set Configuration register C bit 6 "CLKSEL" to "1". See Section 1.1.9 for more information about configuration data.

**1.1.5 Boot ROM (Remote Program Load PROM)**

Depending on the intended use of your design, you may wish to provide a boot PROM, or a socket for a boot PROM. A boot PROM allows the PC to load the operating system from a server on the network, without needing a disk drive on the PC. AT/LANTIC supports boot PROM sizes of 8k, 16k, 32k and 64k. The AT/LANTIC also supports the use of FLASH ROM through the use of a write signal. This may be used to allow in-situ programming, or updating of boot PROM code by the user.

Adaptor cards are typically supplied with an empty boot PROM socket. Boot PROMs are available from network operating system vendors or third parties. They are typically 8 kbytes or 16 kbytes in a 28-pin package. The boot prom size can be configured by the user to be any size and at any address between C0000h and DFFFFh, using configuration register C bits 0-3 "BPS0-3".

Configuration register B bit 6 "BPWR" specifies if the AT/LANTIC will allow write access to the PROM: "0" = read only, "1" = write enabled. (See Section 1.1.9, Configuration.)

For a standard ISA bus configuration, 250 ns PROM, or faster, should be used. Details of how to calculate boot PROM speeds are given in Section 2.5.

**1.1.6 Cable Interfaces**

AT/LANTIC supports three types of cable interface:

- TPI 10Base-T, Twisted Pair
  - AUI for connection to 10Base5, also known as "thick" Ethernet
  - Coax 10Base2, also known as thin Ethernet
- The TPI interface connects to the AT/LANTIC as follows:

The AT/LANTIC selects between the AUI/coax interfaces and TPI internally. Note that, in addition to 10Base-T compatible twisted pair, the AT/LANTIC supports the use of higher loss cable systems. This allows cables to be longer than the 10Base-T specification, or allows the use of shielded cables. Refer to Section 4.8 of the AT/LANTIC data sheet.

The AUI interface requires an isolation transformer, and resistors, as shown in Figure 5. The AUI interface enables the use of an off board transceiver to connect to other types of media such as Thick Ethernet or Fiber Optic cabling.

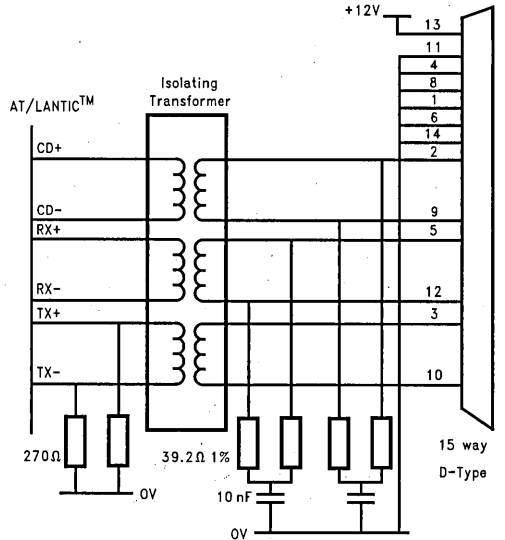

FIGURE 5. AUI Interface Circuit

FIGURE 4. Twisted Pair Interface

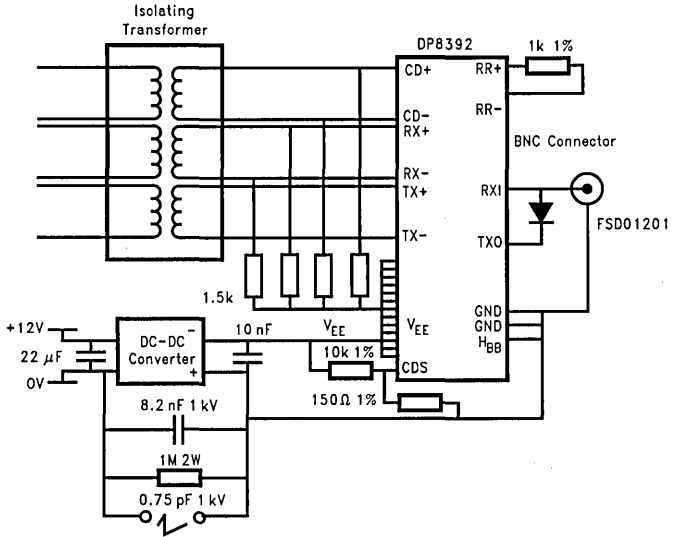

FIGURE 6. Coax Interface Circuit

TL/F/11850-6

The Coax interface requires an isolation transformer, a DC-DC converter and the DP8392 Coax Transceiver Interface as shown in *Figure 6*.

If it is desirable to implement a design that supports both AUI and Thin Ethernet cabling schemes, and provides for selection between the two interfaces the coax interface should connect to the AUI interface as shown in *Figure 7*. In order to use the AUI connector, the coax interface must be disabled. AT/LANTIC™ selects AUI or coax with an output pin, called "THIN". This signal is used to switch-on the DC-DC converter of the coax interface when THIN is high. When coax is selected, an AUI cable must not be connected to the AUI connector.

*Figure 7* shows a DC-DC converter with an enable input. A DC-DC converter without an enable input can be used, if the supply to the converter is switched by an FET.

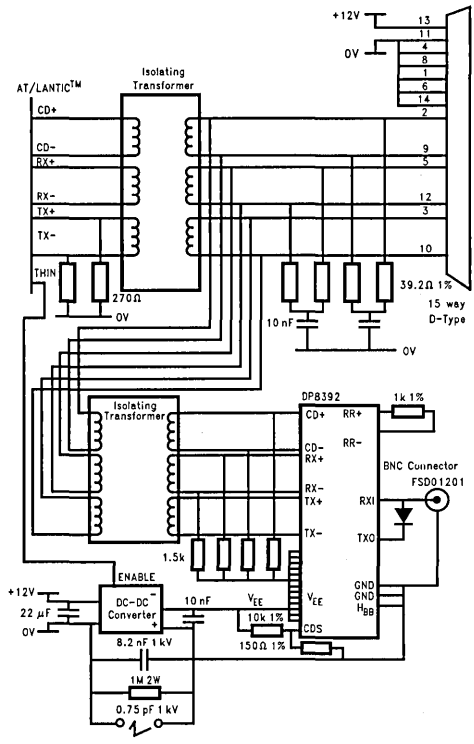

FIGURE 7. AUI and Coax Interface Circuit

TL/F/11850-7

TL/F/11850-8

**FIGURE 8. FET Switch for DC-DC Converter**

The cable interfaces utilize a number of magnetic components as shown in the previous figures. The specifications for these components are shown below.

AUI and Coax Interface isolation transformer:

- 1:1 turns ratio
- 100  $\mu$ H inductance
- 500V isolation

Coax DC-DC converter:

- +12V input (could use +5V connected to the +5V supply)
- 9V output voltage
- 200 mA output current
- 500V isolation

Active-high enable input (if required)

The 10BASE-T interface uses an integrated Filter-Transformer-Choke combination.

Specific component recommendations are listed in the Local Area Networks Data Book in the Magnetics Vendors Application Note.

### 1.1.7 LED Interface Options

AT/LANTIC has dedicated outputs for driving several LEDs. These outputs are capable of a maximum current per LED output of 16 mA. Do not decrease the resistor value below 330 $\Omega$ , or the AT/LANTIC maximum current will be exceeded.

TL/F/11850-9

**FIGURE 9. LED Circuit**

It may be desirable to connect LEDs to any or all of the possible outputs. When used the LEDs can provide the following information:

- TxLED Transmit activity
- RxLED Receive activity (all packets on network)
- COLED Collision
- GDLNK TPI Link Ok, or testing disabled
- POLED TPI Polarity reversed

In some cases the polarity of the LED is reversed from that which the designer would like to use (e.g., the LED is off under a condition that the designer would like it to be on). To handle this, it is possible to use the following circuit, *Figure 10*, to invert the meaning of an LED (e.g., instead of a "Good Link" LED the LED can be defined as "Link fail"):

TL/F/11850-19

**FIGURE 10. Inverted LED Circuit**

### 1.1.8 Low Power

In some portable applications it is necessary to shut-off sub-systems in order to conserve power. AT/LANTIC has been designed so that it is possible to remove the power from the majority of the chip whilst still powering the ISA interface circuit, thus protecting the ISA bus. In low power state, the current drain is less than 100  $\mu$ A.

If "Low Power" is not required, tie the LOWPWR pin to 0V.

If "Low Power" operation is required, the following must be noted:

1. An external device is required to disconnect the PLLV<sub>CC</sub>, PV<sub>CC</sub>, OV<sub>CC</sub> and V<sub>CC</sub> pins. This device must have a low voltage drop when "on". A suitable device is the NDS9400 which has a 0.25 $\Omega$  on-resistance.
2. When the supply to the PLLV<sub>CC</sub>, PV<sub>CC</sub>, OV<sub>CC</sub> and V<sub>CC</sub> pins is turned off, the LOWPWR pin must be driven high. This disables internal buffers and reduces current drain to a minimum.
3. When recovering from low power state to normal operation, after restoring the power and driving LOWPWR low, the RESET pin must be driven high for more than 400  $\mu$ s to reset the controller.
4. Note that the DWID pin has an internal pull down. If this is tied high for 16-bit operation, it should be tied to the switched V<sub>CC</sub> to minimize current drain in the low power state.

### 1.1.9 Configuration

Three registers in the AT/LANTIC are loaded with configuration data at reset. This configuration specifies all the design choices (e.g., 4 or 8 interrupts) and the user installation choices (e.g., the I/O address).

This data can either be stored in the EEPROM, or be specified by resistors optionally connected to the CA0-7, CB0-7 and CC0-7 pins (also known as MSD0-15 and MSA1-8).

The benefits of the Jumperless EEPROM solution are that it is smaller and cheaper (no resistors or jumpers), and that the user can change the configuration without opening the computer. This may be especially important in a motherboard application. Additionally, the software used to change the configuration can attempt to check for address conflicts etc., and protect the user from making mistakes.

One potential problem with this solution, for adapter cards, is that the default settings as shipped may cause an address conflict in some cases. Such a conflict would prevent accesses to the card which are needed to change the address to a safe one.

To overcome this problem, AT/LANTIC has a "disabled" option. Configuration software can find an I/O address that is free, and then wake up the AT/LANTIC. Whilst disabled, AT/LANTIC monitors I/O accesses to 278h (a printer port). On the fourth consecutive write to 278h, AT/LANTIC loads the configuration from the write data, and wakes up.

The benefits of the Jumpered solution are that no software is needed to set the configuration. This may be important to system builders when choosing an adapter card, for whom jumpers may be faster to use than software.

Whichever configuration method you choose, you will need to determine, for each configuration bit, what the default value should be, and whether the bit can be changed by a user or is fixed by design. The following tables may assist you in this. Note that a full description of each configuration bit can be found in Section 5 of the AT/LANTIC data sheet.

Bit	Use
<b>Config A:</b>	
0	I/O Address
1	I/O Address
2	I/O Address
3	Interrupt
4	Interrupt
5	Interrupt (if 8 selected)
6	Fast read (See Section 1.1.9)
7	NE2000/Shared Memory
<b>Config B:</b>	
0	AUI/Coax/TPI
1	AUI/Coax/TPI
2	Good Link Test Disable
3	IO16 Bug Fix Enable
4	IO CHRDY Bug Fix Enable
5	—
6	Boot PROM Write Enable
7	—
<b>Config C:</b>	
0	Boot PROM Addr and Size
1	Boot PROM Addr and Size
2	Boot PROM Addr and Size
3	Boot PROM Addr and Size
4	RAM Size 8k or 32k
5	4 or 8 Interrupts
6	Core CLK = 20 MHz or BSCLK
7	Allow Access to Configure Regs(1)

**Note 1:** Config C bit 7 "SOFTEN" allows configuration software to read and write config registers A & B. Any changes to the config registers are overwritten by the EEPROM or jumper configuration the next time that the AT/LANTIC is fully reset. If access to the config registers is disabled, it is also not possible to change the EEPROM contents.

To implement a Jumperless (EEPROM) solution, the EECONFIG pin should be tied to +5V. The default configuration must be programmed into the EEPROM during manufacture. See Section 1.3 for details of how to program the EEPROM.

If config register C bit 7 "SOFTEN" is "0":

1. Config registers A and B can be examined by software (to check the configuration).
2. Config registers A and B can be modified by software to temporarily change the adapter settings. The settings are restored to the values in the EEPROM when the AT/LANTIC is next fully reset.
3. The values for config registers A, B and C that are held in the EEPROM can be changed by software. This can include setting config register C bit 7 to "1", which will prevent further access to config registers. If this is done, the settings can only be changed again if AT/LANTIC is reset with EECONFIG pulled low (i.e., jumpered mode).

If config register C bit 7 "SOFTEN" is "1":

1. Config registers A and B cannot be read or written by software.
2. The values for config registers A, B and C that are held in the EEPROM cannot be changed by software.

To implement a Jumpered solution, the EECONFIG pin should be tied to 0V. For each configuration bit you must define the state of the corresponding AT/LANTIC pin at reset. If the bit is fixed by design, you should connect 47k or 10k pull-up for a "1", or leave alone for a "0". If it is user-selectable, you should connect a pull-up via a jumper.

If config register C bit 7 "SOFTEN" is "0":

1. Config registers A and B can be examined by software (to check the configuration).
2. Config registers A and B can be modified by software to temporarily change the adapter settings. The settings are restored according to the jumpers when the AT/LANTIC is next fully reset.

If config register C bit 7 "SOFTEN" is "1":

1. Config registers A and B cannot be read or written by software.

#### OTHER CONFIGURATION OPTIONS

There are two other methods of configuring the AT/LANTIC. If using these methods, the interface will not properly emulate NE2000 adapter cards, and will not work with standard drivers.

**Partially Jumpered Solution:** This is a jumpered solution where only some of the options are jumpered, e.g., I/O address and boot PROM address. Since configuration registers A and B can be rewritten by software, a program could be used to complete the configuration process as part of the software boot sequence.

**No EEPROM, partially jumpered solution:** This is the same as the above solution, except that the EEPROM is not fitted. The purpose is to reduce cost. In this case, there is no Ethernet node address available, so a non-standard driver is required, which obtains its Ethernet address from another source.

**1.2 Layout Considerations**

**1.2.1 ISA Bus**

In a multi-layer PCB with good ground plane, there should be little risk of difficulty due to layout. However, if a 2 layer design is envisaged, a lot of care is required for the ground track routing. The AT/LANTIC drives 16 data lines (SD0-15) with fast high-current drivers. Ground routing should be arranged as a grid, so that there is a good return current path between the AT/LANTIC and all the ISA bus 0V connections.

**1.2.2 Twisted Pair (TPI)**

The length of tracks in the TPI circuit should be kept short and straight, and the lengths of the differential signal tracks

should be kept approximately equal. If using a multi-layer board, the power and ground planes should be removed in the area of the TPI to reduce capacitive coupling of noise from the power planes. The area should not have other signals passing through it. It may be desirable to have chassis ground used around the area of the connector to provide a shield for EMI noise radiation.

Tracks between the filter/isolation transformer and the RJ45 "telephone" socket should have an isolation barrier of at least 2mm to any other track or component.

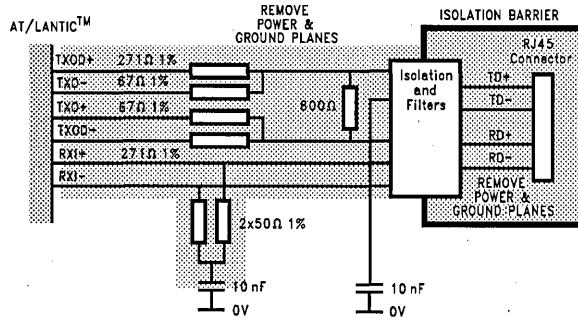

FIGURE 11. TPI Layout

TL/F/11850-11

**1.2.3 Attachment Unit Interface (AUI)**

Tracks should be kept short and straight where possible. The D-type shell (and the metal bracket it is fitted to) should be connected to digital ground via a 10 nF capacitor.

**1.2.4 Thin Ethernet (Coax)**

The DP8392C Coax Transceiver Interface should be placed close to the BNC connector, so that the connection between them is short. There should be no other tracks in this area, and on multi-layer PCBs the power and ground layers should be removed.

The DP8392CV requires an area of copper on the PCB surface to act as a heatsink. This is documented in the DP8392CV data sheet.

All the coax interface components between the isolation transformer and the BNC must be surrounded by an isolation barrier of at least 2mm, which must include the power and ground layers of a multi-layer PCB. The isolation transformer and the DC-DC converter bridge the isolation barrier, plus a resistor, a capacitor and a spark gap. On a multi-layer PCB the isolated power and ground planes should be used for VEE and ISOLATED\_GND.

FIGURE 12. Coax Layout

TL/F/11850-12

**1.2.5 PLL**

In order to improve performance of the receiver PLL, the PLL supply pin should be connected via a simple RC filter, located close to the AT/LANTIC PLLV<sub>CC</sub> pin.

TL/F/11850-13

**FIGURE 13. PLL Supply Decoupling**

**1.3 EEPROM Programming**

Initial values must be placed in the EEPROM before it can be used. The following table shows the EEPROM address map (all values in HEX):

Addr	Bits 15-8	Bits 7-0
00	Node Addr 1	Node Addr 0
01	Node Addr 3	Node Addr 2
02	Node Addr 5	Node Addr 4
03	Checksum	05 (8013 Type)
04	00 (Not Used)	00 (Not Used)
05	00 (Not Used)	00 (Not Used)
06	00 (Not Used)	00 (Not Used)
07	57 (ASCII "W")	57 (ASCII "W")
08	42 (ASCII "B")	42 (ASCII "B")
09	00 (Not Used)	00 (Not Used)
0A	00 (Not Used)	00 (Not Used)
0B	00 (Not Used)	00 (Not Used)
0C	00 (Not Used)	00 (Not Used)
0D	00 (Not Used)	00 (Not Used)
0E	Config B	Config A
0F	73H (Note 1)	Config C

**Note 1:** In initial documentation in the data sheet this byte was listed as having a value of FFH. In order to accommodate future expansion of features on the AT/LANTIC, this byte should be programmed with a 73H.

In a jumperless solution, Config A, B and C values must be set according to the default configuration, as discussed in Section 1.1.9.

Config A, B and C are ignored in a jumpered configuration. The Checksum is calculated so that the least significant byte of the sum of the first 8 bytes in the EEPROM is FF (hex).

i.e., ( Node Addr 0  
 + Node Addr 1  
 + Node Addr 2  
 + Node Addr 3  
 + Node Addr 4  
 + Node Addr 5  
 + 05  
 + Checksum ) and FFh = FFh

The Ethernet node address must be unique to each unit produced.

Note that only Config A, B and C bytes can be changed by user software.

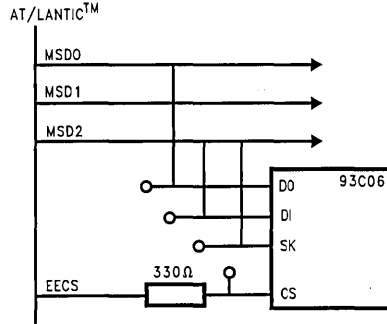

**How to Program the EEPROM**

The simplest way to program the EEPROM is before it is fitted into the PCB.

In some cases, however, it may be preferable to be able to program the EEPROM after board manufacture. This requires either a special programming connector on the PCB, or a "bed of nails" programming jig to access signals on the board. Additionally, a series resistor is required in the EECS signal between AT/LANTIC and the EEPROM.

To program the EEPROM, power must be applied to the PCB and the RESET pin must be forced high on AT/LANTIC. You can then apply the programming waveforms to the EEPROM.

Refer to the 93C06 data sheet for programming details.

TL/F/11850-14

**FIGURE 14. EEPROM In-Situ Programming**

**1.4 Additional End-User Requirements**

The end user may require some of the following items:

**1.4.1 Configuration Software**

If you are offering a jumperless solution, the user will require configuration software. National Semiconductor is able to offer source code for a configuration software package.

Configuration software is unnecessary for jumpered solutions.

**1.4.2 Driver Software**

You may wish to offer drivers with your solution. National Semiconductor offers a selection of drivers for popular network operating systems—contact your representative for the latest list. At the time of printing, National Semiconductor offers the following drivers:

- Novell Network ODI for DOS
- Novell Network ODI for OS/2
- Novell Network ODI for server
- NDIS 2.0
- NDIS 3.0 (available soon)
- SCO UNIX
- PC TCP Packet Driver

**1.4.3 Documentation (Installation Guide)**

We suggest that your documentation includes the following topics:

**Configuration**

If you have a jumpered solution, the user will have no software assistance, and you will have to document how to choose addresses and interrupts without causing conflicts, and how to set the jumpers.

In a jumperless solution, some assistance is given by the configuration program in determining addresses and interrupts currently in use. You will have to document how to run the software, and, for adapter cards, how to cope with installation into systems that require manual installation (for example, it may not be possible to detect I/O space usage if there are no pull-ups on the data bus).

### Bus Compatibility Modes

Some PC's use chip sets that have impossible timing requirements. If this is the case, the driver or configuration software tests will report a problem with the buffer RAM.

In machines with this timing problem, AT/LANTIC offers two "fixes". We recommend trying the "IO16" fix first. If that is not successful, use the "CHRDY" fix instead.

See Section 2.3.6 for a description of how these "fixes" work.

## SOFTWARE INSTALLATION

You may wish to describe how to install the configuration and driver software in a typical application.

## 2.0 REFERENCE INFORMATION

### 2.1 Architecture

#### 2.1.1 NIC Core

The AT/LANTIC controller contains a DP8390 NIC (Network Interface Controller) core. This controller was used as a discrete part on the NE2000 and WD Ethercard Plus adapter cards. The operation of the NIC core is fundamental to the NE2000, WD Plus and consequently the AT/LANTIC.

All packets transmitted and received are sent via a dedicated buffer memory. A "local" DMA controller within the NIC transfers the data between the buffer RAM and the NIC's serializer/deserializer. This approach means that there are no critical performance requirements placed on the host computer (i.e., the PC).

At initialization time, the network software (the driver) tells the NIC to reserve a section of the buffer RAM for receive packet data. Since packets may be received without warning, the receive buffer is usually as large as possible. The NIC uses the receive buffer as a cyclic buffer, and maintains hardware pointers to put data in the correct place and ensure that data not yet read by the host is not overwritten.

When transmitting a packet, the host places the data into the buffer RAM (not in the receive buffer area), and issues a transmit command to the NIC, specifying RAM start address and length.

The host may access the buffer RAM in one of two ways:

**Using the remote DMA channel:** The NIC has another DMA controller for host transfers. This allows the host to transfer a block of data to or from the buffer RAM by writing to or reading from a single data transfer port. The NE2000 adapter uses this technique. The data transfer port is I/O mapped, and this method is often called "I/O MODE".

**Memory mapped:** Alternatively, the buffer memory can be mapped into the host address space. This allows the host to directly access any buffer RAM location. Each access requires arbitration between the NIC and the host. This method is used by the WD Plus adapter, and is commonly referred to as "SHARED MEMORY MODE" because the memory is shared between the NIC and the host.

In the AT/LANTIC, all arbitration and handshaking is handled internally for both I/O and Shared Memory modes.

### 2.1.2 NE2000

The key features of the NE2000 are:

1. The NIC registers and the data transfer port are I/O mapped on the ISA bus.
2. The boot PROM is memory mapped on the ISA bus.
3. There is an Ethernet address PROM mapped onto the NIC buffer RAM bus. The PROM is 32 bytes, but only 16 bytes can be read. Which 16 bytes depends on whether the card is in an 8- or 16-bit slot.

In the AT/LANTIC, the Ethernet address PROM is implemented as registers, which are loaded at reset from the EEPROM.

### 2.1.3 Shared Memory Mode

The key features of the shared memory mode are:

1. NIC core and "shared memory control registers" are I/O mapped on the ISA bus.
2. A PROM containing Ethernet address is also I/O mapped on the ISA bus.
3. Buffer memory is memory mapped on the ISA bus at an address determined by the "shared memory control registers".
4. The boot PROM is memory mapped on the ISA bus.

In the AT/LANTIC, the Ethernet address PROM is implemented as registers, which are loaded at reset from the EEPROM.

It should be noted that although the shared memory mode is hardware compatible with the WD Plus architecture, drivers written by WD/SMC check for a specific IEEE address range before enabling the driver.

## 2.2 Memory and I/O Maps

Please refer to Section 5 of the AT/LANTIC data sheet for details of how to use the registers shown here.

### 2.2.1 NE2000 8-Bit and 16-Bit

The ISA I/O map comprises a block of 32 addresses which can be located at one of 7 base addresses (240h, 280h, 2C0h, 300h, 320h, 340h and 360h).

The NIC registers and reset port are BYTE wide.

The data transfer port is the same width as the interface.

TL/F/11850-15

The NIC buffer memory map varies according to the RAM size, and also the interface width as programmed into an NIC register. This register should be set according to whether the interface is 8- or 16-bit.

Note that an 8 bit interface can be either an 8-bit design or a 16-bit adapter in an 8-bit slot.

**8k x 8 RAMs, 16-Bit Interface**

Addr	
0000	PROM
001E	
0020	Aliases of PROM
3FFE	
4000	16 kbytes of Buffer RAM

8000	Alias of 0000 to 7FFE
FFFE	

**8k x 8 RAMs, 8-Bit Interface**

Addr	
0000	PROM
001F	
0020	Aliases of PROM
3FFF	
4000	8 kbytes of Buffer RAM
5FFF	
6000	Alias of Buffer RAM
7FFF	
8000	Alias of 0000 to 7FFF
FFFF	

**32k x 8 RAMs, 16-Bit Interface**

Addr	
0000	PROM
001E	
0020	Aliases of PROM
00FE	
0100	63.75 kbytes of Buffer RAM
FFFE	

**32k x 8 RAMs, 8-Bit Interface**

Addr	
0000	PROM
001F	
0020	Aliases of PROM
00FF	
0100	Alias of Buffer RAM
7FFF	
8000	32 kbytes of Buffer RAM
FFFF	

The PROM is always read-only.

In a 16-bit configuration, the PROM is arranged as follows:

Addr	D15-8	D7-0
00	Invalid	Node Addr 0
02	Invalid	Node Addr 1
04	Invalid	Node Addr 2
06	Invalid	Node Addr 3
08	Invalid	Node Addr 4
0A	Invalid	Node Addr 5
0C		
to	Invalid	00h
1A		
1C	Invalid	42h/57h*
1E	Invalid	42h/57h*

In an 8-bit configuration, the PROM is arranged as follows:

Addr	D7-0
00	Node Addr 0
01	Node Addr 0
02	Node Addr 1
03	Node Addr 1
04	Node Addr 2
05	Node Addr 2
06	Node Addr 3
07	Node Addr 3
08	Node Addr 4
09	Node Addr 4
0	Node Addr 5
0A	Node Addr 5
0C	
to	00h
1B	
1C	42h/57h*
1D	42h/57h*
1E	42h/57h*
1F	42h/57h*

\*The value found at PROM addresses 1C to 1F is determined by the logic level on the DWID pin:

- 42h ("B") if DWID = 0 8-bit (byte) interface
- 57h ("W") if DWID = 1 16-bit (word) interface

The NIC must be programmed for 8- or 16-bit operation before it is possible to read the PROM. It is therefore normal practice for software to set 8-bit mode and read the PROM using 8-bit I/O instructions in order that the actual bus size can be determined from the value at PROM address 1C-1F.

**2.2.2 Shared Memory Mode**

The ISA I/O map comprises a block of 32 addresses which can be located at one of 7 base addresses (240h, 280h, 2C0h, 300h, 320h, 340h and 360h).

All the registers are BYTE wide.

Addr	D7-0	
00	Control 1	
01	AT detect	(Read Only)
02	Unused	
03	Unused	
04	Unused	
05	Control 2	
06	Unused	
07	Unused	
08	Node Addr 0	(Read Only)
09	Node Addr 1	(Read Only)
0A	Node Addr 2	(Read Only)
0B	Node Addr 3	(Read Only)
0C	Node Addr 4	(Read Only)
0D	Node Addr 5	(Read Only)
0E	05h	(Read Only)
0F	Checksum	(Read Only)
10 to 1F	NIC registers	

The NIC buffer memory map varies according to the RAM size, and the bus width which is programmed into an NIC register. This should be set according to whether the interface is 8- or 16-bit. The bus size is detected by the hardware on the DWID pin. This information is available to software by reading the AT Detect register.

Note that an 8-bit interface can be either an 8-bit design or a 16-bit adapter in an 8-bit slot.

**2.3 ISA Bus Description**

This section is a brief tutorial for those unfamiliar with the ISA bus.

For the most part, the ISA bus should be considered asynchronous. There are two ISA bus address spaces: I/O and memory.

**2.3.1 I/O Cycles**

I/O cycles are generated when the CPU performs IN or OUT instructions. An I/O cycle is signalled on the bus by IORD (read) or IOWR (write) strobes being active (low). During IORD or IOWR cycles, the address is given on SA0-9. I/O devices must qualify the IORD or IOWR strobe with a valid address, and the AEN signal, which must be low.

FIGURE 15. I/O Read Cycle

FIGURE 16. I/O Write Cycle

**2.3.2 Memory Cycles**

Memory cycles are generated when the CPU performs MOV instructions. In most PC systems, memory accesses to system RAM are private to the motherboard and do not cause ISA bus activity.

Thus it is usual to only see accesses to devices on the ISA bus.

Similar to I/O cycles, memory cycles have memory read and write strobes. Unlike I/O cycles, however, there are two of each.

For an 8-bit adapter card, memory strobes SMRD and SMWR are used, together with address SA0-19. This allows the memory device to decode any address range in the bottom 1 Mbyte of the CPU address space. SMRD and SMWR strobes are not active for memory accesses above 1 Mbyte ( $\geq 100000h$ ).

For a 16-bit adapter, memory strobes MRD and MWR are used. These are active for memory accesses to any address. The adapter card must therefore additionally test address lines LA17-23.

FIGURE 17. Memory Read Cycle

FIGURE 18. Memory Write Cycle

**2.3.3 Cycle Timing**

For all cycles, the system will use a set of default timings. These vary according to whether the access is I/O or memory, and whether the adapter card is 8- or 16-bit.

Adaptor cards can extend any cycle beyond the default timing by driving the CHRDY (Channel Ready) signal to 0V (meaning not ready). The cycle will be extended until CHRDY is released. A pull up on the system board pulls CHRDY high again—adapter cards are not allowed to drive it high.

FIGURE 19. Extended ISA Cycle

Some cycles can also be shortened by adapter cards by driving a signal OWS low. This signal is not used by AT/LANTIC.

**2.3.4 8-Bit and 16-Bit Cycles**

For all cycles, the system will assume that an 8-bit device is being accessed. If a 16-bit transfer is requested by the CPU, the system will automatically convert it into two 8-bit cycles. When a 16-bit device is accessed, it informs the system of its presence, so that the data can be transferred in one cycle.

Timing requirements for memory accesses mean that the system needs to know the size of the device being accessed (8- or 16-bits) before the strobe is asserted. At this time, the device does not know whether the address corresponds to I/O or memory space. The ISA bus therefore uses two signals to indicate that a device is 16 bits: IO16 and M16.

IO16 is driven low by a device that detects an address on SA0-9 according to a word I/O port.

FIGURE 20. IO16 Cycle

M16 is driven low by a device that detects a valid address on LA17-23 for 16-bit memory. LA17-23 are unlatched address lines that are valid earlier than SA0-19. They become invalid before the end of the cycle. M16 is latched by the system. The device is required to latch LA17-23 for use by its address decoder. The BALE signal should be used as the latch enable for the LA address latch.

FIGURE 21. M16 Cycle

The size of the system transfer is indicated on signals SA0 and SBHE:

SA0	SBHE	
L	H	Byte transfer, even address
H	L	Byte transfer, odd address
L	L	Word transfer
H	H	Not used

SBHE has the same timing as SA0-19.

**2.3.5 DMA and Refresh Cycles**

DMA cycles are direct transfers between an I/O port and memory. One I/O strobe and one memory strobe are used together for the cycle. The I/O device is selected by one of 7 DACK signals. The memory device is selected by the LA17-23 and SA0-19 address lines. In order that the I/O device corresponding to SA0-9 does not respond, the AEN signal is driven high; I/O devices are only allowed to respond if AEN is low. ISA DMA is not used by AT/LANTIC.

Refresh cycles occur every 15.6  $\mu$ s. They are similar to memory read cycles, except that the REFRESH signal is active. Refresh is not used by AT/LANTIC.

**2.3.6 Bus Timing Compatibility Modes**

In some PCs using certain chipsets, the timing requirement for an adapter card to drive CHRDY from receiving an active IORD or IOWD is impossible to meet. The consequence is that the ISA bus completes the cycle even though the AT/LANTIC requires more time. AT/LANTIC incorporates logic to detect this condition, and has two ways of overcoming the problem.

If the condition occurs, configuration register B bit 5 "BE" is set to "1". This can be used by software to warn that a fix is required.

The two timing change modes are:

**IO16 Mode**

The problem only occurs for 16-bit cycles. IO16 is normally asserted whenever the address SA0-9 is valid. By additionally requiring that IORD or IOWR is asserted before IO16 is driven low, the offending chipsets are fooled into accepting 8-bit timing for CHRDY, while still transferring 16-bits correctly.

**FIGURE 22. IO16 Timing Change Mode**

**CHRDY Mode**

It is possible to drive CHRDY low early, qualified by SA0-9 and AEN without IORD or IOWR. If a valid address is present, and AT/LANTIC requires a longer-than-default cycle, this circuit starts driving CHRDY low as soon as BALE is active. If, at any time, MRD or MWR memory strobes become asserted, then CHRDY is released immediately. Otherwise, CHRDY is held low until the next falling edge of ISACKL after BALE has gone low. In a typical system, this clock edge is immediately followed by IORD or IOWR being asserted. The small "gap" between ISACKL and IORD or IOWR will not normally be long enough for CHRDY to be pulled high by the pull-up resistor.

**FIGURE 23. CHRDY Fix**

**2.4 Boot PROM**

The boot PROM interface uses the AT/LANTIC to decode the ISA address, and to provide data bus drivers onto the ISA bus. Because the PROM data is connected to the NIC memory support data bus, arbitration is required to access the PROM. The boot PROM is not mapped onto the NIC memory map.

If the MSWR signal is connected, a FLASH boot PROM can be used, allowing in-situ programming or updating.

If the PROM is read-only, the configuration register B bit 6 "BPWR" should be set to "0" to prevent bus contention if write cycles are attempted.

The boot PROM appears as an 8-bit device, regardless of the size of the interface. However there is a special case where it will not work properly. When emulating a WD Plus adapter, AT/LANTIC uses 16-bit wide buffer RAM, which it declares as 16-bit to the ISA bus by driving M16 low. The decode logic for M16 uses only LA17-23, i.e., a 128 kbyte region—this is an ISA bus limitation. If the boot PROM and the buffer memory are placed within the same 128 kbyte region, the boot PROM will appear to the ISA bus as a 16-bit device. Since the PROM can only produce 8-bits of data, it will fail.

Boot PROMs can be written to overcome this problem by first copying the PROM contents to system memory, and then executing from the copy instead. The PROM therefore need not be accessed at the same time as the shared RAM is enabled.

**2.5 Boot PROM and RAM Timing Calculations**

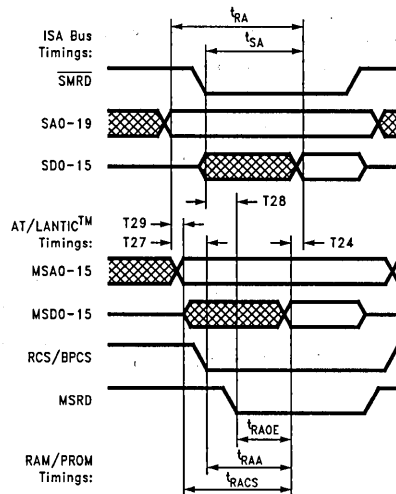

Boot PROM timings are derived from the ISA bus timings minus AT/LANTIC propagation delays.

RAM timings are the worst case of two situations: ISA bus accesses, similar to the Boot PROM, and AT/LANTIC DMA channel accesses.

For 8-bit cards, 8-bit ISA timings should be used for both RAM and boot PROM.

For 16-bit cards, 16-bit ISA timings should be used for the buffer RAM, and 8-bit timings should be used for the boot PROM.

**2.5.1 Boot PROM/RAM ISA Read Timing**

**FIGURE 24. Boot PROM/RAM ISA Read**

Access time from OE:

$$t_{RAOE} = t_{RA} \text{ min} - T28\text{max} - T24\text{max}$$

Access time from address:

$$t_{RAA} = t_{SA} \text{ min} - T29\text{max} - T24\text{max}$$

Access time from CS:

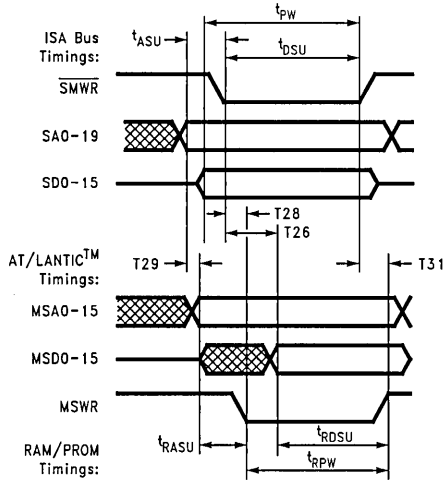

$$t_{RACS} = t_{SA} \text{ min} - T27\text{max} - T24\text{max}$$

For a typical 8 MHz ISA bus:

$$t_{RA} \text{ min} = 480 \text{ ns (8 bit) or } 160 \text{ ns (16 bit),}$$

$$t_{SA} \text{ min} = 570 \text{ ns (8 bit) or } 200 \text{ ns (16 bit).}$$

**2.5.2 Boot PROM/RAM ISA Write Timing**

TL/F/11850-26

**FIGURE 25. Boot PROM/RAM ISA Write**

Address setup time:

$$t_{RASU} = t_{ASU} \text{ min} + t28\text{min} - T29\text{max}$$

Data setup time:

$$t_{RDSU} = t_{DSU} \text{ min} + t31 \text{ min} - T26\text{max}$$

Write pulse width:

$$t_{RPW} = t_{PW} \text{ min} + t31 \text{ min} - T28\text{max}$$

For a typical 8 MHz ISA bus:

$$t_{RASU} \text{ min} = 90 \text{ ns (8 bit) or } 28 \text{ ns (16 bit),}$$

$$t_{RPW} \text{ min} = 530 \text{ ns (8 bit) or } 154 \text{ ns (16 bit),}$$

$$t_{RDSU} \text{ min} = 470 \text{ ns (8 bit) or } 105 \text{ ns (16 bit).}$$

**2.5.3 RAM DMA Timing**

These timings are given in the AT/LANTIC data sheet Section 8, under "I/O port or FIFO transfers".

$$t_{RAOE} = T3 - T7,$$

$$t_{RAA} = T2 + T3 - T7,$$

$$t_{RACS} = T4 - T7,$$

$$t_{RASU} = T2,$$

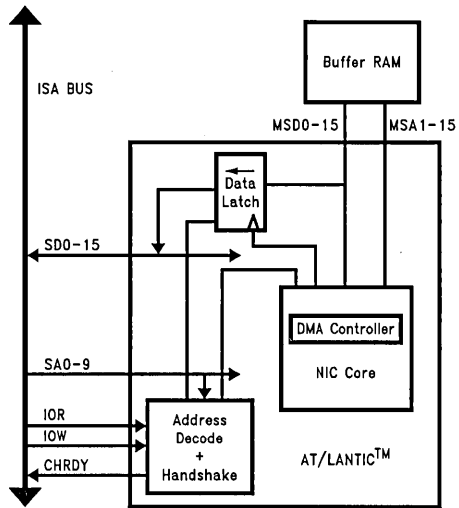

$$t_{RDSU} = T9,$$

$$t_{RPW} = T3$$

**2.6 Fast Read Feature**

This is a feature designed into AT/LANTIC to improve the performance of the remote DMA channel in NE2000 mode. The actual performance measured will depend on the platform that AT/LANTIC is used with, and the test configuration used.

The architecture of the remote DMA channel is as shown:

TL/F/11850-27

**FIGURE 26. Remote DMA Controller**

When the remote DMA read is started, by I/O writes to the NIC remote DMA controller, the buffer RAM is accessed at the first address and the data is latched in the data transfer latch. The PC then reads this data over the ISA bus. At the end of the IORD strobe, the DMA controller fetches data from the next RAM address and latches it into the latch. Hardware handshake logic prevents the PC from completing a read cycle until the data is ready.

TL/F/11850-28

**FIGURE 27. Remote DMA Read Timing**

The request for more data from the DMA controller is not made until the end of the IORD strobe. When fast read operation is enabled, the request for more data is made as soon as CHRDY is released, before the end of the IORD. For cycles that do not require CHRDY, i.e. the data is already in the latch, more data is requested at the start of the IORD strobe.

**FIGURE 28. Fast Read Remote DMA Timing**

There is a danger, in very slow machines, that the new data will be latched into the data transfer latch before the end of the current IORD cycle. For this reason, Fast Read is not recommended for 8-bit systems.

The NIC core is specified to take a minimum of 11 clocks between data being requested and the latch being updated. A typical system with an NIC core clock of 20 MHz will therefore take at least 550 ns. Fast Read mode is safe in any system where the IORD strobe width, or the CHRDY to IORD high delay does not exceed 550ns.

## 2.7 Reset Operation

AT/LANTIC has different degrees of RESET according to the duration of the RESET pulse. The pulse width is measured by counting X1 clocks (20 MHz), so the timing period can only begin after the oscillator has started.

In order to prevent noise problems, a RESET pulse of less than 350 ns will be ignored. The RESET pulse must be at least 400 ns to be guaranteed to be recognized.

A RESET pulse of at least 400 ns will reset the internal logic, including the 8390 NIC core, and will tristate all I/O pins. A 60k pull down will be enabled for each configuration pin MSD0-15 and MSA1-8.

If the RESET pulse is more than 400 ns long, configuration data and Ethernet node address will be loaded. The load sequence begins when RESET goes low, and can take up to 320  $\mu$ s. During this time, all ISA bus cycles are ignored.

# Layout Guidelines for an Ethernet Adapter Using the DP83907 AT/LANTIC™ II

National Semiconductor  
Application Note 973

AN-973

## OVERVIEW

This application outlines board layout and design considerations when using the DP83907.

## Board Design and Layout

In a multi-layer PCB with good ground and power planes, there should be little risk of noise problems due to layout. When designing a two-layer board special care is needed. The DP83907 drives 16 data lines (SD0-15) with fast high-current drivers that will cause ground bounce if proper care is not taken in laying out the VCC and GND lines. Ground routing should be arranged in a grid to ensure good return current paths between the DP83907 and all the ISA bus ground connections. Analog and Digital VCC and GND lines should not overlap to prevent crosstalk noise.

### 1.0 Crystal and Oscillator Design

Care should be taken when connecting a crystal. Stray capacitance (e.g., from PC board traces and plated-through holes around X1 and X2 pins) can shift the crystal's frequency out of range, causing the transmitted frequency to exceed the 0.01% tolerance specified by the IEEE. The crystal or oscillator layout should locate all components close to the X1 and X2 pins and should use short traces to avoid excess capacitance and inductance. When using a standard size crystal the crystal should be laid flat with power planes voided in that area. When using a low-profile crystal this is not necessary.

### 1.1 Decoupling for the DP83907

The DP83907 is composed of multiple functional blocks. The analog and digital functional blocks should be run on separate power rails.

Since the power supply pins on the DP83907 are all connected to the same 5V/0V supply in the ISA connector, noise from other slots in the system will be coupled to the power supply pins on the DP83907. This problem is particularly serious in two-layer boards having no separate power or ground planes. To minimize the impact, the DP83907 should be run on separate VCC and ground traces whenever possible. These traces should join near the PC ISA bus connector and be properly filtered.

The first area which requires attention is the switching on the DP83907's System Data (SD) bus. This bus provides high current drive, TRI-STATE®, fast rise and fall times and is a major noise contributor. The VCC pins which provide power to SD bus drivers and the GND pins which are the return path should be carefully decoupled to reduce the

noise. In order to reduce noise the power supply pins and the ground pins on the DP83907 should be decoupled by 0.1  $\mu$ F and 1000 pF capacitors, with the capacitors connected as close as possible to the chip and the plane.

FIGURE 1. Power and Ground Decoupling

This should be done on all the VCC and GND pairs which are pins 20-23, 26-27, 48-49, 35-32, 70-75, 103-100, 109-110. Exceptions are analog VCC and GND pins 40 and 41 which have different decoupling requirements and are discussed in Section 1.2.

The rest of the GND pins except for pin 41 (AGND) should be directly connected to the ground plane.

The second area where care must be taken is in isolation of "quiet" output and input signals from "noisy" output signals. In this regard, the SD outputs should be a minimum of a double space away from ANY other signal trace, preferably with a ground island in between. Similarly, the IRQ traces should be kept isolated from other signals.

Additionally, care must be taken to prevent fast control signals (IOCHRDY, IO16) causing crosstalk on sensitive inputs. To this end, IO16 must be separated by a double space from input signals (SA0, SA1 ...). In the case of IOCHRDY, the ground pin supplying IOCHRDY (pin 14) must be connected through a ferrite bead (26Z @ 100 MHz) and IOCHRDY must be separated from AEN by at LEAST a double space, preferably with an isolation ground island placed in between. This island should connect to 0V only at the edge connector.

These layout considerations have been taken into account in the latest DP83907EB-AT board design. Manufacturers must follow these recommendations in their design to avoid possible noise related problems.

FIGURE 2. Signal Isolation Detail View

TL/F/12334-4

### 1.2 PLL Power Supply Noise

In order to improve the performance of the PLL, a single pole filter should be used on the PLL power supply pin. This is shown on *Figure 3*.

FIGURE 3. PLL  $V_{CC}$  Noise Filter

TL/F/12334-2

### 1.3 PC ISA Bus Interface

Decoupling of noise from the ISA Bus power supply is achieved using 0.1  $\mu\text{F}$ , 100 pF and 22  $\mu\text{F}$  capacitors (used to filter out lower frequency noise in the order of a few kHz). All these three capacitors are placed near the ISA bus connector. This is done for both power supplies of the ISA bus.

*Care should also be taken to place the DP83907 as close to the edge connector as possible, with the aim of keeping the ground tracks to a minimum length.*

### 1.4 Attachment Unit Interface

The AUI signals are differential signals. Each pair of these differential signals should be routed in adjacent channels. The traces should go as straight as possible and avoid forming loops to minimize the potential of magnetic coupling. It is not necessary to void the power plane under them.

### 1.5 Twisted Pair Interface

The transmit signals should be of the same length and as close as possible. These signals are TXOD+, TXOD-, TXO+ and TXO-.

The receive signals should also be of the same length and as close as possible.

The transmit and receive signals should be kept away from each other.

The resistors should be directly tied between the RTX and REQ pins to TPVCC or TPGND.

### 1.6 Coaxial Transceiver Interface (CTI)

The Coax Transceiver Interface (DP8392CN) should be placed very close to the BNC connector. This will allow the TXO/RXI trace to be short and straight. The area under these traces should be voided of all other signal and power planes (as shown in *Figure 4*) in order to meet the IEEE 802.3 input capacitance requirements. The BNC connector on the evaluation board is a standard part, however, "quiet" connectors are readily available for better noise figures and FCC qualification. The CTI requires an area of copper for heat dissipation. This is also shown in *Figure 4* and is documented in the DP8392C data sheet. The ground shield of the BNC connector and coax cable are resistively and capacitively decoupled to chassis ground. There is a chassis ground strip on each layer of the board. This is connected to the chassis of the PC through the 15-pin AUI connector's metal body. Chassis ground is then capacitively decoupled to digital ground through capacitors. The chassis ground trace along the front of the board forms a "shield" so that noise is not emitted into or received from the environment.

TL/F/12334-3

FIGURE 4. DP83907EB-AT CTI Layout Diagram

### 1.7 FCC Considerations

For applications requiring FCC class B certification it is strongly recommended that the existing BNC connector be replaced with a *filtered* BNC connector and capacitors C45 and C54 removed.

A filtered BNC connector similar to p/n 413515 from AMP incorporated or p/n 456-117 from Amphenol Corp. (or equivalent) will suffice.

### 1.0 INTRODUCTION

The DP83907 AT/LANTIC II Evaluation Board provides system designers a simple method of interfacing PC ISA (Industry Standard Architecture) bus based system to Ethernet. This Evaluation board provides complete 16-bit 10 Base-T, 10Base2 and 10Base5 Ethernet solutions in a half-size jumperless ISA adapter card. It is IEEE 802.3 compliant and NE2000/NE2000Plus I/O mode compatible.

Built into the DP83907 is an Ethernet Media Access Control unit, a Manchester Encoder/Decoder, Twisted Pair Transceiver, an AUI, ISA bus, EEPROM and SRAM interfaces. It uses the EEPROM to store the board's configuration and IEEE node address and two 8kx8 SRAMs to buffer transmit and receive packets. The 10Base2 network interface is implemented with the addition of a 1:1 pulse transformer, a DC-DC Converter and a DP8392 Coaxial Transceiver Interface (CTI). Refer to the block diagram in *Figure 1*.

#### About This Guide

This guide describes the DP83907 AT/LANTIC™ II Evaluation Board and the underlying hardware design considerations

### 2.0 EVALUATION BOARD FEATURES

- Designed with the DP83907.
- Jumper-less design.
- Half-size PC AT adapter card.
- NE2000 / NE2000Plus I/O mode compatible.
- 10Base2 connectivity.
- 16 kByte SRAM packet buffer.
- Serial EEPROM stores the board's configuration and IEEE node address.
- Serial EEPROM can be programmed in-situ.
- Boot ROM socket to allow disk-less boot from NetWare, Lan Manager and other network operating systems.
- 8 interrupts.
- Status LEDs for transmit, receive and collision.

FIGURE 1. DP83907EB Block Diagram

TL/F/12335-1

**3.0 HARDWARE DESIGN CONSIDERATIONS**

This section describes the signal interfaces with the DP83907 in designing this Evaluation Board.

**3.1 Crystal and Oscillator**

The DP83907 has been designed to operate with either a crystal or an oscillator module. The Evaluation Board comes assembled with the crystal option. The crystal should conform to the following specifications.

- AT cut parallel resonance crystal
- Series resistance  $\leq 40\ \Omega$
- Specified load capacitance  $\leq 20\ \text{pF}$
- Accuracy: 50 ppm
- Typical load:  $50\ \mu\text{W} - 75\ \mu\text{W}$

Note, the X2 pin is not guaranteed to provide a TTL compatible logic output and should not be used to drive external logic.

FIGURE 2. Crystal Circuit

If an oscillator module is used, its output should be connected directly to X1, while X2 is left unconnected. The load capacitors should not be used. The oscillator clock should be :

- TTL or CMOS output with a 0.01% freq. tolerance
- 40%–60% duty cycle

**3.2 ISA Bus Interface**

The DP83907EB can be used in 8- or 16-bit ISA slots. 8- or 16-bit mode is determined by MSA9 at reset. For an adapter card this pin can be used to automatically detect if the card has been plugged into an 8- or 16-bit slot by connecting MSA9 via a 10 k $\Omega$  pull-up resistor to V<sub>CC</sub>. When connected to a 16-bit slot MSA9 will be pulled high enabling 16-bit mode. When plugged into an 8-bit slot, MSA9 will be floating enabling 8-bit mode.

For applications requiring 8-bit only interface, MSA9, SD8-15, /IO16 should be left open.

**3.3 Memory Support Interface**

The Memory Support Interface is used by the DP83907's local DMA and auto-configuration. This includes the SRAMs and the EEPROM. Figure 1 shows how the SRAMs and EEPROM are connected to the Memory Support Bus.

On power up, MSA10 must be pulled high to load the EEPROM contents to its internal registers and make them accessible by software. The two 8kx8 SRAMs are used as receive and transmit packet buffers during network data exchanges.

**3.3.1 Buffer SRAM**

The two SRAMs provide 8k words (16-bit) of memory for the DP83907 to buffer received and transmit packets. For an 8-bit-only interface, only one SRAM is needed with the data bus connected to MSD0-7.

For a standard ISA bus configuration, 100 ns SRAMs or faster should be used. Details of how to calculate SRAM speeds can be found in Ref. [3].

**3.3.2 EEPROM**

The DP83907 uses its EECS and MSD0-2 pins for accessing the serial EEPROM (NM93C06). MSD0-2 serve as DO, DI, and SK respectively.

The EEPROM is normally read automatically upon power-on reset. One can modify its content by software thereafter.

There is a possibility that a randomly programmed EEPROM may cause the host system to hang. If this happens, Jumper J2 can be installed (MSA10 pin pulled to GND). This will disable the EEPROM from loading and the DP83907 will initialize to the default settings. The EEPROM can then be correctly programmed by either of the two methods described in section 3.6.2.

**3.4 Boot ROM**

A boot ROM allows the PC to load the operating system from a server on the network without needing a disk drive on the PC (Diskless Workstation). Boot ROMs are available from network operating system vendors or from third parties.

The DP83907EB is supplied with an empty boot ROM socket. Boot ROM sizes of 8kB, 32kB and 64kB are supported. It can be located at particular addresses between C0000h and DFFFFh by programming configuration register C bits 0-3 "BPS0-3". For addresses refer to Reference [1].

The boot ROM address lines must be connected directly to the ISA Bus.

The boot ROM data lines are connected to the DP83907's MSD bus. When the system reads within the selected memory area, the DP83907 reads the data in through MSD0-7 and drives it onto the system data bus. The DP83907 supplies the chip select to the device. See *Figure 3*.

For a standard ISA bus configuration a 250ns ROM or faster should be used. Details of how to calculate boot ROM speeds can be found in Reference [3].

**3.5 Interrupt and Status LEDs**

There are eight interrupt request pins on the DP83907, namely IRQ3-5, IRQ9-12 and IRQ15. The operation of these outputs are determined by configuration register A. The DP83907 has only one Interrupt mode. Configuration Register A controls which one of the 8 interrupt lines will be driven, the others are TRI-STATED. The interrupt outputs should be connected to the following ISA interrupt lines, in the order given, to maintain NE2000 Architecture compatibility: 3, 4, 5, 9, 10, 11, 12 and 15.

**Table I. Direct Drive Interrupt Assignment**

DP83907	ISA Bus
IRQ3	IRQ3
IRQ4	IRQ4
IRQ5	IRQ5
IRQ9	IRQ9
IRQ10	IRQ10
IRQ11	IRQ11
IRQ12	IRQ12
IRQ15	IRQ15

The configuration register A is used for interrupt selection. Bits 3, 4, 5 are set in the following manner for different interrupt lines:

**Table II. Output Interrupt Assignment**

DP83907			ISA Bus
5	4	3	IRQs
INT2	INT1	INT0	IRQs
0	0	0	IRQ 3
0	0	1	IRQ 4
0	1	0	IRQ 5
0	1	1	IRQ 9
1	0	0	IRQ 10
1	0	1	IRQ 11
1	1	0	IRQ 12
1	1	1	IRQ 15

**Status LEDs**

These pins are open-drain, active low outputs and serve as ACT\_LED, GDLNK\_LED and COL\_LED respectively. The maximum sinking current of these outputs are 24 mA. The current limiting resistors should be chosen so that this requirement is not violated. The LED circuit of the DP83907EB is shown in *Figure 5*.

**FIGURE 3. Boot ROM Interface**

TL/F/12335-3

FIGURE 5. LED Circuit

TL/F/12335-4

**3.6 Configuration**

The DP83907 has three configuration registers A, B and C; one signature register and a PROM store register array. All these registers must be properly initialized before the DP83907 can be operational. Table 3-5 may assist you in this task. Note that a full description is given in Reference [1].

**Table III. Configuration Registers**

Config A Register

Bit	Symbol	Use
0-2	IOAD0-2	Select IO address
3-5	INT0-2	Interrupt
6	FRd/Wr	Fast read/write
7	RES	Reserved (must be zero)

Config B Register

Bit	Symbol	Use
0-1	PHYS0- PHYS1	Physical Layer Interface
2	GDLINK	GOOD LINK
3	IO16CON	IO16 bug fix enable
4	RES	Reserved (must be zero)
5	BE	Bus Error Status
6	BPWR	BOOT PROM Write
7	EELOAD	Enable Loading EEPROM

Config C Register

Bit	Symbol	Use
0-3	BPS0-3	Boot ROM addr and size
4	RES	Reserved (must be zero)
5	RES	Reserved (must be one)
6	RES	Reserved (must be zero)
7	SOFEN	Config Reg Access Disable

**Table IV. Signature Register**

Bit	Symbol	Use
0-3	REV0-3	DP83907 Identity (1000)
4	EEPR	Enable EEPROM In-situ Program
5-7	SIG5-7	Board Revision (Note 1)

**Note 1.** This reflects the trapping state of MSA11-13, which can be fixed by manufacturers for board revision identification.

**3.6.1 Default Configuration**

During power-on reset, the DP83907 loads configuration registers A, B and C and bits 5-7 of the signature register from the memory support bus. Subsequently, the DP83907 reads the first 7 words from the EEPROM and maps them into its PROM store. If in 16-bit mode (MSA9 sampled high on power-on reset), it also reads the next word in the EEPROM and appends this. If in 8-bit mode (MSA9 floating), it skips a word, then reads and appends the next word. Mapping from the EEPROM onto the PROM store is shown in the DP83907 data sheet. The EEPROM should be programmed according to Table 5 for NE2000/P<sub>lus</sub> compatibility.

If the MSA10 pin is sensed high, the last two words of the EEPROM are also loaded. Configuration registers A, B and C are re-initialized with the EEPROM content. Hence, a jumper-less solution can be achieved. If the last byte read from EEPROM is 73H, programming in-situ is not allowed. Section 3.6.2 will elaborate more on this.

**Table V. EEPROM CONTENTS (NM93C46/NM93C06)**

	D15	D0
0FH	73H	Config Reg. C
3FH (Note 1)		
0EH	Config Reg. B	Config Reg. A
3EH (Note 1)		
09H-0DH	Not used	Not used
08H	42H	42H
07H	57H	57H
06H	Not used	SUM (Note 2)
05H	Driver ID (Note 3)	0DH
04H	H/W Feature (Note 4)	00H
03H	00H	00H
02H	E'net Addr 5	E'net Addr 4
01H	E'net Addr 3	E'net Addr 2
00H	E'net Addr 1	E'net Addr 0

**Note 1.** If an NM93C46 EEPROM is used then addresses 0FH and 0EH need to be changed to 3FH and 3EH respectively.

**Note 2.** This field contains the sum of the first 6 words (00H-05H).

**Note 3.** Novell Driver ID is 01H.

**Note 4.** This field contains the hardware features of the physical media. The bit 0, 1, 2 should be set respectively for the twisted-pair, thin Ethernet and thick Ethernet.

**3.6.2 Configuration Modification**

For an implementation using jumpers, one can change the jumper setting on the DP83907's memory support bus. This will effectively modify the DP83907's configuration upon power up.

For a jumper-less solution one can program the DP83907's configuration registers A, B and C. Special procedures must be followed as listed in Table 6.

**Table VI. Config Registers Access**

Configuration Registers	Read/Write Requirements	
	Read	Write
A	Page 0 of NIC's registers selected	Preceded by a read on Config A
B	Page 0 of NIC's registers selected	Preceded by a read on Config B
C	Page 0 of NIC's registers selected by 3rd consecutive read of Config A	Preceded by 3rd consecutive read of Config A

To make it a permanent change, one must write the new configuration into the EEPROM. It can be done by either of the two methods described below.

**(1) Indirect Write to EEPROM**

Three bytes of the EEPROM, storing configuration registers A, B and C values, can be modified by a special pseudo code. EELOAD acts as load enable and must be set to one. The DP83907 serializes the data and writes them into the EEPROM. The EELOAD bit (Bit 7 of configuration register B) will be reset by the DP83907 when it completes the load EEPROM operation. It has full control on all the interface signals EECS, DI and SK. Note that this algorithm does not change the configuration registers directly, i.e., the new state only appears on the next power up.

**EEPROM-LOAD ( )**

```

{
    Disable Interrupts( );
    Value = Read(Config_B);
    Value = Value AND GDLINK
    Value = Value OR EELOAD
    Write(Config_B, Value)
    Read(Config_B)
    Write(Config_B, Config_for_A)
    Write(Config_B, Config_for_B)
    Write(Config_B, Config_for_C)
    While(Value AND EELOAD)
    {
        Value = Read(Config_B)
        Wait( );
    }
    Enable Interrupt( )
}

```

In the pseudo code above, interrupt is disabled, GDLINK bit preserved, and the EELOAD bit of configuration B serves as load enable.

**(2) In-situ EEPROM programming**

If the uppermost byte of the EEPROM does not contain 73H, the EEPR bit of the signature register will be zero, and the entire content of the EEPROM can be modified.

One must first set the EELOAD bit (load enable), and subsequent writes to the data transfer port will have SD1-3 driven onto the EECS, SK and DI pins, allowing users to have full control on writing to the EEPROM.

Similar to the previous case, one must apply a power-on reset for the DP83907 to load the new configuration data from the EEPROM.

With in-situ programmability, manufacturers do not have to pre-program the EEPROM before board assembly. It also provides much more flexibility because the entire EEPROM content can be modified at will.

By programming 73H to the uppermost byte, the EEPROM is protected from further changes, except for configuration register A, B and C, which can still be changed with an indirect write to the EEPROM.

**3.6.3 IO16 mode**

In some PCs using certain chip sets, the timing requirements in 16-bit I/O cycle cannot be achieved by the DP83907. As a consequence the host system does not recognize the CHRDY signal and does not insert wait states. The system executes a standard 16-bit cycle and deasserts  $\overline{IORD}$  or  $\overline{IOWR}$  even if the DP83907 is not ready. The DP83907 incorporates logic to detect this condition, Configuration register B bit 5 "BE" is set to "1" if the condition is detected. This can be used by software to warn the user that a fix is required.

By setting bit 3 of configuration register B, the DP83907 enters IO16 mode. It generates  $\overline{IO16}$  after  $\overline{IORD}$  or  $\overline{IOWR}$ . The offending chip sets are fooled into accepting 8-bit timing for CHRDY, while still transferring 16 bits correctly.

**3.6.4 Jumperless Operation Support**

One of the biggest problems in installing new adapters in a PC is not knowing the available resources within that machine. The DP83907 software configuration overcomes that problem. The conflicts possible in the I/O base selection can be overcome by a special mode for software configuration of the I/O base address. By using this mode, and by using the configuration storage capability of the EEPROM, a fully software configurable design on the ISA bus can be realized without address conflict problems.

This mode is invoked by having the DP83907 default to jumper-less software configuration option in the I/O base selection. This mode enables configuration register A to be mapped to address location 278H which is defined to be a printer port's data register. If software writes to this location four consecutive times, on the fourth write the DP83907 will load the data written into the I/O address bits of Configuration Register A. This data should set the I/O base address to a known conflict-free value. The DP83907 can now be configured and operated at the desired base I/O address. If desired, the configuration software could change the EEPROM content to the new values eliminating the need to reconfigure upon each power up. Alternately the software could leave the EEPROM alone and execute the configuration using the printer port's data register upon each power up. This configuration scheme will only work once after each power-up. Therefore the user can not enable the DP83907 from reserved mode, change it back into reserved mode and enable it again. A power-on reset must occur between the first time it is enabled from the reserved mode and the second.

### 3.7 Twisted Pair Interface (TPI)

The Twisted Pair interface is simple, it requires components external to the DP83907 which are pre-emphasis resistors, some capacitors and a transformer/filter module.

#### 3.7.1 ON-CHIP Filters

The on-chip filters are enabled via an external pull-up resistors on MSD12 at configuration. Only an isolation transformer and a few impedance matching resistors are needed for the transmit and receive twisted pair interface.

#### 3.7.2 RTX Resistor

In on-chip filter mode, the value of TPI VOD when measured driving a  $100\Omega$  load may not meet the IEEE-802.3 specification over temperature and process without the use of a resistor of RTX. This does not adversely affect system performance.

An R9 resistor value of  $82.5\text{ k}\Omega$  ( $\pm 1\%$ ) to  $V_{CC}$  is recommended.

- Increasing the value of this resistor will lower the value of VOD.
- Decreasing the value of this resistor will increase the value of VOD.

#### 3.7.3 Non Cat3 Cable

When using non-Cat3 cable such as type 9, 2 pair, 26AWG cable, the following modification is suggested to ensure optimum operating performance.

- Install a  $2200\text{ pF}$  ( $\pm 10\%$ ) capacitor across each  $10.5\Omega$  summing resistor, i.e., R11 and R13.
- Remove any R9 resistor.
- Install a  $24.3\text{ k}\Omega$  ( $\pm 1\%$ ) resistor from RTX to GND, i.e., R10.

### 3.8 Attachment Unit Interface (AUI)

The DP83907 can be used with external Medium Attachment Unit (MAU). The interface is via the 15-pin D-type connector and is a direct interface to the DP83907's ENDEC. The DP83907's ENDEC only requires  $39.2\Omega$  terminations on receive and collision inputs. The transmit outputs do not require any pull-down resistors.

#### 3.9 UTP/STP Function

The TPI Transceiver supports both shielded (STP) and unshielded twisted pair (UTP) cable. UTP is the default but STP can be enabled during configuration by a pull-up resistor on MSA7 or by setting bit D6 high of configuration register C. In UTP mode TXO+ and TXOD+ are driven and TXO- and TXOD- are TRI-STATED. In STP mode TXO- and TXOD- are driven and TXO+ and TXOD+ are TRI-STATED.

#### 3.10 AUTO-SWITCH Function

The auto-switch function can be enabled at configuration by pull-up resistor on MSA5 or by setting bit D4 high of the configuration register C. When auto-switch is enabled link integrity should also be enabled. It allows the transceiver to switch between TP and AUI outputs. If there is an absence of link pulses the transceiver will switch to AUI mode. Similarly when the transceiver starts detecting link pulses it will switch to TP mode. The switching between modes is done after the current packet has been transmitted or received. If the twisted pair output is jabbering and gets into link fail state then the switch to AUI mode is only done after the jabbering is done including the times it takes to unjab (unjab time). When auto-switching is enabled the THIN output is automatically generated if AUI is selected.

TL/F/12335-5

FIGURE 6. Circuitry to connect the DP83907 to Twisted pair cable with internal filter.

## 4.0 SOFTWARE SUPPORT

### 4.1 Configuration and Diagnostics Software

If you are offering a jumper-less solution, the user will require configuration software. The DP83907EB-AT comes with configuration and diagnostics software, called AT5CFG.

AT5CFG will detect and list all the boards installed in the system. The I/O address and interrupt assignment will also be shown. A warning message will appear if there is any conflict in resource allocation.

There are 2 options of saving a changed configuration. Saving a configuration temporarily will render the EEPROM unmodified. Once the system is powered up again the configuration will default to the original settings. Saving the configuration to the EEPROM will permanently store the configuration until another modification is made. The software enable bit (bit 7 of the configuration register C) must be zero for changing configuration register A, B and C by software.

The adapter initialization option will check to see whether a configurable board is present. If so, its configuration parameters will be read and displayed. Otherwise, an error message will be displayed. If the board is non-configurable, the user will be alerted by a warning message. The diagnostic option will do a simple test on cache, interrupt and buffer memory.

The advanced network diagnostic, "Ping Pong Test", can be run only after the board is initialized and passes the diagnostic test described above. Two stations are needed, one master and one slave. In order to test both transmit and receive logic, each station should be tested as a master and slave.

### 4.2 EEPROM in-situ Programming

The software called EEPROM is used to program the Evaluation Board's EEPROM in-situ. There is also a data file holding previous programmed data to facilitate repeated programming. An error message will be prompted if there is no DP83907 present or the programming in-situ feature has been disabled.

### 4.3 Driver Software

The DP83907 can use all NE2000 drivers and NE2000plus drivers in I/O mode only.

## Systems-Oriented Network Interface Controller with Twisted Pair Interface

### General Description

The SONIC-T (Systems-Oriented Network Interface Controller with Twisted Pair) is a second-generation Ethernet Controller designed to meet the demands of today's high-speed 32- and 16-bit systems. Its system interface operates with a high speed DMA that typically consumes less than 5% of the bus bandwidth. Selectable bus modes provide both big and little endian byte ordering and a clean interface to standard microprocessors. The linked-list buffer management system of SONIC-T offers maximum flexibility in a variety of environments from PC-oriented adapters to high-speed motherboard designs. Furthermore, the SONIC-T integrates a fully-compatible IEEE 802.3 Encoder/Decoder (ENDEC) and a Twisted Pair Interface which provide a one-chip solution for Ethernet when using 10BASE-T. When using 10BASE2 or 10BASE5, the SONIC-T may be paired with the DP8392 Coaxial Transceiver Interface to achieve a simple 2-chip solution.

For increased performance, the SONIC-T implements a unique buffer management scheme to efficiently process receive and transmit packets in system memory. No intermediate packet copy is necessary. The receive buffer management uses three areas in memory for (1) allocating additional resources, (2) indicating status information, and (3) buffering packet data. During reception, the SONIC-T stores packets in the buffer area, then indicates receive status and control information in the descriptor area. The system allocates more memory resources to the SONIC-T by adding

descriptors to the memory resource area. The transmit buffer management uses two areas in memory:

1. indicating status and control information;
2. fetching packet data.

The system can create a transmit queue allowing multiple packets to be transmitted from a single transmit command. The packet data can reside on any arbitrary byte boundary and can exist in several non-contiguous locations.

### Features

- 32-bit non-multiplexed address and data bus
- Auto AUI/TPI selection
- High-speed interruptible DMA
- Linked-list buffer management maximizes flexibility
- Two independent 32-byte transmit and receive FIFOs
- Bus compatibility for all standard microprocessors
- Supports big and little endian formats
- Integrated IEEE 802.3 ENDEC
- Integrated Twisted Pair Interface
- Complete address filtering for up to 16 physical and/or multicast addresses
- 32-bit general-purpose timer
- Loopback diagnostics
- Fabricated in low-power CMOS
- 160 PQFP package
- Full network management facilities support the 802.3 layer management standard
- Integrated support for bridge and repeater applications

## 2.0 Pin Description

I = Input  
 O = Output  
 Z = TRI-STATE® Input, TTL compatible  
 ECL = Emitter Coupled Logic type drivers for interfacing to the Attachment Unit Interface.  
 TP = Totem Pole type drivers. These drivers are driven either high or low and are always driven. Drive levels are CMOS compatible.

TRI = TRI-STATE drivers. These pins are driven high, low or TRI-STATE. Drive levels are CMOS compatible. These pins may also be inputs (depending on the pin).  
 OC = Open Collector type drivers. These drivers are TRI-STATE when inactive and are driven low when active. These pins may also be inputs (depending on the pin).  
 TPI = Twisted Pair Interface.  
 Pin names which contain a "/" indicate dual function pins.

TABLE 2-1. Pin Description

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS</b>			
EXT		I	<b>EXTERNAL ENDEC SELECT:</b> Tying this pin to $V_{CC}$ (EXT = 1) disables the internal ENDEC and allows an external ENDEC to be used. Tying this pin to ground (EXT = 0) enables the internal ENDEC. This pin must be tied either to $V_{CC}$ or ground. Note the alternate pin definitions for CRS <sub>o</sub> /CRS <sub>i</sub> , COL <sub>o</sub> /COL <sub>i</sub> , RXD <sub>o</sub> /RXD <sub>i</sub> , RXCo/RXC <sub>i</sub> , and TXCo/TXC <sub>i</sub> . When EXT = 0 the first pin definition is used and when EXT = 1 the second pin definition is used.
AUI/TP		I	<b>ATTACHMENT UNIT INTERFACE (AUI)/TWISTED PAIR (TP) SELECT:</b> Tying this pin to $V_{CC}$ (AUI/TP = 1) enables the AUI mode for interface with the ENDEC unit. Tying this pin to GND (AUI/TP = 0) enables the TPI Module mode for interface with the ENDEC unit.
TXO <sub>d+</sub> , TXO <sub>+</sub> , TXO <sub>-</sub> , TXO <sub>d-</sub>	TPI	O	<b>TWISTED PAIR TRANSMIT OUTPUTS:</b> These high drive CMOS level outputs are resistively combined external to the chip to produce a differential output signal with equalization to compensate for Intersymbol Interference (ISI) on the twisted pair medium.
RXI <sub>+</sub> , RXI <sub>-</sub>	TPI	I	<b>TWISTED PAIR RECEIVE INPUTS:</b> These inputs feed a differential amplifier which passes valid data to the ENDEC module.
TXLED	TP	O	<b>TRANSMIT:</b> An active low output. It is asserted for approximately 50 ms whenever the SONIC-T Controller transmits data in either AUI or TPI modes.
RXLED	TP	O	<b>RECEIVE:</b> An active low output. It is asserted for approximately 50 ms whenever receive data is detected in either AUI or TPI mode.
COLED	TP	O	<b>COLLISION:</b> An active low output. It is asserted for approximately 50 ms whenever the SONIC-T Controller detects a collision in either AUI or TPI modes.
POLED	TP	O	<b>POLARITY:</b> An active low output. This signal is normally inactive. When the TPI module detects seven consecutive link pulses or three consecutive received packets with reversed polarity, it is asserted.
LNKLED	TP	O	<b>GOOD LINK:</b> An active low output. This pin operates as an output to display link integrity status if this function has not been disabled by the LNKDIS pin described below. This output is off if the SONIC-T Controller is in AUI mode or if link testing is enabled and the link integrity is bad (i.e., the twisted pair link has been broken). This output is on if the SONIC-T Controller is in Twisted Pair Interface (TPI) mode, link integrity checking is enabled and the link integrity is good (i.e., the twisted pair link has not been broken) or if the link testing is disabled.
LNKDIS		I	<b>LINK DISABLE:</b> When this pin is tied to GND (LNKDIS = 0), the link test pulse generation and integrity checking function are both disabled.
LOWSQL		I	<b>LOW SQUELCH SELECT:</b> Tying this pin to $V_{CC}$ (LOWSQL = 1) sets the squelch mode to use a squelch threshold level lower than that of the 10BASE-T specification (see Section 3.1).

## 2.0 Pin Description (Continued)

TABLE 2-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS (Continued)</b>			
CD+		I	<b>AUI COLLISION +</b> : The positive differential collision input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
CD-		I	<b>AUI COLLISION -</b> : The negative differential collision input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
RX+		I	<b>AUI RECEIVE +</b> : The positive differential receive data input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
RX-		I	<b>AUI RECEIVE -</b> : The negative differential receive data input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
TX+	ECL	O	<b>AUI TRANSMIT +</b> : The positive differential transmit output to the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
TX-	ECL	O	<b>AUI TRANSMIT -</b> : The negative differential transmit output to the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
CRSo/ CRSi	TP	O I	<b>CARRIER SENSE OUTPUT (CRSo)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the CRSo signal is internally connected between the ENDEC and MAC units. It is asserted on the first valid high-to-low transition in the receive data (RX $\pm$ ). This signal remains active 1.5 bit times after the last bit of data. Although this signal is used internally by the SONIC-T, it is also provided as an output to the user. <b>CARRIER SENSE INPUT (CRSi)</b> from an external ENDEC (EXT = 1): The CRSi signal is activated high when the external ENDEC detects valid data at its receive inputs.
COLo/ COLi	TP	O I	<b>COLLISION OUTPUT (COLo)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the COLo signal is internally connected between the ENDEC and MAC units. This signal generates an active high signal when the 10 MHz collision signal from the transceiver is detected. Although this signal is used internally by the SONIC-T, it is also provided as an output to the user. <b>COLLISION DETECT INPUT (COLi)</b> from an external ENDEC (EXT = 1): The COLi signal is activated from an external ENDEC when a collision is detected. This pin is monitored during transmissions from the beginning of the Start of Frame Delimiter (SFD) to the end of the packet. At the end of transmission, this signal is monitored by the SONIC-T for CD heartbeat.
RXDo/ RXDi/ EXUSR0	TP TRI	O I O, Z	This pin will be TRI-STATE until the DCR has been written to. (See Section 6.3.2, EXBUS, for more information.) <b>RECEIVE DATA OUTPUT (RXDo)</b> from the internal ENDEC (EXT = 0): NRZ data output. When EXT = 0 the RXDo signal is internally connected between the ENDEC and MAC units. This signal must be sampled on the rising edge of the receive clock output (RXCo). Although this signal is used internally by the SONIC-T, it is also provided as an output to the user. <b>RECEIVE DATA INPUT (RXDi)</b> from an external ENDEC (EXT = 1): The NRZ data decoded from the external ENDEC. This data is clocked in on the rising edge of RXCi. <b>EXTENDED USER OUTPUT (EXUSR0)</b> : When EXBUS has been set (see Section 6.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC-T becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (see Section 6.3.7).
RXCo/ RXCi/ EXUSR1	TP TRI	O I O, Z	This pin will be TRI-STATE until the DCR has been written to. (See Section 6.3.2, EXBUS, for more information.) <b>RECEIVE CLOCK OUTPUT (RXCo)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the RXCo signal is internally connected between the ENDEC and MAC units. This signal is the receive clock that is derived from the Manchester data stream. It remains active 5-bit times after the deassertion of CRSo. Although this signal is used internally by the SONIC-T it is also provided as an output to the user. <b>RECEIVE CLOCK INPUT (RXCi)</b> from an external ENDEC (EXT = 1): The receive clock that is derived from the Manchester data stream. This signal is generated from an external ENDEC. <b>EXTENDED USER OUTPUT (EXUSR1)</b> : When EXBUS has been set (see Section 6.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC-T becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (see Section 6.3.7).

## 2.0 Pin Description (Continued)

TABLE 2-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS (Continued)</b>			
TXD/ EXUSR3	TP TRI	O O, Z	This pin will be TRI-STATE until the DCR has been written to. (See Section 6.3.2, EXBUS, for more information.) <b>TRANSMIT DATA (TXD):</b> The serial NRZ data from the MAC unit which is to be decoded by an external ENDEC. Data is valid on the rising edge of TXC. Although this signal is used internally by the SONIC-T it is also provided as an output to the user. <b>EXTENDED USER OUTPUT (EXUSR3):</b> When EXBUS has been set (see Section 6.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC-T becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (see Section 6.3.7).
TXE	TP	O	<b>TRANSMIT ENABLE:</b> This pin is driven high when the SONIC-T begins transmission and remains active until the last byte is transmitted. Although this signal is used internally by the SONIC-T it is also provided as an output to the user.
TXCo/ TXCi/ STERM	TRI	O, Z I I	This pin will be TRI-STATE until the DCR has been written to. (See Section 6.3.2, EXBUS, for more information.) <b>TRANSMIT CLOCK OUTPUT (TXCo)</b> from the internal ENDEC (EXT = 0): This 10 MHz transmit clock output is derived from the 20 MHz oscillator input. When EXT = 0 the TXCo signal is internally connected between the ENDEC and MAC units. Although this signal is used internally by the SONIC-T, it is also provided as an output to the user. <b>TRANSMIT CLOCK INPUT (TXCi)</b> from an external ENDEC (EXT = 1): This input clock from an external ENDEC is used for shifting data out of the MAC unit serializer. This clock is nominally 10 MHz. <b>SYNCHRONOUS TERMINATION (STERM):</b> When the SONIC-T is a bus master, it samples this pin before terminating its memory cycle. This pin is sampled synchronously and may only be used in asynchronous bus mode when BMODE = 1. (See Section 7.2.5 for more details.)
LBK/ EXUSR2	TP TRI	O O, Z	This pin will be TRI-STATE until the DCR has been written to. (See Section 6.3.2, EXBUS, for more information.) <b>LOOPBACK (LBK):</b> When ENDEC Loopback mode is enabled, LBK is asserted high. Although this signal is used internally by the SONIC-T it is also provided as an output to the user. <b>EXTENDED USER OUTPUT (EXUSR2):</b> When EXBUS has been set (see Section 6.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC-T becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (see Section 6.3.7).
PCOMP	TRI	O, Z	<b>PACKET COMPRESSION:</b> This pin is used with the Management Bus of the DP83950, Repeater Interface Controller (RIC). The SONIC-T can be programmed to assert PCOMP whenever there is a CAM match, or when there is not a match. The RIC uses this signal to compress (shorten) a received packet for management purposes and to reduce memory usage. (See the DP83950 datasheet for more details on the RIC Management Bus.) The operation of this pin is controlled by bits 1 and 2 in the DCR2 register. PCOMP will remain TRI-STATE until these bits are written to. This signal is asserted right after the 4th bit of the 7th byte of the incoming packet and is deasserted one transmit clock (TXC) after CSR is driven low.
PREJ		I	<b>PACKET REJECT:</b> This signal is used to reject received packets. When asserted low for at least two receive clock cycles (RXC), the SONIC-T will reject the incoming packet. This pin can be asserted up to the 2nd to the last bit of reception to reject a packet.

## 2.0 Pin Description (Continued)

TABLE 2-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS (Continued)</b>			
OSCIN		I	<b>CRYSTAL FEEDBACK INPUT OR EXTERNAL OSCILLATOR INPUT:</b> This signal is used to provide clocking signals for the internal ENDEC. A crystal may be connected to this pin along with OSCOUT, or an oscillator module may be used. See Section 8.1.3 for more information about using an oscillator or crystal.
OSCOUT	TP	O	<b>CRYSTAL FEEDBACK OUTPUT:</b> This signal is used to provide clocking signals for the internal ENDEC. A crystal can be connected to this pin along with OSCIN. See Section 8.1.3 for more information about using an oscillator or crystal.
<b>BUS INTERFACE PINS (BOTH BUS MODES)</b>			
BMODE		I	<b>BUS MODE:</b> This input enables the SONIC-T to be compatible with standard microprocessor buses. The level of this pin affects byte ordering (little or big endian) and controls the operation of the bus interface control signals. A high level (tied to $V_{CC}$ ) selects Motorola mode (big endian) and a low level (tied to ground) selects National/Intel mode (little endian). Note the alternate pin definitions for $\overline{AS}/ADS$ , $M\overline{R}\overline{W}/MWR$ , $\overline{INT}/INT$ , $\overline{B}\overline{R}/HOLD$ , $\overline{B}\overline{G}/HLDA$ , $S\overline{R}\overline{W}/SWR$ , $D\overline{SACK}0/\overline{RDY}0$ , and $D\overline{SACK}1/\overline{RDY}1$ . (See Sections 7.3.1, 7.3.4, and 7.3.5 for bus interface information.)
D31–D0	TRI	I, O, Z	<b>DATA BUS:</b> These bidirectional lines are used to transfer data on the system bus. When the SONIC-T is a bus master, 16-bit data is transferred on D15–D0 and 32-bit data is transferred on D31–D0. When the SONIC-T is accessed as a slave, register data is driven onto line D15–D0. D31–D16 are held TRI-STATE.
A31–A1	TRI	O, Z	<b>ADDRESS BUS:</b> These signals are used by the SONIC-T to drive the DMA address after the SONIC-T has acquired the bus. Since the SONIC-T aligns data to word boundaries, only 31 address lines are needed.
RA5–RA0		I	<b>REGISTER ADDRESS BUS:</b> These signals are used to access SONIC-T's internal registers. When the SONIC-T is accessed, the CPU drives these lines to select the desired SONIC-T register.
$\overline{RESET}$		I	<b>RESET:</b> This signal is used to hardware reset the SONIC-T. When asserted low, the SONIC-T transitions into the reset state after 10 transmit clocks or 10 bus clocks if the bus clock period is greater than the transmit clock period.
S2–S0	TP	O	<b>BUS STATUS:</b> These three signals provide a continuous status of the current SONIC-T bus operations. See Section 7.3.3 for status definitions.
BCLK		I	<b>BUS CLOCK:</b> This clock provides the timing for the SONIC-T DMA engine.
$\overline{CS}$		I	<b>CHIP SELECT:</b> The system asserts this pin low to access the SONIC-T's registers. The registers are selected by placing an address on lines RA5–RA0. <b>Note:</b> Both $\overline{CS}$ and $\overline{MREQ}$ must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting edge of the first signal and the asserting edge of the second signal.

## 2.0 Pin Description (Continued)

TABLE 2-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>BUS INTERFACE PINS (BOTH BUS MODES) (Continued)</b>			
$\overline{SAS}$		I	<b>SLAVE ADDRESS STROBE:</b> The system asserts this pin to latch the register address on lines RA0–RA5.
$\overline{DS}$	TRI	O, Z	<b>DATA STROBE:</b> When the SONIC-T is bus master, it drives this pin low during a read cycle to indicate that the slave device may drive data onto the bus; in a write cycle, this pin indicates that the SONIC-T has placed valid data onto the bus.
$\overline{BRT}$		I	<b>BUS RETRY:</b> When the SONIC-T is bus master, the system asserts this signal to rectify a potentially correctable bus error. This pin has two modes. Mode 1 (the LBR in the Data Configuration Register is set to 0): Assertion of this pin forces the SONIC-T to terminate the current bus cycle and will repeat the same cycle after $\overline{BRT}$ has been deasserted. Mode 2 (the LBR bit in the Data Configuration register is set to 1): Assertion of this signal forces the SONIC-T to retry the bus operation as in Mode 1. However, the SONIC-T will not continue DMA operations until the BR bit in the ISR is reset.
$\overline{ECS}$	TRI	O, Z	<b>EARLY CYCLE START:</b> This output gives the system earliest indication that a memory operation is occurring. This signal is driven low at the rising edge of T1 and high at the falling edge of T1.
<b>SHARED-MEMORY ACCESS PINS</b>			
$\overline{MREQ}$		I	<b>MEMORY REQUEST:</b> The system asserts this signal low when it attempts to access the shared-buffer RAM. The on-chip arbiter resolves accesses between the system and the SONIC-T. <b>Note:</b> Both $\overline{CS}$ and $\overline{MREQ}$ must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting edge of the first signal and the asserting edge of the second signal.
$\overline{SMACK}$	TP	O	<b>SLAVE AND MEMORY ACKNOWLEDGE:</b> SONIC-T asserts this dual function pin low in response to either a Chip Select ( $\overline{CS}$ ) or a Memory Request ( $\overline{MREQ}$ ) when the SONIC-T's registers or its buffer memory is available for accessing. This pin can be used for enabling bus drivers for dual-bus systems.
<b>BUS INTERFACE PINS (NATIONAL/INTEL MODE, BMODE = 0)</b>			
$\overline{ADS}$	TRI	O, Z	<b>ADDRESS STROBE (<math>\overline{ADS}</math>):</b> The rising edge indicates valid status and address.
$\overline{MWR}$	TRI	O, Z	<b>MEMORY WRITE/READ STROBE <math>\overline{MWR}</math>:</b> When the SONIC-T has acquired the bus, this signal indicates the direction of the data transfer. The signal is low during a read cycle and high during a write cycle.
$\overline{INT}$	TP	O	<b>INTERRUPT (<math>\overline{INT}</math>):</b> Indicates that an interrupt (if enabled) is pending from one of the sources indicated by the Interrupt Status register. Interrupts that are disabled in the Interrupt Mask register will not activate this signal.
$\overline{HOLD}$	TP	O	<b>HOLD REQUEST (<math>\overline{HOLD}</math>):</b> The SONIC-T drives this pin high when it intends to use the bus and is driven low when inactive.
$\overline{HLDA}$		I	<b>HOLD ACKNOWLEDGE (<math>\overline{HLDA}</math>):</b> This signal is used to inform the SONIC-T that it has attained the bus. When the system asserts this pin high, the SONIC-T has gained ownership of the bus.
$\overline{BGACK}$	TRI	O, Z	<b>BUS GRANT ACKNOWLEDGE:</b> This pin is only used when BMODE = 1.
$\overline{SWR}$		I	<b>SLAVE READ/WRITE STROBE (<math>\overline{SWR}</math>):</b> The system asserts this pin to indicate whether it will read from or write to the SONIC-T's registers. This signal is asserted low during a read and high during a write.
$\overline{RDYi}$		I	<b>READY INPUT (<math>\overline{RDYi}</math>, BMODE = 0):</b> When the SONIC-T is a bus master, the system asserts this signal high to insert wait-states and low to terminate the memory cycle. This signal is sampled synchronously or asynchronously depending on the state of the SBUS bit. (See Sections 7.3.5 and 6.3.2 for details.)
$\overline{RDYo}$	TP	O	<b>READY OUTPUT (<math>\overline{RDYo}</math>):</b> When a register is accessed, the SONIC-T asserts this signal to terminate the slave cycle.

## 2.0 Pin Description (Continued)

TABLE 2-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>BUS INTERFACE PINS (MOTOROLA MODE, BMODE = 1)</b>			
$\overline{AS}$	TRI	O, Z	<b>ADDRESS STROBE (<math>\overline{AS}</math>):</b> The falling edge indicates valid status and address. The rising edge indicates the termination of the memory cycle.
$\overline{MRW}$	TRI	O, Z	<b>MEMORY READ/WRITE STROBE (<math>\overline{MRW}</math>):</b> When the SONIC-T has acquired the bus, this signal indicates the direction of the data transfer. This signal is high during a read cycle and low during a write cycle.
$\overline{INT}$	OC	O, Z	<b>INTERRUPT (<math>\overline{INT}</math>):</b> Indicates that an interrupt (if enabled) is pending from one of the sources indicated by the Interrupt Status register. Interrupts that are disabled in the Interrupt Mask register will not activate this signal.
$\overline{BR}$	OC	O, Z	<b>BUS REQUEST (<math>\overline{BR}</math>):</b> The SONIC-T asserts this pin low when it attempts to gain access to the bus. When inactive this signal is at TRI-STATE.
$\overline{BG}$		I	<b>BUS GRANT (<math>\overline{BG}</math>):</b> This signal is a bus grant. The system asserts this pin low to indicate potential mastership of the bus.
$\overline{BGACK}$	TRI	O, Z	<b>BUS GRANT ACKNOWLEDGE:</b> The SONIC-T asserts this pin low when it has determined that it can gain ownership of the bus. The SONIC-T checks the following conditions before driving $\overline{BGACK}$ : <ol style="list-style-type: none"> <li><math>\overline{BG}</math> has been received through the bus arbitration process.</li> <li><math>\overline{AS}</math> is deasserted, indicating that the previous master has finished using the bus.</li> <li><math>\overline{DSACK0}</math> and <math>\overline{DSACK1}</math> are deasserted, indicating that the previous slave device is off the bus.</li> <li><math>\overline{BGACK}</math> is deasserted, indicating that the previous master is off the bus.</li> </ol>
$\overline{SRW}$		I	<b>SLAVE READ/WRITE (<math>\overline{SRW}</math>):</b> The system asserts this pin to indicate whether it will read from or write to the SONIC-T's registers. This signal is asserted high during a read and low during a write.
$\overline{DSACK0}$ $\overline{DSACK1}$	TRI TRI	I, O, Z I, O, Z	<b>DATA AND SIZE ACKNOWLEDGE 0 AND 1 (<math>\overline{DSACK0,1}</math> BMODE = 1):</b> These pins are the output slave acknowledge to the system when the SONIC-T registers have been accessed and the input slave acknowledgement when the SONIC-T is busmaster. When a register has been accessed, the SONIC-T drives both $\overline{DSACK0}$ and $\overline{DSACK1}$ pins low to terminate the slave cycle. (Note that the SONIC-T responds as a 32-bit peripheral by driving both $\overline{DSACK0}$ and $\overline{DSACK1}$ low, but drives data only on lines D0–D15. Lines D16–D32 are driven, but invalid.) When the SONIC-T is bus master, it samples these pins before terminating its memory cycle. When SONIC-T is in 32-bit bus master mode, both $\overline{DSACK0}$ and $\overline{DSACK1}$ must be asserted to terminate the cycle. However, if the SONIC-T is in 16-bit bus master mode, only the assertion of $\overline{DSACK1}$ is required to terminate the cycle. These pins are sampled synchronously or asynchronously depending on the state of the SBUS bit in the Data Configuration register. (See Section 7.3.5 for details.) Note that the SONIC-T does not allow dynamic bus sizing. Bus size is statically defined in the Data Configuration register (see Section 6.3.2).
<b>USER DEFINABLE PINS</b>			
USR0,1	TRI	I, O, Z	<b>USER DEFINE 0,1:</b> These signals are inputs when the SONIC-T is hardware reset and are outputs when the SONIC-T is a bus master (HLDA or $\overline{BGACK}$ asserted). When hard reset ( $\overline{RST}$ ) is low, these signals input directly into bits 8 and 9 of the Data Configuration Register (DCR) respectively. The levels on these pins are latched on the rising edge of $\overline{RST}$ . During busmaster operations (HLDA or $\overline{BGACK}$ is active), these pins are outputs whose levels are programmable through bits 11 and 12 of the DCR respectively. The USR0,1 pins should be pulled up to $V_{CC}$ or pulled down to ground. A 4.7 k $\Omega$ pull-up resistor is recommended.

### 3.0 Functional Description

The SONIC-T (Figure 3-1) consists of a twisted pair interface (TPI) module, an encoder/decoder (ENDEC) unit, a media access control (MAC) unit, separate receive and transmit FIFOs, a system buffer management engine, and a user programmable system bus interface unit on a single chip. SONIC-T is highly pipelined providing maximum system level performance. This section provides a functional overview of the SONIC-T.

#### 3.1 TWISTED PAIR INTERFACE MODULE

The TPI consists of five main logic functions:

- a. the Smart Squelch, which determines when valid data is present on the differential receive inputs (RXI±),
- b. the Collision Detector, which checks for simultaneous transmission and reception of data on the differential transmit output (TXO±) and differential receive input (RXI±) pins,
- c. the Link Detector/Generator, which checks the integrity of the cable connecting the two twisted pair modules,

- d. the Jabber, which disables the transmitter if it attempts to transmit a longer than legal packet, and
- e. the Transmitter, which utilizes a Transmit Driver and a Pre-emphasis to transmit Manchester encoded data to the twisted pair network via summing resistors and a transformer/filter.

**Smart Squelch:** The SONIC-T Controller implements an intelligent receive squelch on the RXI± differential inputs to ensure that impulse noise on the receive inputs will not be mistaken for a valid signal.

The squelch circuitry employs a combination of amplitude and timing measurements to determine the validity of data on the twisted pair inputs. There are two voltage level options for the smart squelch. One mode, 10BASE-T mode (Figure 3-2), uses levels that meet the 10BASE-T specification. The second mode, reduced squelch mode, uses a lower squelch threshold level, and can be used in longer cable applications where smaller signal levels may be applied. The squelch level mode can be selected using the LOWSQL input pin (see Section 2.0).

FIGURE 3-1. SONIC-T Block Diagram

TL/F/11719-4

FIGURE 3-2. Twisted Pair Squelch Waveform (10BASE-T Mode)

TL/F/11719-5

### 3.0 Functional Description (Continued)

The signal at the start of the packet is checked by the smart squelch, and any pulses not exceeding the squelch level (either positive or negative, depending upon polarity) will be rejected. Once this first squelch level is overcome correctly, the opposite squelch level must then be exceeded within 150 ns. Finally, the signal must exceed the original squelch level within the next 150 ns time period to ensure that the input waveform will not be rejected. The checking procedure typically results in the loss of three bits at the beginning of each packet.

Only after all these conditions have been satisfied will a control signal be generated to indicate to the remainder of the circuitry that valid data is present. At this time the smart squelch circuitry is reset.

In the reduced squelch mode the operation is identical except that the lower squelch levels shown in *Figure 3-2* are used.

Valid data is considered to be present until either squelch level has not been generated for a time period of more than 150 ns indicating the End of Packet. Once good data has been detected, the squelch levels are reduced to minimize the effect of noise causing premature End of Packet detection.

**Collision:** A collision is detected by the TPI module when the receive and transmit channels are simultaneously active. If the TPI is receiving when a collision is detected it is reported to the controller immediately. If, however, the TPI is transmitting when a collision is detected, the collision is not reported until seven bits have been received while in the collision state. This prevents a collision being reported incorrectly due to noise on the network. The signal to the controller remains for the duration of the collision.

Approximately 1  $\mu$ s after the transmission of each packet, a signal called the Signal Quality Error (SQE) is generated which typically consists of 10 cycles of a 10 MHz signal. This 10 MHz signal, also called the Heartbeat, ensures the continued functioning of the collision circuitry.

**Link Detector/Generator:** The link generator is a timer circuit that generates a link pulse, produced by the transmitter section, as defined by the 10BASE-T specification. The 100 ns wide pulse is transmitted on the TXO+ output every 16 ms in the absence of transmit data.

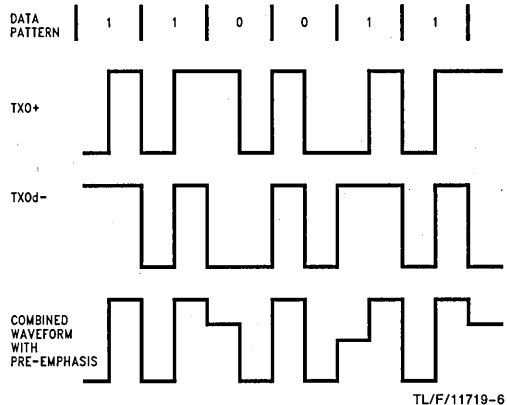

This link pulse is used to check the integrity of the connection to the remote MAU. The link detection circuit checks for valid pulses that are received from the remote unit. If valid link pulses are not received, the link detector will disable the transmit, receive, and collision detection functions.

The LINKLED output can directly drive a LED to show that there is a good twisted pair link. For normal conditions the LED will be on. The link integrity function can be disabled by asserting the LNKDIS input pin.

**Jabber:** The jabber timer monitors the transmitter and disables the transmission if the transmitter is active for greater than 26 ms. The transmitter is then disabled for the whole time that the ENDEC module's internal transmit enable is asserted. This signal has to be deasserted for approximately 750 ms (the unjab time) before the Jabber re-enables the transmit outputs.

**Transmitter:** The transmitter consists of four signals, the true and complement Manchester encoded data (TXO $\pm$ ) and these signals delayed by 50 ns (TXOd $\pm$ ).

These four signals are resistively combined (see Section 8.2), TXO+ with TXOd- and TXO- with TXOd+, in a configuration referred to as pre-emphasis. This digital pre-emphasis is required to compensate for the low-pass filter effects of the twisted pair cable which causes greater attenuation to the 10 MHz (50 ns) pulses of the Manchester encoded waveform than the 5 MHz (100 ns) pulses.

**FIGURE 3-3. Typical Summed Transmit Waveform**

The signal with pre-emphasis is generated by resistively combining TXO+ and TXOd- (*Figure 3-3*). This signal along with its complement is passed to the transmit filter.

**Status Information:** Status information is provided by the SONIC-T Controller on the RXLED, TXLED, COLED, LINKLED, and POLED outputs as described in the pin description table. These outputs (*Figure 3-4*) are suitable for driving status LEDs.

**FIGURE 3-4. Typical SONIC-T LED Connection**

## 3.0 Functional Description (Continued)

### 3.2 IEEE 802.3 ENCODER/DECODER (ENDEC) UNIT

The Encoder/Decoder (ENDEC) unit is the interface between either the Twisted Pair Interface Module or the Ethernet transceiver and the Media Access Control (MAC) unit. Providing the Manchester data encoding and decoding functions for IEEE 802.3 Ethernet, Thin-Ethernet, or Twisted Pair types of local area networks, the ENDEC operations of SONIC-T are identical to those of the DP83910A CMOS Serial Network Interface device. During transmission, the ENDEC unit combines non-return-zero (NRZ) data from the MAC section and clock pulses to produce Manchester data and sends the converted data differentially to the transceiver. Conversely, during reception, an analog Phase Lock Loop (PLL) decodes the Manchester data into both NRZ formatted data and a receive clock. The SONIC-T ENDEC unit is a functionally complete Manchester encoder/decoder incorporating a balanced driver and receiver, an on-board crystal oscillator, a collision signal translator, and a diagnostic loopback. The features include:

- Compatibility with Ethernet I and II, IEEE 802.3 10BASE5, 10BASE2, and 10BASE-T
- 10Mb/s Manchester encoding/decoding with receive clock recovery
- No precision components requirement
- Loopback capability for diagnostics
- Squelch circuitry at the receive and collision inputs reject noise
- Connection to the transceiver (Attachment Unit Interface) cable via external pulse transformer

#### 3.2.1 ENDEC Operation

The primary function of the ENDEC unit (*Figure 3-5*) is to perform the encoding and decoding necessary for compatibility between the differential pair Manchester encoded data of the transceiver and the Non-Return-to-Zero (NRZ) serial data of the MAC unit data line. In addition to encoding and decoding the data stream, the ENDEC also supplies all of the special signals (e.g., collision detect, carrier sense, and clocks) necessary to the MAC unit. The signals provided to the MAC unit from the on-chip ENDEC are also provided as outputs to the user.

#### Manchester Encoder and Differential Output Driver:

During transmission to the network, the ENDEC unit translates the NRZ serial data from the MAC unit into differential pair Manchester encoded data. To perform this operation the NRZ bit stream from the MAC unit is passed through the Manchester encoder block of the ENDEC unit. Once the bit stream is encoded, it is transmitted out differentially to the transmit differential pair through the transmit driver.

The SONIC-T Controller is compatible with the IEEE 802.3 "full-step" standard. That is, the Transmit+ and Transmit- differential outputs are at equal voltages while they are idle at the primary of the isolation transformer at the network interface. This voltage relationship provides a zero differential voltage for operation with transformer coupled loads. (See Section 8.1 for network interfacing considerations.)

**Manchester Decoder:** During reception from the network, the differential receive data from the transceiver is converted from Manchester encoded data into NRZ serial data and a receive clock, which are sent to the receive data and clock inputs of the MAC unit. To perform this operation, the signal is passed to the PLL decoder block once it is received from the differential receiver. The PLL decodes the data and generates a data receive clock and a NRZ serial data stream to the MAC unit.

Data typically becomes valid from the decoder within 6 bit times, and the decoder detects the end of a frame when no more mid-bit transitions are detected. (See Section 8.1 for network interfacing considerations.)

**Special Signals:** In addition to performing the Manchester encoding and decoding function, the ENDEC unit provides control and clocking signals to the MAC unit. The ENDEC sends a carrier sense (CRS) signal that indicates to the MAC unit that data is present from the network on the ENDEC's receive differential pair. When the ENDEC's collision receiver detects a 10 MHz signal on the differential collision input pair, the ENDEC unit provides the MAC unit with a collision detection signal (COL). COL indicates that a collision is taking place somewhere on the network.

FIGURE 3-5. Block Diagram of Ethernet ENDEC

TL/F/11719-8

1-549

### 3.0 Functional Description (Continued)

The ENDEC also provides both the receive and transmit clocks to the MAC unit. The transmit clock is one half of the oscillator input and the receive clock is extracted from the input data by the PLL.

**Oscillator:** The oscillator generates the 10 MHz transmit clock signal for network timing. The oscillator is controlled by a parallel resonant crystal or by an external clock (see Section 8.1.3). The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock (TXC) for the MAC section. The oscillator also provides an internal clock signal for the encoding and decoding circuits.

**Loopback Functions:** The SONIC-T provides three loopback modes which allow for loopback testing at the MAC, ENDEC and external transceiver level (see Section 3.7 for details). It is important to note that when the SONIC-T is transmitting, the transmitted packet will always be looped back by the external transceiver. The SONIC-T takes advantage of this to monitor the transmitted packet. See the explanation of the Receive State Machine in Section 3.3.1 for more information about monitoring transmitted packets.

#### 3.2.2 Selecting an External ENDEC

An option is provided on SONIC-T to disable the on-chip ENDEC unit and use an external ENDEC. The internal IEEE 802.3 ENDEC can be bypassed by connecting the EXT pin to  $V_{CC}$  (EXT = 1). In this mode the MAC signals are redirected out from the chip, allowing an external ENDEC to be used. See Section 2.0 for the alternate pin definitions.

#### 3.3 MEDIA ACCESS CONTROL (MAC) UNIT

The Media Access Control (MAC) unit performs the control functions for the media access of transmitting and receiving packets over Twisted Pair or AUI. During transmission, the MAC unit frames information from the transmit FIFO and supplies serialized data to the ENDEC unit. During reception, the incoming information from the ENDEC unit is deserialized, the frame checked for valid reception, and the data is transferred to the receive FIFO. Control and status registers on the SONIC-T govern the operation of the MAC unit.

##### 3.3.1 MAC Receive Section

The receive section (*Figure 3-6*) controls the MAC receive operations during reception, loopback, and transmission. During reception, the deserializer goes active after detecting the 2-bit Start of Frame Delimiter (SFD) pattern (see Section 4.1). It then frames the incoming bits into octet boundaries and transfers the data to the 32-byte receive FIFO. Concurrently the address comparator compares the Destination

Address Field to the addresses stored in the chip's Content Addressable Memory (CAM) address registers. If a match occurs, the deserializer passes the remainder of the packet to the receive FIFO. The packet is decapsulated when the carrier sense input pin (CRS) goes inactive. At the end of reception the receive section checks the following:

- Frame alignment errors
- CRC errors
- Length errors (runt packets)

The appropriate status is indicated in the Receive Control register (see Section 6.3.3). In loopback operations, the receive section operates the same as during normal reception.

During transmission, the receive section remains active to allow monitoring of the self-received packet. The Cyclic Redundancy Code (CRC) checker operates as normal, and the Source Address field is compared with the CAM address entries. Status of the CRC check and the source address comparison is indicated by the PMB bit in the Transmit Control register (see Section 6.3.4). No data is written to the receive FIFO during transmit operations.

The receive section consists of the following blocks detailed below.

**Receive State Machine (RSM):** The RSM insures the proper sequencing for normal reception and self-reception during transmission. When the network is inactive, the RSM remains in an idle state continually monitoring for network activity. If the network becomes active, the RSM allows the deserializer to write data into the receive FIFO. During this state, the following conditions may prevent the complete reception of the packet.

- FIFO Overrun—The receive FIFO has been completely filled before the SONIC-T could buffer the data to memory.
- CAM Address Mismatch—The packet is rejected because of a mismatch between the destination address of the packet and the address in the CAM.
- Memory Resource Error—There are no more resources (buffers or descriptors) available for buffering the incoming packets.
- Collision or Other Error—A collision occurred on the network or some other error, such as a CRC error, occurred (this is true if the SONIC-T has been told to reject packets on a collision, or reject packets with errors).

If these conditions do not occur, the RSM processes the packet indicating the appropriate status in the Receive Control register.

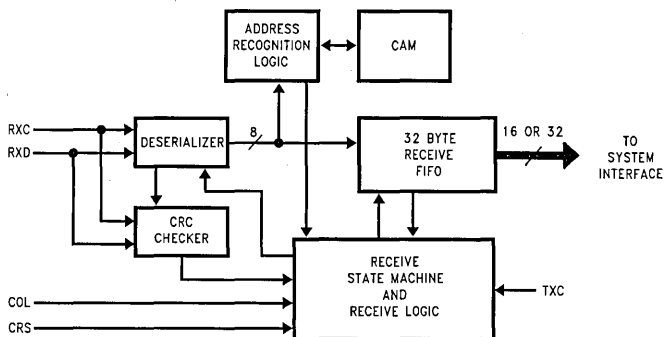

FIGURE 3-6. MAC Receiver

TL/F/11719-9

### 3.0 Functional Description (Continued)

During transmission of a packet from the SONIC-T, the transceiver will always loop the packet back to the SONIC-T. The SONIC-T will use this to monitor the packet as it is being transmitted. The CRC and source address of the looped back packet are checked with the CRC and source address that were transmitted. If they do not match, an error bit is set in the status of the transmitted packet (see Packet Monitored Bad, PMB, in the Transmit Control Register, Section 6.3.4). Data is not written to the receive FIFO during this monitoring process unless a Loopback mode has been selected (see Section 3.7).

**Receive Logic:** The receive logic contains the command, control, and status registers that govern the operations of the receive section. It generates the control signals for writing data to the receive FIFO, processes error signals obtained from the CRC checker and the deserializer, activates the "packet reject" signal to the RSM for rejecting packets, and posts the applicable status in the Receive Control register.

**Deserializer:** This section deserializes the serial input data stream and provides a byte clock for the address comparator and receive logic. It also synchronizes the CRC checker to begin operation (after SFD is detected), and checks for proper frame alignment with respect to CRS going inactive at the end of reception.

**Address Comparator:** The address comparator latches the Destination Address (during reception or loopback) or Source Address (during transmission) and determines whether the address matches one of the entries in the CAM.

**CRC Checker:** The CRC checker calculates the 4-byte Frame Check Sequence (FCS) field from the incoming data stream and compares it with the last 4-bytes of the received packet. The CRC checker is active for both normal reception and self-reception during transmission.

**Content Addressable Memory (CAM):** The CAM contains 16 user programmable entries and 1 pre-programmed Broadcast address entry for complete filtering of received packets. The CAM can be loaded with any combination of Physical and Multicast Addresses (see Section 4.2). See Section 6.1 for the procedure on loading the CAM registers.

#### 3.3.2 MAC Transmit Section

The transmit section (Figure 3-7) is responsible for reading data from the transmit FIFO and transmitting a serial data

stream onto the network in conformance with the IEEE 802.3 Carrier Sense Multiple Access with Collision Detection (CSMA/CD) standard. The Transmit Section consists of the following blocks.

**Transmit State Machine (TSM):** The TSM controls the functions of the serializer, preamble generator, and JAM generator. It determines the proper sequence of events that the transmitter follows under various network conditions. If no collision occurs, the transmitter prefixes a 62-bit preamble and 2-bit Start of Frame Delimiter (SFD) at the beginning of each packet and then sends the serialized data. At the end of the packet, an optional 4-byte CRC pattern is appended. If a collision occurs, the transmitter switches from transmitting data to sending a 4-byte Jam pattern to notify all nodes that a collision has occurred. Should the collision occur during the preamble, the transmitter waits for it to complete before jamming. After the transmission has completed, the transmitter writes status in the Transmit Control register (see Section 6.3.4).

**Protocol State Machine:** The protocol state machine assures that the SONIC-T obeys the CSMA/CD protocol. Before transmitting, this state machine monitors the carrier sense and collision signals for network activity. If any other nodes are currently transmitting, the SONIC-T defers its transmission until the network is quiet. It then transmits after its Interframe Gap Timer (9.6  $\mu$ s) has expired. The Interframe Gap time is divided into two portions. During the first 6.4  $\mu$ s, any new network activity will restart the Interframe Gap timer. Beyond this time, however, network activity is ignored and the state machine waits the remaining 3.2  $\mu$ s before transmitting. If the SONIC-T experiences a collision during a transmission, it switches from transmitting data to transmitting a 4-byte JAM pattern (4 bytes of all 1's), before ceasing to transmit. The SONIC-T then waits a random number of slot times (51.2  $\mu$ s) determined by the *Truncated Binary Exponential Backoff Algorithm* before reattempting another transmission. In this algorithm, the number of slot times to delay before the *n*th retransmission is chosen to be a random integer *r* in the range of:

$$0 \leq r \leq 2^k$$

where  $k = \min(n,10)$

If a collision occurs on the 16th transmit attempt, the SONIC-T aborts transmitting the packet and reports an "Excessive Collisions" error in the Transmit Control register.

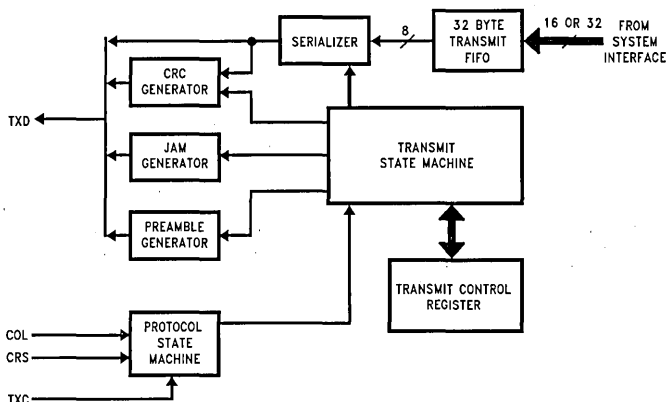

FIGURE 3-7. MAC Transmitter

TL/F/11719-10

### 3.0 Functional Description (Continued)

**Serializer:** After data has been written into the 32-byte transmit FIFO, the serializer reads byte wide data from the FIFO and sends a NRZ data stream to the Manchester encoder. The rate at which data is transmitted is determined by the transmit clock (TXC). The serialized data is transmitted after the SFD.

**Preamble Generator:** The preamble generator prefixes a 62-bit alternating "1,0" pattern and a 2-bit "1,1" SFD pattern at the beginning of each packet. This allows receiving nodes to synchronize to the incoming data. The preamble is always transmitted in its entirety even in the event of a collision. This assures that the minimum collision fragment is 96 bits (64 bits of normal preamble, and 4 bytes, or 32 bits of JAM pattern).

**CRC Generator:** The CRC generator calculates the 4-byte FCS field from the transmitted serial data stream. If enabled, the 4-byte FCS field is appended to the end of the transmitted packet (see Section 4.6).

For bridging or switched ethernet applications the CRC Generator can be inhibited by setting bit 13 in the Transmit Control Register (Section 6.3.4). This feature is used when an ethernet segment has already received a packet with a CRC appended and needs to forward it another ethernet segment.

**Jam Generator:** The Jam generator produces a 4-byte pattern of all 1's to assure that all nodes on the network sense the collision. When a collision occurs, the SONIC-T stops transmitting data and enables the Jam generator. If a collision occurs during the preamble, the SONIC-T finishes transmitting the preamble before enabling the Jam generator (see Preamble Generator above).

#### 3.4 DATA WIDTH AND BYTE ORDERING

The SONIC-T can be programmed to operate with either 32-bit or 16-bit wide memory. The data width is configured during initialization by programming the DW bit in the Data Configuration Register (DCR) (see Section 6.3.2). If the 16-bit data path is selected, data is driven on pins D15-D0. The SONIC-T also provides both Little Endian and Big Endian byte-ordering capability for compatibility with National/Intel or Motorola microprocessors respectively by selecting the proper level on the Bus Mode (BMODE) pin.

**Little Endian (National/Intel) Mode (BMODE = 0):** The byte orientation for received and transmitted data in the Receive Buffer Area (RBA) and Transmit Buffer Area (TBA) of system memory is as follows:

**Big Endian (Motorola) Mode (BMODE = 1):** The byte orientation for received and transmitted data in the RBA and TBA is as follows:

#### 3.5 FIFO AND CONTROL LOGIC

The SONIC-T incorporates two independent 32-byte FIFOs for transferring data to/from the system interface and from/to the network. The FIFOs, providing temporary storage of data, free the host system from the real-time demands on the network.

The way in which the FIFOs are emptied and filled is controlled by the FIFO threshold values and the Block Mode Select bits (BMS) (see Section 6.3.2). The threshold values determine how full or empty the FIFOs are allowed to be before the SONIC-T will request access of the bus to get more data from memory or buffer more data to memory. When Block Mode is enabled, the number of bytes transferred is determined by the threshold value. For example, if the threshold for the receive FIFO is 4 words, then the SONIC-T will always transfer 4 words from the receive FIFO to memory. If Empty/Fill mode is enabled, however, the number of bytes transferred is the number required to fill the transmit FIFO or empty the receive FIFO. The manner in which the threshold affects reception and transmission of packets is discussed below in Sections 3.5.1 and 3.5.2.

##### 3.5.1 Receive FIFO

To accommodate the different transfer rates, the receive FIFO (*Figure 3-8*) serves as a buffer between the 8-bit network (deserializer) interface and the 16/32-bit system interface. The FIFO is arranged as a 4-byte wide by 8 deep memory array (8-long words, or 32 bytes) controlled by three sections of logic. During reception, the Byte Ordering logic directs the byte stream from the deserializer into the FIFO using one of four write pointers. Depending on the selected byte-ordering mode, data is written either least significant byte first or most significant byte first to accommodate little or big endian byte-ordering formats respectively. As data enters the FIFO, the Threshold Logic monitors the number of bytes written in from the deserializer. The programmable threshold (RFT1,0 in the Data Configuration Register, see Section 6.3.2) determines the number of words (or long words) written into the FIFO from the MAC unit before a direct memory access (DMA) request for system memory occurs. When the threshold is reached, the

### 3.0 Functional Description (Continued)

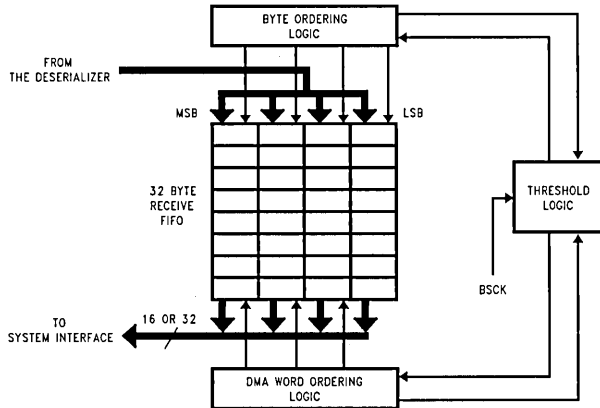

FIGURE 3-8. Receive FIFO

TL/F/11719-11

Threshold Logic enables the Buffer Management Engine to read a programmed number of 16- or 32-bit words (depending upon the selected data width) from the FIFO and transfer them to the system interface (the system memory) using DMA. The threshold is reached when the number of bytes in the receive FIFO is greater than the value of the threshold. For example, if the threshold is 4 words (8 bytes), then the Threshold Logic will not cause the Buffer Management Engine to write to memory until there are more than 8 bytes in the FIFO.

The Buffer Management Engine reads either the upper or lower half (16 bits) of the FIFO in 16-bit mode or reads the complete long word (32 bits) in 32-bit mode. If, after the transfer is complete, the number of bytes in the FIFO is less than the threshold, then the SONIC-T is done. This is always the case when the SONIC-T is in Empty/Fill Mode. If, however, for some reason (e.g., latency on the bus) the number of bytes in the FIFO is still greater than the threshold value, the Threshold Logic will cause the Buffer Management Engine to do a DMA request to write to memory again. This latter case is usually only possible when the SONIC-T is in Block Mode.

When in Block Mode, each time the SONIC-T requests the bus, only a number of bytes equal to the threshold value will be transferred. The Threshold Logic continues to monitor the number of bytes written in from the deserializer and enables the Buffer Management Engine every time the threshold has been reached. This process continues until the end of the packet.

Once the end of the packet has been reached, the serializer will fill out the last word (16-bit mode) or long word (32-bit mode) if the last byte did not end on a word or long word boundary respectively. The fill byte will be 0FFh. Immediately after the last byte (or fill byte) in the FIFO, the received packets status will be written into the FIFO. The entire packet, including any fill bytes and the received packet status will be buffered to memory. When a packet is buffered to memory by the Buffer Management Engine, it is always taken from the FIFO in words or long words and buffered to memory on word (16-bit mode) or long word (32-bit mode) boundaries. Data from a packet cannot be buffered on odd byte boundaries for 16-bit mode, and odd word boundaries for 32-bit mode (see Section 5.3). For more information on the receive packet buffering process, see Section 5.4.

#### 3.5.2 Transmit FIFO

Similar to the Receive FIFO, the Transmit FIFO (Figure 3-9) serves as a buffer between the 16/32-bit system interface and the network (serializer) interface. The Transmit FIFO is also arranged as a 4 byte by 8 deep memory array (8 long words or 32 bytes) controlled by three sections of logic. Before transmission can begin, the Buffer Management Engine fetches a programmed number of 16- or 32-bit words from memory and transfers them to the FIFO. The Buffer Management Engine writes either the upper or lower half (16 bits) into the FIFO for 16-bit mode or writes the complete long word (32 bits) during 32-bit mode.

The Threshold Logic monitors the number of bytes as they are written into the FIFO. When the threshold has been reached, the Transmit Byte Ordering state machine begins reading bytes from the FIFO to produce a continuous byte stream for the serializer. The threshold is met when the number of bytes in the FIFO is greater than the value of the threshold. For example, if the transmit threshold is 4 words (8 bytes), the Transmit Byte Ordering state machine will not begin reading bytes from the FIFO until there are 9 or more bytes in the buffer. The Buffer Management Engine continues replenishing the FIFO until the end of the packet. It does this by making multiple DMA requests to the system interface. Whenever the number of bytes in the FIFO is equal to or less than the threshold value, the Buffer Management Engine will do a DMA request. If Block Mode is set, then after each request has been granted by the system, the Buffer Management Engine will transfer a number of bytes equal to the threshold value into the FIFO. If Empty/Fill Mode is set, the FIFO will be completely filled in one DMA request.

Since data may be organized in big or little endian byte ordering format, the Transmit Byte Ordering state machine uses one of four read pointers to locate the proper byte within the 4 byte wide FIFO. It also determines the valid number of bytes in the FIFO. For packets which begin or end at odd bytes in the FIFO, the Buffer Management Engine writes extraneous bytes into the FIFO. The Transmit Byte Ordering state machine detects these bytes and only transfers the valid bytes to the serializer. The Buffer Management Engine can read data from memory on any byte boundary (see Section 5.3). See Section 5.5 for more information on transmit buffering.

### 3.0 Functional Description (Continued)

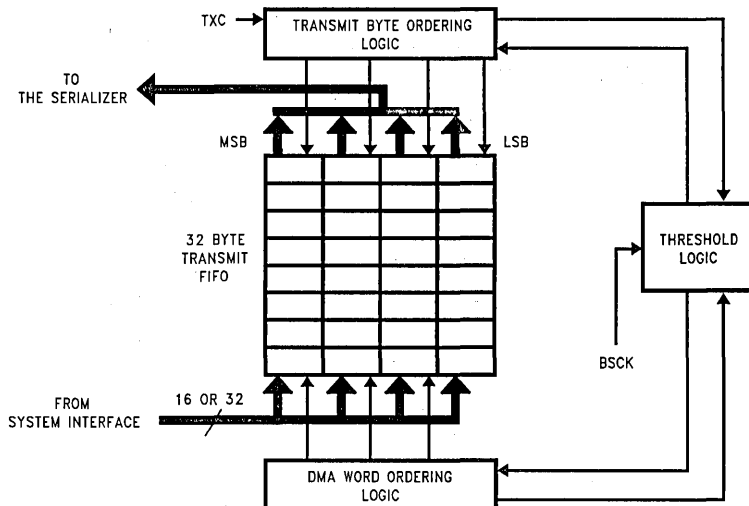

FIGURE 3-9. Transmit FIFO

#### 3.6 STATUS AND CONFIGURATION REGISTERS

The SONIC-T contains a set of status/control registers for conveying status and control information to/from the host system. The SONIC-T uses these registers for loading commands generated from the system, indicating transmit and receive status, buffering data to/from memory, and providing interrupt control. Each register is 16 bits in length. See Section 6.0 for a description of the registers.

#### 3.7 BUS INTERFACE

The system interface (Figure 3-10) consists of the pins necessary for interfacing to a variety of buses. It includes the I/O drivers for the data and address lines, bus access control for standard microprocessors, ready logic for synchronous or asynchronous systems, slave access control, interrupt control, and shared-memory access control. The functional signal groups are shown in Figure 3-10. See Section 7.0 for a complete description of the SONIC-T bus interface.

#### 3.8 LOOPBACK AND DIAGNOSTICS

The SONIC-T provides three loopback modes for self-testing from the controller interface to the transceiver interface. The loopback function is provided to allow self-testing of the chip's internal transmit and receive operations. During loopback, transmitted packets are routed back to the receive section of the SONIC-T where they are filtered by the address recognition logic and buffered to memory if accepted. Transmit and receive status and interrupts remain active during loopback. This means that when using loopback, it is as if the packet was transmitted and received by two separate chips that are connected to the same bus and memory.

**MAC Loopback:** Transmitted data is looped back at the MAC. Data is not sent from the MAC to either the internal ENDEC or an external ENDEC (the external ENDEC interface pins will not be driven), hence, data is not transmitted from the chip. Even though the ENDEC is not used in MAC loopback, the ENDEC clock (an oscillator or crystal for the internal ENDEC or TXC for an external ENDEC) must be driven. Network activity, such as a collision, does not affect

MAC loopback, and the CSMA/CD MAC protocol is not completely followed.

**ENDEC Loopback:** Transmitted data is looped back at the ENDEC. If the internal ENDEC is used, data is switched from the transmit section of the ENDEC to the receive section (Figure 3-5). Data is not transmitted from the chip and the collision lines,  $CD_{\pm}$ , are ignored, hence, network activity does not affect ENDEC loopback. The LBK signal from the MAC tells the internal ENDEC to go into loopback mode. If an external ENDEC is used, it should operate in loopback mode when the LBK signal is asserted. CSMA/CD MAC protocol is followed even though data is not transmitted from the chip.

**Transceiver Loopback:** Transmitted data is looped back at the external transceiver (which is always the case regardless of the SONIC-T's loopback mode). CSMA/CD MAC protocol is followed since data will be transmitted from the chip. This means that transceiver loopback is affected by network activity. The basic difference between Transceiver Loopback Mode and the other loopback modes is that the SONIC-T loads the receive FIFO and buffers the packet to memory. In normal operations, the SONIC-T only monitors the packet that is looped back by the transceiver, but does not fill the receive FIFO and buffer the packet.

##### 3.8.1 Loopback Procedure

The following procedure describes the loopback operation.

1. Initialize the Transmit and Receive Area as described in Sections 5.4 and 5.5.
2. Load one of the CAM address registers (see Section 6.1), with the Destination Address of the packet if you are verifying the SONIC-T's address recognition capability.
3. Load one of the CAM address registers with the Source Address of the packet if it is different than the Destination Address to avoid getting a Packet Monitored Bad (PMB) error in the Transmit Status (see Section 6.3.4).

### 3.0 Functional Description (Continued)

4. Program the Receive Control register with the desired receive filter and the loopback mode (LB1, LB0). In case of transceiver loopback, besides setting LB1 and LB0 to 1, the XWRAP bit in the DCR2 must also set to 1.

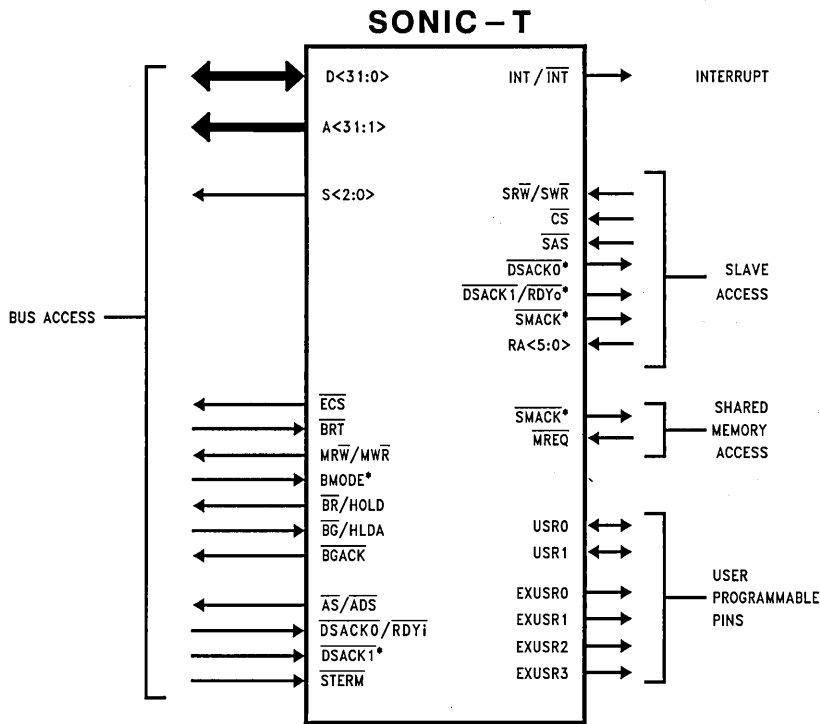

5. Issue the transmit command (TXP) and enable the receiver (RXEN) in the Command register.

The SONIC-T completes the loopback operation after the packet has been completely received (or rejected if there is an address mismatch). The Transmit Control and Receive Control registers treat the loopback packet as it would in normal operation and indicate status accordingly. Interrupts are also generated if enabled in the Interrupt Mask register.

**Note:** For MAC Loopback, only one packet may be queued up for proper operation. This restriction occurs because the transmit MAC section, which does not generate an Interframe Gap (IFG) time between transmitted packets, does not allow the receive MAC section to update receive status. There are no restrictions for the other loopback modes.

### 3.9 NETWORK MANAGEMENT FUNCTIONS

The SONIC-T fully supports the Layer Management IEEE 802.3 standard to allow a node to monitor the overall performance of the network. These statistics are available on a per packet basis at the end of reception or transmission. In addition, the SONIC-T provides three tally counters to tabulate CRC errors, Frame Alignment errors, and missed packets. Table 3-1 shows the statistics indicated by the SONIC-T.

TL/F/11719-13

\*Note: DSACK0,1 are used for both Bus and Slave Access Control and are bidirectional. SMACK is used for both Slave access and shared memory access. The BMODE pin selects between National/Intel or Motorola type busses.

Single Collision Frames	(Note)	NC0-NC4
Multiple Collision Frames	(Note)	NC0-NC4
Collision Frames	(Note)	NC0-NC4
Frames with Deferred Transmissions	TCR (Note)	DEF
Late Collisions	TCR (Note)	OWC
Excessive Collisions	TCR (Note)	EXC
Excessive Deferral	TCR (Note)	EXD
Internal MAC Transmit Error	TCR (Note)	BCM,FU
Frames Received OK	RCR (Note)	PRX
Multicast Frames Received OK	RCR (Note)	MC
Broadcast Frames Received OK	RCR (Note)	BC
Frame Check Sequence Errors	CRCT RCR	All CRC
Alignment Errors	FAET RCR	All FAE
Frame Lost due to Internal MAC Receive Error	MPT ISR	All RFO

Note: The number of collisions and the contents of the Transmit Control register are posted in the Txpkt.status field (see Section 5.5.1.2). The contents of the Receive Control register are posted in the RXPkt.status field (see Section 5.4.3).

### 4.0 Transmit/Receive IEEE 802.3 Frame Format

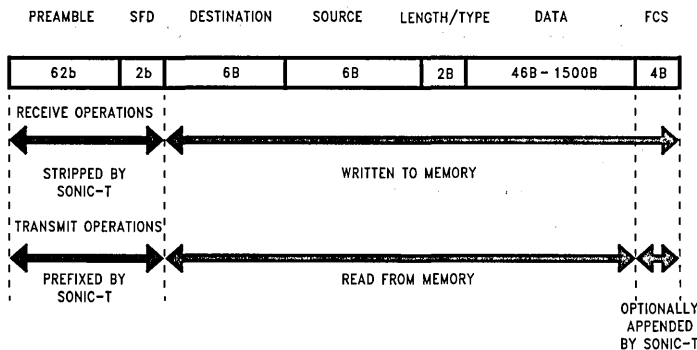

A standard IEEE 802.3 packet (Figure 4-1) consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data and Frame Check Sequence (FCS). The typical format is shown in Figure 4-1. The packets are Manchester encoded and decoded by the ENDEC unit and transferred serially to/from the MAC unit using NRZ data with a clock. All fields are of fixed length except for the data field. The SONIC-T generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

#### 4.1 PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted, each packet contains 62 bits of an alternating 1,0 preamble. Some of this preamble may be lost as the packet travels through the network. Byte alignment is performed when the Start of Frame Delimiter (SFD) pattern, consisting of two consecutive 1's, is detected.

#### 4.2 DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted pack-

Note: B = bytes  
b = bits

FIGURE 4-1. IEEE 802.3 Packet Structure

TL/F/11719-14

## 4.0 Transmit/Receive IEEE 802.3 Frame Format (Continued)

ets from reaching a node. There are three types of address formats supported by the SONIC-T: Physical, Multicast, and Broadcast.

**Physical Address:** The physical address is a unique address that corresponds only to a single node. All physical addresses have the LSB of the first byte of the address set to "0". These addresses are compared to the internally stored CAM (Content Addressable Memory) address entries. All bits in the destination address must match an entry in the CAM in order for the SONIC-T to accept the packet.

**Multicast Address:** Multicast addresses, which have the LSB of the first byte of the address set to "1", are treated similarly as physical addresses, i.e., they must match an entry in the CAM. This allows perfect filtering of Multicast packets and eliminates the need for a hashing algorithm for mapping Multicast packets.

**Broadcast Address:** If the address consists of all 1's, it is a Broadcast address, indicating that the packet is intended for all nodes.

The SONIC-T also provides a promiscuous mode which allows reception of all physical address packets. Physical, Multicast, Broadcast, and promiscuous address modes can be selected via the Receive Control register.

### 4.3 SOURCE ADDRESS

The source address is the physical address of the sending node. Source addresses cannot be multicast or broadcast addresses. This field must be passed to the SONIC-T's transmit buffer from the system software. During transmission, the SONIC-T compares the Source address with its internal CAM address entries before monitoring the CRC of the self-received packet. If the source address of the packet transmitted does not match a value in the CAM, the packet monitored bad flag (PMB) will be set in the transmit status field of the transmit descriptor (see Sections 5.5.1.2 and 6.3.4). The SONIC-T does not provide Source Address insertion. However, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. (See Section 5.5.1.)

### 4.4 LENGTH/TYPE FIELD

For IEEE 802.3 type packets, this field indicates the number of bytes that are contained in the data field of the packet. For Ethernet I and II networks, this field indicates the type of packet. The SONIC-T does not operate on this field.

### 4.5 DATA FIELD

The data field has a variable octet length ranging from 46 to 1500 bytes as defined by the Ethernet specification. Messages longer than 1500 bytes need to be broken into multiple packets for IEEE 802.3 networks. Data fields shorter than 46 bytes require appending a pad to bring the complete frame length to 64 bytes. If the data field is padded, the number of valid bytes are indicated in the length field. The SONIC-T does not append pad bytes for short packets during transmission, nor check for oversize packets during reception. However, the user's driver software can easily append the pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes (see Section 5.5.1). Although the Ethernet specification defines the maximum number of bytes in the data field, the SONIC-T can transmit and receive packets up to 64k bytes.

### 4.6 FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of error-free packets. During reception, an

error-free packet results in a specific pattern in the CRC generator. The AUTODIN II ( $X_{32} + X_{26} + X_{23} + X_{22} + X_{16} + X_{12} + X_{11} + X_{10} + X_8 + X_7 + X_5 + X_4 + X_2 + X_1 + 1$ ) polynomial is used for the CRC calculations. The SONIC-T may optionally append the CRC sequence during transmission, and checks the CRC both during normal reception and self-reception during a transmission (see Section 3.3.1).

### 4.7 MAC (MEDIA ACCESS CONTROL) CONFORMANCE

The SONIC-T is designed to be compliant to the IEEE 802.3 MAC Conformance specification. The SONIC-T implements most MAC functions in silicon and provides hooks for the user software to handle the remaining functions. The MAC Conformance specifications are summarized in Table 4-1.

TABLE 4-1. MAC Conformance Specifications

Conformance Test Name	Support By		
	SONIC-T	User Driver Software	Notes
Minimum Frame Size	X		
Maximum Frame Size	X	X	1
Address Generation	X	X	2

Jam Size (after SFD)	X		
Jam Size (in Preamble)	X		

**Note 1:** The SONIC-T provides the byte count of the entire packet in the RXpkt.byte\_count (see Section 5.4.3). The user's driver software may perform further filtering of the packet based upon the byte count.

**Note 2:** The SONIC-T does not provide Source Address insertion; however, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. (See Section 5.5.1.)

**Note 3:** The SONIC-T does not provide Pad generation; however, the user's driver software can easily append the Pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes. (See Section 5.5.1.)

## 5.0 Buffer Management

### 5.1 BUFFER MANAGEMENT OVERVIEW

The SONIC-T's buffer management scheme is based on separate buffers and descriptors (*Figures 5-3 and 5-12*). Packets that are received or transmitted are placed in buffers called the Receive Buffer Area (RBA) and the Transmit Buffer Area (TBA). The system keeps track of packets in these buffers using the information in the Receive Descriptor Area (RDA) and the Transmit Descriptor Area (TDA). A single (TDA) points to a single TBA, but multiple RDAs can point to a single RBA (one RDA per packet in the buffer). The Receive Resource Area (RRA), which is another form of descriptor, is used to keep track of the actual buffer.

When packets are transmitted, the system sets up the packets in one or more TBAs with a TDA pointing to each TBA. There can only be one packet per TBA/TDA pair. A single TBA, however, may be made up of several fragments of data dispersed in memory. There is one TDA pointing to each TBA which specifies information about the buffer's size, location in memory, number of fragments and status after transmission. The TDAs are linked together in a linked list. The system causes the SONIC-T to transmit the packets by passing the first TDA to the SONIC-T and issuing the transmit command.

Before a packet can be received, an RDA and RBA must be set up by the system. RDAs are made up as a linked list similar to TDAs. An RDA is not linked to a particular RBA, though. Instead, an RDA is linked specifically to a packet after it has been buffered into an RBA. More than one packet can be buffered into the same RBA, but each packet gets its own RDA. A received packet can not be scattered into fragments. The system only needs to tell the SONIC-T where the first RDA and where the RDAs are. Since an RDA never specifically points to an RBA, the RRA is used to keep track of the RBAs. The RRA is a circular queue of pointers and buffer sizes (not a linked list). When the SONIC-T receives a packet, it is buffered into an RBA and a unique corresponding RDA is written to so that it points to and describes the new packet. If the RBA does not have enough space to buffer the next packet, a new RBA is obtained from the RRA.

### 5.2 DESCRIPTOR AREAS

Descriptors are the basis of the buffer management scheme used by the SONIC-T. An RDA points to a received packet within an RBA, an RRA points to an RBA and a TDA points to a TBA which contains a packet to be transmitted. The conventions and registers used to describe these descriptors are discussed in the next three sections.

#### 5.2.1 Naming Convention for Descriptors

The fields which make up the descriptors are named in a consistent manner to assist in remembering the usage of each descriptor. Each descriptor name consists of three components in the following format.

[RX/TX][descriptor name].[field]

The first two capital letters indicate whether the descriptor is used for transmission (TX) or reception (RX), and is then followed by the descriptor name having one of two names.

rsrc = Resource descriptor  
pkt = Packet descriptor

The last component consists of a field name to distinguish it from the other fields of a descriptor. The field name is separated from the descriptor name by a period ("."). An example of a descriptor is shown in *Figure 5-1*.

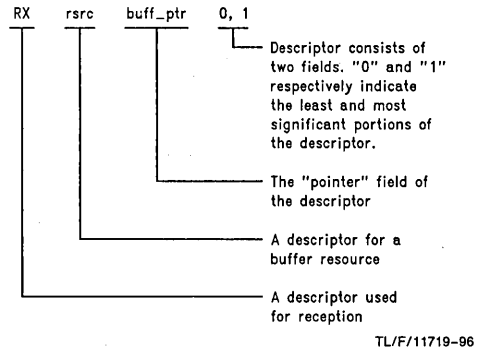

FIGURE 5-1. Receive Buffer Descriptor Example

#### 5.2.2 Abbreviations

Abbreviations are used to describe the SONIC-T registers and data structures in memory. The "0" and "1" in the abbreviations indicate the least and most significant portions of the registers or descriptors. Table 5-1 lists the naming convention abbreviations for descriptors.

#### 5.2.3 Buffer Management Base Addresses

The SONIC-T uses three areas in memory to store descriptor information: the Transmit Descriptor Area (TDA), the Receive Descriptor Area (RDA), and the Receive Resource Area (RRA). The SONIC-T accesses these areas by concatenating a 16-bit base address register with a 16-bit offset register. The base address register supplies a fixed upper 16 bits of address and the offset registers provide the lower 16 bits of address. The base address registers are the Upper Transmit Descriptor Address (UTDA), Upper Receive Descriptor Address (URDA), and the Upper Receive Resource Address (URRA) registers. The corresponding offset registers are shown below.

Upper Address Registers	Offset Registers
URRA	RSA, REA, RWP, RRP
URDA	CRDA
UTDA	CTDA

Table 5-1 defines the register mnemonics.

*Figure 5-2* shows an example of the Transmit Descriptor Area and the Receive Descriptor Area being located by the UTDA and URDA registers. The descriptor areas, RDA, TDA, and RRA are allowed to have the same base address, i.e., URRA=URDA=UTDA. Care, however, must be taken to prevent these areas from overwriting each other.

## 5.0 Buffer Management (Continued)

### 5.3 DESCRIPTOR DATA ALIGNMENT

All fields used by descriptors (RXpkt.xxx, RXsrc.xxx, and TXpkt.xxx) are word quantities (16-bit) and must be aligned to word boundaries (A0=0) for 16-bit memory and to long word boundaries (A1,A0=0,0) for 32-bit memory. The Receive Buffer Area (RBA) must also be aligned to a word boundary in 16-bit mode and a long word boundary in 32-bit mode. The fragments in the Transmit Buffer Area (TBA), however, may be aligned on any arbitrary byte boundary.

### 5.4 RECEIVE BUFFER MANAGEMENT

The Receive Buffer Management operates on three areas in memory into which data, status, and control information are written during reception (*Figure 5-3*). These three areas must be initialized (Section 5.4.4) before enabling the receiver (setting the RXEN bit in the Command Register). The Receive Resource Area (RRA) contains descriptors that locate Receive Buffer Areas in system memory. These descriptors are denoted by R1, R2, etc. in *Figure 5-3*. Packets (denoted by P1, P2, etc.) can then be buffered into the corresponding RBAs. Depending on the size of each buffer area and the size of the packet(s), multiple or single packets are buffered into each RBA. The Receive Descriptor Area (RDA) contains status and control information for each packet (D1, D2, etc. in *Figure 5-3*) corresponding to each received packet (D1 goes with P1, D2 with P2, etc.).

When a packet arrives, the address recognition logic checks the address for a Physical, Multicast, or Broadcast match and if the packet is accepted, the SONIC-T buffers the packet contiguously into the selected Receive Buffer Area (RBA). Because of the previous end-of-packet processing, the SONIC-T assures that the complete packet is written into a single contiguous block. When the packet ends, the SONIC-T writes the receive status, byte count, and location of the packet into the Receive Descriptor Area (RDA). The SONIC-T then updates its pointers to locate the next available descriptor and checks the remaining words available in the RBA. If sufficient space remains, the SONIC-T buffers the next packet immediately after the previous packet. If the current buffer is out of space the SONIC-T fetches a Resource Descriptor from the Receive Resource Area (RRA) acquiring an additional buffer that has been previously allocated by the system.

### 5.4.1 Receive Resource Area (RRA)

As buffer memory is consumed by the SONIC-T for storing data, the Receive Resource Area (RRA) provides a mechanism that allows the system to allocate additional buffer space for the SONIC-T. The system loads this area with Resource Descriptors that the SONIC-T, in turn, reads as its current buffer space is used up. Each Resource Descriptor consists of a 32-bit buffer pointer locating the starting point of the RBA and a 32-bit word count that indicates the size of the buffer in words (2 bytes per word). The buffer pointer and word count are contiguously located using the format shown in *Figure 5-4* with each component composed of 16-bit fields. The SONIC-T stores this information internally and concatenates the corresponding fields to create 32-bit long words for the buffer pointer and word count. Note that in 32-bit mode the upper word (D<31:16>) is not used by the SONIC-T. This area may be used for other purposes since the SONIC-T never writes into the RRA.

The SONIC-T organizes the RRA as a circular queue for efficient processing of descriptors. Four registers define the RRA. The first two, the Resource Start Area (RSA) and the Resource End Area (REA) registers, determine the starting and ending locations of the RRA, and the other two registers update the RRA. The system adds descriptors at the address specified by the Resource Write Pointer (RWP), and the SONIC-T reads the next descriptor designated by the Resource Read Pointer (RRP). The RRP is advanced 4 words in 16-bit mode (4 long words in 32-bit mode) after the SONIC-T finishes reading the RRA and automatically wraps around to the beginning of the RRA once the end has been reached. When a descriptor in the RRA is read, the RXsrc.buf\_pt0,1 is loaded into the CRBA0,1 registers and the RXsrc.buf\_wc0,1 is loaded into the RBWC0,1 registers.

The alignment of the RRA is confined to either word or long word boundaries, depending upon the data width mode. In 16-bit mode, the RRA must be aligned to a word boundary (A0 is always zero) and in 32-bit mode, the RRA is aligned to a long word boundary (A0 and A1 are always zero).

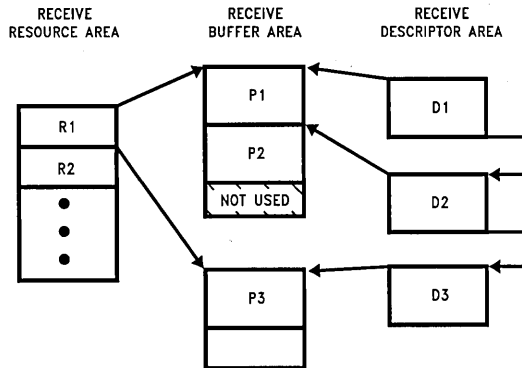

FIGURE 5-3. Overview of Receive Buffer Management

TL/F/11719-16

## 5.0 Buffer Management (Continued)

### 5.4.2 Receive Buffer Area (RBA)

The SONIC-T stores the actual data of a received packet in the RBA. The RBAs are designated by the Resource Descriptors in the RRA as described above. The `RXsrc.buf_wc0,1` fields of the RRA indicate the length of the RBA. When the SONIC-T gets an RBA from the RRA, the `RXsrc.buf_wc0,1` values are loaded into the Remaining Buffer Word Count registers (`RBWC0,1`). These registers keep track of how much space (in words) is left in the buffer. When a packet is buffered in a RBA, it is buffered contiguously (the SONIC-T will not scatter a packet into multiple buffers or fragments). Therefore, if there is not enough space left in a RBA after buffering a packet to buffer at least one more maximum sized packet (the maximum legal sized packet expected to be received from the network), a new buffer must be acquired. The End of Buffer Count (EOBC) register is used to tell the SONIC-T the maximum packet size that the SONIC-T will need to buffer.

#### 5.4.2.1 End of Buffer Count (EOBC)

The EOBC is a boundary in the RBA based from the bottom of the buffer. The value written into the EOBC is the maximum expected size (in words) of the network packet that the SONIC-T will have to buffer. This word count creates a line in the RBA that, when crossed, causes the SONIC-T to fetch a new RBA resource from the RRA.

**Note:** The EOBC is a word count, not a byte count. Also, the value programmed into EOBC must be a double word (32-bit) quantity when the SONIC-T is in 32-bit mode (e.g., in 32-bit mode, EOBC should be set to 760 words, not 759 words even though the maximum size of an IEEE 802.3 packet is 759 words for double word boundary alignment).

#### 5.4.2.2 Buffering the Last Packet in an RBA

At the start of reception, the SONIC-T stores the packet beginning at the Current Receive Buffer Address (`CRBA0,1`) and continues until the reception is complete. Concurrent with reception, the SONIC-T decrements the Remaining Buffer Word Count (`RBWC0,1`) by one in 16-bit mode or by two in 32-bit mode. At the end of reception, if the packet has crossed the EOBC boundary, the SONIC-T knows that the next packet might not fit in the RBA. This check is done by comparing the `RBWC0,1` registers with the EOBC. If `RBWC0,1` is less than the EOBC (the last packet buffered has crossed the EOBC boundary), the SONIC-T fetches the next resource descriptor in the RRA. If `RBWC0,1` is greater than or equal to the EOBC (the EOBC boundary has not been crossed) the next packet reception continues at the present location pointed to by `CRBA0,1` in the same RBA. *Figure 5-5* illustrates the SONIC-T's actions for (1)  $RBWC0,1 \geq EOBC$  and (2)  $RBWC0,1 < EOBC$ . See Section 5.4.4.4 for specific information about setting the EOBC.

**Note:** It is important that the EOBC boundary be "crossed." In other words, case #1 in *Figure 5-5* must exist before case #2 exists. If case #2 occurs without case #1 having occurred first, the test for  $RBWC0,1 < EOBC$  will not work properly and the SONIC-T will not fetch a new buffer. The result of this will be a buffer overflow (RBAE in the Interrupt Status Register, Section 6.3.6).

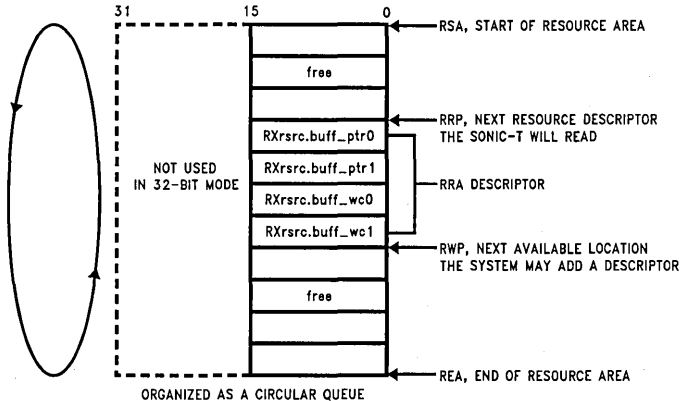

FIGURE 5-4. Receive Resource Area Format

TL/F/11719-17

Case #1: SONIC-T buffers next packet in same RBA.  
Case #2: SONIC-T detects an exhausted RBA and will buffer the next packet in another RBA.

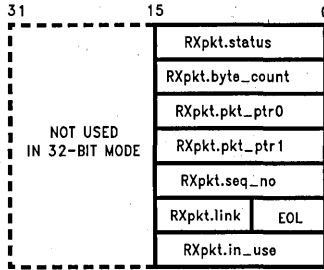

FIGURE 5-5. Receive Buffer Area

TL/F/11719-18

## 5.0 Buffer Management (Continued)

### 5.4.3 Receive Descriptor Area (RDA)

After the SONIC-T buffers a packet to memory, it writes 6 words of status and control information into the RDA reads the link field to the next Receive Descriptor, and writes to the in-use field of the current descriptor. In 32-bit mode the upper word, D<31:16>, is not used. This unused area in memory should not be used for other purposes, since the SONIC-T may still write into these locations. Each Receive Descriptor consists of the following sections: (Figure 5-6).

TL/F/11719-19

FIGURE 5-6. Receive Descriptor Format

**receive status:** indicates status of the received packet. The SONIC-T writes the Receive Control register values into this field. Figure 5-7 shows the receive status format. This field is loaded from the contents of the Receive Control register. Note that ERR, RNT, BRD, PRO, and AMC are configuration bits and are programmed during initialization. See Section 6.3.3 for the description of the Receive Control register.

FIGURE 5-7. Receive Status Format

**byte count:** gives the length of the complete packet from the start of Destination Address to the end of Frame Check Sequence (FCS).

**packet pointer:** a 32-bit pointer that locates the packet in the RBA. The SONIC-T writes the contents of the CRBA0,1 registers into this field.

**sequence numbers:** this field displays the contents of two 8-bit counters (modulo 256) that sequence the RBAs used and the packets buffered. These counters assist the system in determining when an RBA has been completely processed. The sequence numbers allow the system to tally the packets that have been processed within a particular RBA. There are two sequence numbers that describe a packet: the RBA Sequence Number and the Packet Sequence Number. When a packet is buffered to memory, the SONIC-T maintains a single RBA Sequence Number for all packets in an RBA and sequences the Packet Number for succeeding packets in the RBA. When the SONIC-T uses the next RBA, it increments the RBA Sequence Number and clears the Packet Sequence Number. The RBA's sequence counter is not incremented when the Read RRA command is issued in the Command register. The format of the Receive Sequence Numbers is shown in Figure 5-8. These counters are reset during a SONIC-T hardware reset or by writing zero to them.

FIGURE 5-8. Receive Sequence Number Format

**receive link field:** a 15-bit pointer (A15-A1) that locates the next receive descriptor. The LSB of this field is the End Of List (EOL) bit and indicates the last descriptor in the list. (Initialized by the system.)

**In-use field:** this field provides a handshake between the system and the SONIC-T to indicate the ownership of the descriptor. When the system avails a descriptor to the SONIC-T, it writes a non-zero value into this field. The SONIC-T, in turn, sets this field to all "0's" when it has finished processing the descriptor. (That is, when the CRDA register has advanced to the next receive descriptor.) Generally, the SONIC-T releases control after writing the status and control information into the RDA. If, however, the SONIC-T has reached the last descriptor in the list, it maintains ownership of the descriptor until the system has appended additional descriptors to the list. The SONIC-T then relinquishes control after receiving the next packet. (See Section 5.4.6.1 for details on when the SONIC-T writes to this field.) The receive packet descriptor format is shown in Figure 5-6.

### 5.4.4 Receive Buffer Management Initialization

The Receive Resource, Descriptor, and Buffer areas (RRA, RDA, RBA) in memory and the appropriate SONIC-T registers must be properly initialized before the SONIC-T begins buffering packets. This section describes the initialization process.

#### 5.4.4.1 Initializing The Descriptor Page

All descriptor areas (RRA, RDA, and TDA) used by the SONIC-T reside within areas up to 32k (word) or 16k (long word) pages. This page may be placed anywhere within the 32-bit address range by loading the upper 16 address lines into the UTDA, URDA, and URRR registers.

#### 5.4.4.2 Initializing The RRA

The initialization of the RRA consists of loading the four SONIC-T RRA registers and writing the resource descriptor information to memory.

The RRA registers are loaded with the following values.

**Resource Start Area (RSA) register:** The RSA is loaded with the lower 16-bit address of the beginning of the RRA.

**Resource End Area (REA) register:** The REA is loaded with the lower 16-bit address of the end of the RRA. The end of the RRA is defined as the address of the last RXrsrc.ptr0 field in the RRA plus 4 words in 16-bit mode or 4 long words in 32-bit mode (Figure 5-4).

**Resource Read Pointer (RRP) register:** The RRP is loaded with the lower 16-bit address of the first resource descriptor the SONIC-T reads.

**Resource Write Pointer (RWP) register:** The RWP is loaded with the lower 16-bit address of the next vacant location where a resource descriptor will be placed by the system.

**Note:** The RWP register must only point to either (1) the RXrsrc.ptr0 field of one of the RRA Descriptors, (2) the memory address that the RSA points to (the start of the RRA), or (3) the memory address that the REA points to (the end of the RRA). When the RWP = RRP comparison is made, it is performed after the complete RRA descriptor has been read and not during the fetch. Failure to set the RWP to any of the above values prevents the RWP = RRP comparison from ever becoming true.

## 5.0 Buffer Management (Continued)

All RRA registers are concatenated with the URRRA register for generating the full 32-bit address.

The resource descriptors that the system writes to the RRA consists of four fields: (1) RXrsrc.buf\_ptr0, (2) RXrsrc.buf\_ptr1, (3) RXrsrc.buf\_wc0, and (4) RXrsrc.buf\_wc1. The fields must be contiguous (they cannot straddle the end points) and are written in the order shown in Figure 5-9. The "0" and "1" in the descriptors denote the least and most significant portions for the Buffer Pointer and Word Count. The first two fields supply the 32-bit starting location of the Receive Buffer Area (RBA), and the second two define the number of 16-bit words that the RBA occupies.

Note that two restrictions apply to the Buffer Pointer and Word Count. First, in 32-bit mode, since the SONIC-T always writes long words, an even count must be written to RXrsrc.buf\_wc0. Second, the Buffer Pointer must either be pointing to a word boundary in 16-bit mode (A0=0) or a long word boundary in 32-bit mode (A0,A1=0,0). Note also that the descriptors must be properly aligned in the RRA as discussed in Section 5.3.

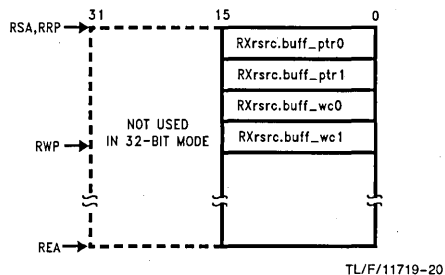

FIGURE 5-9. RRA Initialization

After configuring the RRA, the RRA Read command (setting RRRA bit in the Command register) may be given. This command causes the SONIC-T to read the RRA descriptor in a single block operation, and load the following registers (see Section 6.2 for register mnemonics):

- CRBA0 register ← RXrsrc.buf\_ptr0
- CRBA1 register ← RXrsrc.buf\_ptr1
- RBWC0 register ← RXrsrc.buf\_wc0
- RBWC1 register ← RXrsrc.buf\_wc1

When the command has completed, the RRRA bit in the Command register is reset to "0". Generally this command is only issued during initialization. At all other times, the RRA is automatically read as the SONIC-T finishes using an RBA.

### 5.4.4.3 Initializing The RDA

To accept multiple packets from the network, the receive packet descriptors must be linked together via the RXpkt.link fields. Each link field must be written with a 15-bit (A15-A1) pointer to locate the beginning of the next descriptor in the list. The LSB of the RXpkt.link field is the End Of List (EOL) bit and is used to indicate the end of the descriptor list. EOL = 1 for the last descriptor and EOL = 0 for the first or middle descriptors. The RXpkt.in\_use field indicates whether the descriptor is owned by the SONIC-T. The system writes a non-zero value to this field when the descriptor is available, and the SONIC-T writes all "0's" when it finishes using the descriptor. At startup, the Current Receive Descriptor Address (CRDA) register must be loaded with the address of the first RXpkt.status field in order for

the SONIC-T to begin receive processing at the first descriptor. An example of two descriptors linked together is shown in Figure 5-10. The fields initialized by the system are displayed in **bold type**. The other fields are written by the SONIC-T after a packet is accepted. The RXpkt.in\_use field is first written by the system, and then by the SONIC-T. Note that the descriptors must be aligned properly as discussed in Section 5.3. Also note that the URDA register is concatenated with the CRDA register to generate the full 32-bit address.

FIGURE 5-10. RDA Initialization Example

### 5.4.4.4 Initializing the Lower Boundary of the RBA

A "false bottom" is set in the RBA by loading the End Of Buffer Count (EOBC) register with a value equal to the maximum size packet in words (16 bits) that may be received. This creates a lower boundary in the RBA. Whenever the Remaining Buffer Word Count (RBWC0,1) registers decrement below the EOBC register, the SONIC-T buffers the next packet into another RBA. This also guarantees that a packet is always contiguously buffered into a single Receive Buffer Area (RBA). The SONIC-T does not buffer a packet into multiple RBAs. Note that in 32-bit mode, the SONIC-T holds the LSB always low so that it properly compares with the RBWC0,1 registers.

After a hardware reset, the EOBC register is automatically initialized to 2F8h (760 words or 1520 bytes). For 32-bit applications this is the suggested value for EOBC. EOBC defaults to 760 words (1520 bytes) instead of 759 words (1518 bytes) because 1518 is not a double word (32-bit) boundary (see Section 5.4.2.1). If the SONIC-T is used in 16-bit mode, then EOBC should be set to 759 words (1518 bytes) because 1518 is a word (16-bit) boundary.

Sometimes it may be desired to buffer a single packet per RBA. When doing this, it is important to set EOBC and the buffer size correctly. The suggested practice is to set EOBC to a value that is at least 4 bytes, in 32-bit mode, or 2 bytes, in 16-bit mode, less than the buffer size. An example of this for 32-bit mode is to set EOBC to 760 words (1520 bytes)

## 5.0 Buffer Management (Continued)

and the buffer size to 762 words (1524 bytes). A similar example for 16-bit mode would be EOBC = 759 words (1518 bytes) and the buffer size set to 760 words (1520 bytes). The buffer can be any size, but as long as the EOBC is 2 words, for 32-bit mode, or 1 word, for 16-bit mode, less than the buffer size, only one packet will be buffered in that RBA.

**Note 1:** It is possible to filter out most oversized packets by setting the buffer size to 760 words (1520 bytes) in 32-bit mode or 759 words (1518 bytes) in 16-bit mode. EOBC would be set to 758 words (1516 bytes) for both cases. With this configuration, any packet over 1520 bytes, in 32-bit mode, or 1518 bytes, in 16-bit mode, will not be completely buffered because the packet will overflow the buffer. When a packet overflow occurs, a Receive Buffer Area Exceeded interrupt (RBAE in the Interrupt Status Register, Section 6.3.6) will occur.

**Note 2:** When buffering one packet per buffer, it is suggested that the values in Note 1 above be used. Since the minimum legal sized Ethernet packet is 64 bytes, however, it is possible to set EOBC as much as 64 bytes less than the buffer size and still end up with one packet per buffer. Figure 5-11 shows this "range."

### 5.4.5 Beginning Of Reception

At the beginning of reception, the SONIC-T checks its internally stored EOL bit from the previous RXpkt.link field for a "1". If the SONIC-T finds EOL = 1, it recognizes that after the previous reception, there were no more remaining receive packet descriptors. It re-reads the same RXpkt.link field to check if the system has updated this field since the last reception. If the SONIC-T still finds EOL = 1, reception ceases. (See Section 5.5 for adding descriptors to the list.) Otherwise, the SONIC-T begins storing the packet in the RBA starting at the Current Receive Buffer Address (CRBA0,1) registers and continues until the packet has completed. Concurrent with the packet reception, the Remaining Buffer Word Count (RBWC0,1) registers are decremented after each word is written to memory. This register determines the remaining words in the RBA at the end of reception.

### 5.4.6 End Of Packet Processing

At the end of a reception, the SONIC-T enters its end of packet processing sequence to determine whether to accept or reject the packet based on receive errors and packet size. At the end of reception the SONIC-T enters one of the following two sequences:

- Successful reception sequence
- Buffer recovery for runt packets or packets with errors

### 5.4.6.1 Successful Reception

If the SONIC-T accepts the packet, it first writes 5 words of descriptor information in the RDA beginning at the address pointed to by the Current Receive Descriptor Address (CRDA) register. It then reads the RXpkt.link field to advance the CRDA register to the next receive descriptor. The SONIC-T also checks the EOL bit for a "1" in this field. If EOL = 1, no more descriptors are available for the SONIC-T. The SONIC-T recovers the address of the current RXpkt.link field (from a temporary register) and generates a "Receive Descriptors Exhausted" indication in the Interrupt Status register. (See Section 5.4.7 on how to add descriptors.) The SONIC-T maintains ownership of the descriptor by *not* writing to the RXpkt.in\_use field. Otherwise, if EOL = 0, the SONIC-T advances the CRDA register to the next descriptor and resets the RXpkt.in\_use field to all "0's".

The SONIC-T accesses the complete 7 word RDA descriptor in a single block operation.

The SONIC-T also checks if there is remaining space in the RBA. The SONIC-T compares the Remaining Buffer Word Count (RBWC0,1) registers with the static End Of Buffer Count (EOBC). If the RBWC is less than the EOBC, a maximum sized packet will no longer fit in the remaining space in the RBA; hence, the SONIC-T fetches a resource descriptor from the RRA and loads its registers with the pointer and word count of the next available RBA.

### 5.4.6.2 Buffer Recovery For Runt Packets Or Packets With Errors

If a runt packet (less than 64 bytes) or packet with errors arrives and the Receive Control register has been configured to not accept these packets, the SONIC-T recovers its pointers back to the original positions. The CRBA0,1 registers are not advanced and the RBWC0,1 registers are not decremented. The SONIC-T recovers its pointers by maintaining a copy of the buffer address in the Temporary Receive Buffer Address registers (TRBA0,1). The SONIC-T recovers the value in the RBWC0,1 registers from the Temporary Buffer Word Count registers (TBWC0,1).

### 5.4.7 Overflow Conditions

When an overflow condition occurs, the SONIC-T halts its DMA operations to prevent writing into unauthorized memory. The SONIC-T uses the Interrupt Status register (ISR) to indicate three possible overflow conditions that can occur

$$\text{Range of EOBC} = (\text{RXsrc.wc0,1} - 2 \text{ to } \text{RXsrc.wc0,1} - 32)$$

**FIGURE 5-11. Setting EOBC for Single Packet RBA**

TL/F/11719-22

## 5.0 Buffer Management (Continued)

when its receive resources have been exhausted. The system should respond by replenishing the resources that have been exhausted. These overflow conditions (Descriptor Resources Exhausted, Buffer Resources Exhausted, and RBA Limit Exceeded) are indicated in the Interrupt Status register and are detailed as follows:

**Descriptor Resources Exhausted:** This occurs when the SONIC-T has reached the last receive descriptor in the list, meaning that the SONIC-T has detected EOL = 1. The system must supply additional descriptors for continued reception. The system can do this in one of two ways: 1) appending descriptors to the existing list, or 2) creating a separate list.

1. Appending descriptors to the existing list. This is the easiest and preferred way. To do this, the system, after creating the new list, joins the new list to the existing list by simply writing the beginning address of the new list into the RXpkt.link field and setting EOL = 0. At the next reception, the SONIC-T re-reads the last RXpkt.link field, and updates its CRDA register to point to the next descriptor.

2. Creating a separate list. This requires an additional step because the lists are not joined together and requires that the CRDA register be loaded with the address of the RXpkt.link field in the new list.

During this overflow condition, the SONIC-T maintains ownership of the descriptor (RXpkt.in\_use  $\neq$  00h) and waits for the system to add additional descriptors to the list. When the system appends more descriptors, the SONIC-T releases ownership of the descriptor after writing 0000h to the RXpkt.in\_use field.

**Buffer Resources Exhausted:** This occurs when the SONIC-T has detected that the Resource Read Pointer (RRP) and Resource Write Pointer (RWP) registers are equal (i.e., all RRA descriptors have been exhausted). The RBE bit in the Interrupt Status register is set when the SONIC-T finishes using the second to last receive buffer and reads the last RRA descriptor. Actually, the SONIC-T is not truly out of resources, but gives the system an early warning of an impending out of resources condition. To continue reception after the last RBA is used, the system must supply additional RRA descriptor(s), update the RWP register, and clear the RBE bit in the ISR. The SONIC-T rereads the RRA after this bit is cleared.

**RBA Limit Exceeded:** This occurs when a packet does not completely fit within the remaining space of the RBA. This can occur if the EOBC register is not programmed to a value greater than the largest packet that can be received. When this situation occurs, the packet is truncated and the SONIC-T reads the RRA to obtain another RBA. Indication of an RBA limit being exceeded is signified by the Receive Buffer Area Exceeded (RBAE) interrupt being set (see Section 6.3.6). An RDA will not be set up for the truncated packet and the buffer space will not be re-used. To rectify this potential overflow condition, the EOBC register must be loaded with a value equal to or greater than the largest packet that can be accepted. (See Section 5.4.2.)

### 5.5 TRANSMIT BUFFER MANAGEMENT

To begin transmission, the system software issues the Transmit command (TXP = 1 in the CR). The Transmit Buffer Management uses two areas in memory for transmitting packets (Figure 5-12), the Transmit Descriptor Area (TDA)

and the Transmit Buffer Area (TBA). During transmission, the SONIC-T fetches control information from the TDA, loads its appropriate registers, and then transmits the data from the TBA. When the transmission is complete, the SONIC-T writes the status information in the TDA. From a single transmit command, packets can either be transmitted singly or in groups if several descriptors have been linked together.

TL/F/11719-23

FIGURE 5-12. Overview of Transmit Buffer Management

#### 5.5.1 Transmit Descriptor Area (TDA)

The TDA contains descriptors that the system has generated to exchange status and control information. Each descriptor corresponds to a single packet and consists of the following 16-bit fields.

**TXpkt.status:** This field is written by the SONIC-T and provides status of the transmitted packet. (See Section 5.5.1.2 for more details.)

**TXpkt.config:** This field allows programming the SONIC-T to one of the various transmit modes. The SONIC-T reads this field and loads the corresponding configuration bits (PINTR, POWC, CRCI, and EXDIS) into the Transmit Control register. (See Section 5.5.1.1 for more details.)

**TXpkt.pkt\_size:** This field contains the byte count of the entire packet.

**TXpkt.frag\_count:** This field contains the number of fragments the packet is segmented into.

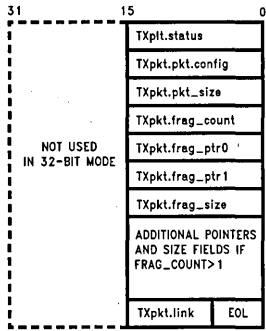

**TXpkt.frag\_ptr0,1:** This field contains a 32-bit pointer which locates the packet fragment to be transmitted in the Transmit Buffer Area (TBA). This pointer is not restricted to any byte alignment.

**TXpkt.frag\_size:** This field contains the byte count of the packet fragment. The minimum fragment size is 1 byte.

**TXpkt.link:** This field contains a 15-bit pointer (A15-A1) to the next TDA descriptor. The LSB, the End Of List (EOL) bit, indicates the last descriptor in the list when set to a "1". When descriptors have been linked together, the SONIC-T transmits back-to-back packets from a single transmit command.

The data of the packet does not need to be contiguous, but can exist in several locations (fragments) in memory. In this case, the TXpkt.frag\_count field is greater than one, and additional TXpkt.frag\_ptr0,1 and TXpkt.frag\_size fields corresponding to each fragment are used. The descriptor format is shown in Figure 5-13. Note that in 32-bit mode the upper word, D<31:16>, is not used.

## 5.0 Buffer Management (Continued)

TL/F/11719-24

FIGURE 5-13. Transmit Descriptor Area

### 5.5.1.1 Transmit Configuration

The TXpkt.config field allows the SONIC-T to be programmed into one of the transmit modes before each transmission. At the beginning of each transmission, the SONIC-T reads this field and loads the PINTR, POWC, CRCI, and EXDIS bits into the Transmit Control Register (TCR). The configuration bits in the TCR correspond directly with the bits in the TXpkt.config field as shown in Figure 5-14. See Section 6.3.4 for the description on the TCR.

15	14	13	12	11	10	9	8
PINTR	POWC	CRCI	EXDIS	X	X	X	X
7	6	5	4	3	2	1	0
X	X	X	X	X	X	X	X

Note: x = don't care

FIGURE 5-14. TXpkt.config Field

### 5.5.1.2 Transmit Status

At the end of each transmission the SONIC-T writes the status bits (<10:0>) of the Transmit Control Register (TCR) and the number of collisions experienced during the transmission into the TXpkt.status field (Figure 5-15, res = reserved). Bits NC4-NC0 indicate the number of collisions where NC4 is the MSB. See Section 6.3.4 for the description of the TCR.

15	14	13	12	11	10	9	8
NC4	NC3	NC2	NC1	NC0	EXD	DEF	NCRS
7	6	5	4	3	2	1	0
CRSL	EXC	OWC	res	PMB	FU	BCM	PTX

FIGURE 5-15. TXpkt.status Field

### 5.5.2 Transmit Buffer Area (TBA)

The TBA contains the fragments of packets that are defined by the descriptors in the TDA. A packet can consist of a single fragment or several fragments, depending upon the fragment count in the TDA descriptor. The fragments also can reside anywhere within the full 32-bit address range, and be aligned to any byte boundary. When an odd byte boundary is given, the SONIC-T automatically begins reading data at the corresponding word boundary in 16-bit mode or a long word boundary in 32-bit mode. The SONIC-T ig-

nores the extraneous bytes which are written into the FIFO during odd byte alignment fragments. The minimum allowed fragment size is 1 byte. Figure 5-12 shows the relationship between the TDA and the TBA for single and multi-fragmented packets.

### 5.5.3 Preparing To Transmit

All fields in the TDA descriptor and the Current Transmit Descriptor Address (CTDA) register of the SONIC-T must be initialized before the Transmit Command (setting the TXP bit in the Command register) can be issued. If more than one packet is queued, the descriptors must be linked together with the TXpkt.link field. The last descriptor must have EOL = 1 and all other descriptors must have EOL = 0. To begin transmission, the system loads the address of the first TXpkt.status field into the CTDA register. Note that the upper 16-bits of address are loaded in the Upper Transmit Descriptor (UTDA) register. The user performs the following transmit initialization.

1. Initialize the TDA
2. Load the CTDA register with the address of the first transmit descriptor
3. Issue the transmit command

Note that if the Source Address of the packet being transmitted is not in the CAM, the Packet Monitored Bad (PMB) bit in the TXpkt.status field will be set (see Section 6.3.4).

#### 5.5.3.1 Transmit Process

When the Transmit Command (TXP = 1 in the Command register) is issued, the SONIC-T fetches the control information in the TDA descriptor, loads its appropriate registers (shown below) and begins transmission. (See Section 6.2 for register mnemonics.)

- TCR ← TXpkt.config
- TPS ← TXpkt.pkt\_size
- TFC ← TXpkt.frag\_count
- TSA0 ← TXpkt.frag\_ptr0
- TSA1 ← TXpkt.frag\_ptr1
- TFS ← TXpkt.frag\_size
- CTDA ← TXpkt.link

(CTDA is loaded after all fragments have been read and successfully transmitted. If the halt transmit command is issued (HTX bit in the Command register is set) the CTDA register is not loaded.)

During transmission, the SONIC-T reads the packet descriptor in the TDA and transmits the data from the TBA. If TXpkt.frag\_count is greater than one, the SONIC-T, after finishing transmission of the fragment, fetches the next TXpkt.frag\_ptr0,1 and TXpkt.frag\_size fields and transmits the next fragment. This process continues until all fragments of a packet are transmitted. At the end of packet transmission, status is written in to the TXpkt.status field. The SONIC-T then reads the TXpkt.link field and checks if EOL = 0. If it is "0", the SONIC-T fetches the next descriptor and transmits the next packet. If EOL = 1 the SONIC-T generates a "Transmission Done" indication in the Interrupt Status register and resets the TXP bit in the Command register.

In the event of a collision, the SONIC-T recovers its pointer in the TDA and retransmits the packet up to 15 times. The SONIC-T maintains a copy of the CTDA register in the Temporary Transmit Descriptor Address (TTDA) register.

## 5.0 Buffer Management (Continued)

The SONIC-T performs a block operation of 6, 3, or 2 accesses in the TDA, depending on where the SONIC-T is in the transmit process. For the first fragment, it reads the TXpkt.config to TXpkt.frag\_size (6 accesses). For the next fragment, if any, it reads the next 3 fields from TXpkt.frag\_ptr0 to TXpkt.frag\_size (3 accesses). At the end of transmission it writes the status information to TXpkt.status and reads the TXpkt.link field (2 accesses).

### 5.5.3.2 Transmit Completion

The SONIC-T stops transmitting under two conditions. In the normal case, the SONIC-T transmits the complete list of descriptors in the TDA and stops after it detects EOL = 1. In the second case, certain transmit errors cause the SONIC-T to abort transmission. If *FIFO Underrun*, *Byte Count Mismatch*, *Excessive Collision*, or *Excessive Deferral* (if enabled) errors occur, transmission ceases. The CTDA register points to the last packet transmitted. The system can also halt transmission under software control by setting the HTX bit in the Command register. Transmission halts after the SONIC-T writes to the TXpkt.status field.

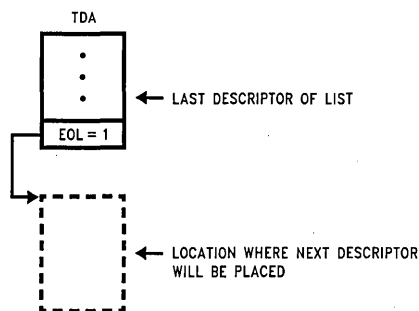

### 5.5.4 Dynamically Adding TDA Descriptors

Descriptors can be dynamically added during transmission without halting the SONIC-T. The SONIC-T can also be guaranteed to transmit the complete list including newly appended descriptors (barring any transmit abort conditions) by observing the following rule: The last TXpkt.link field must point to the next location where a descriptor will be added (see step 3 below and *Figure 5-16*).

The procedure for appending descriptors consists of:

1. Creating a new descriptor with its TXpkt.link pointing to the next vacant descriptor location and its EOL bit set to a "1".
2. Resetting the EOL bit to a "0" of the previously last descriptor.
3. Re-issuing the Transmit command (setting the TXP bit in the Command register).

Step 3 assures that the SONIC-T will transmit all the packets in the list. If the SONIC-T is currently transmitting, the Transmit command has no effect and continues transmitting until it detects EOL = 1. If the SONIC-T had just finished transmitting, it continues transmitting from where it had previously stopped.

TL/F/11719-25

FIGURE 5-16. Initializing Last Link Field

## 6.0 SONIC-T Registers

The SONIC-T contains two sets of registers: The status/control registers and the CAM memory cells. The status/control registers are used to configure, control, and monitor SONIC-T operation. They are directly addressable registers and occupy 64 consecutive address locations in the system memory space (selected by the RA5-RA0 address pins). There are a total of 64 status/control registers divided into the following categories:

**User Registers:** These registers are accessed by the user to configure, control, and monitor SONIC-T operation. These are the only SONIC-T registers the user needs to access. *Figure 6-3* shows the programmer's model and *Table 6-1* lists the attributes of each register.

**Internal Use Registers:** These registers (*Table 6-2*) are used by the SONIC-T during normal operation and are not intended to be accessed by the user.

**National Factory Test Registers:** These registers (*Table 6-3*) are for National factory use only and should never be accessed by the user. Accessing these registers during normal operation can cause improper functioning of the SONIC-T.

### 6.1 THE CAM UNIT

The CAM unit memory cells are indirectly accessed by programming the CAM descriptor area in system memory and issuing the LCAM command (setting the LCAM bit in the Control register). The CAM cells do not occupy address locations in register space and, thus, are not accessible through the RA5-RA0 address pins. The CAM control registers, however, are part of the user register set and must be initialized before issuing the LCAM command (see *Section 6.3.10*).

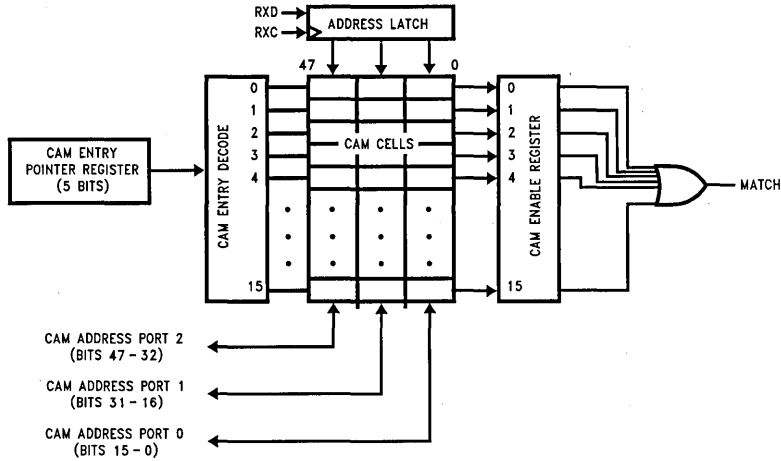

The Content Addressable Memory (CAM) consists of sixteen 48-bit entries for complete address filtering (*Figure 6-1*) of network packets. Each entry corresponds to a 48-bit destination address that is user programmable and can contain any combination of Multicast or Physical addresses. Each entry is partitioned into three 16-bit CAM cells accessible through CAM Address Ports (CAP2, CAP1 and CAP0) with CAP0 corresponding to the least significant 16 bits of the Destination Address and CAP2 corresponding to the most significant bits. The CAM is accessed in a two step process. First, the CAM Entry Pointer is loaded to point to one of the 16 entries. Then, each of the CAM Address Ports is accessed to select the CAM cell. The 16 user programmable CAM entries can be masked out with the CAM Enable register (see *Section 6.3.10*).

**Note:** It is not necessary to program a broadcast address into the CAM when it is desired to accept broadcast packets. Instead, to accept broadcast packets, set the BRD bit in the Receive Control register. If the BRD bit has been set, the CAM is still active. This means that it is possible to accept broadcast packets at the same time as accepting packets that match physical addresses in the CAM.

#### 6.1.1 The Load CAM Command

Because the SONIC-T uses the CAM for a relatively long period of time during reception, it can only be written to via the CAM Descriptor Area (CDA) and is only readable when

## 6.0 SONIC-T Registers (Continued)

TL/F/11719-26

FIGURE 6-1. CAM Organization

the SONIC-T is in software reset. The CDA resides in the same 64k byte block of memory as the Receive Resource Area (RRA) and contains descriptors for loading the CAM registers. These descriptors are contiguous and each descriptor consists of four 16-bit fields (Figure 6-2). In 32-bit mode the upper word,  $D < 31:16 >$ , is not used. The first field contains the value to be loaded into the CAM Entry Pointer and the remaining fields are for the three CAM Address Ports (see Section 6.3.10). In addition, there is one more field after the last descriptor containing the mask for the CAM Enable register. Each of the CAM descriptors are addressed by the CAM Descriptor Pointer (CDP) register.

After the system has initialized the CDA, it can issue the Load CAM command to program the SONIC-T to read the CDA and load the CAM. The procedure for issuing the Load CAM command is as follows.

1. Initialize the Upper Receive Resource Address (URRA) register. Note that the CAM Descriptor Area must reside within the same 64k page as the Receive Resource Area. (See Section 6.3.9.)

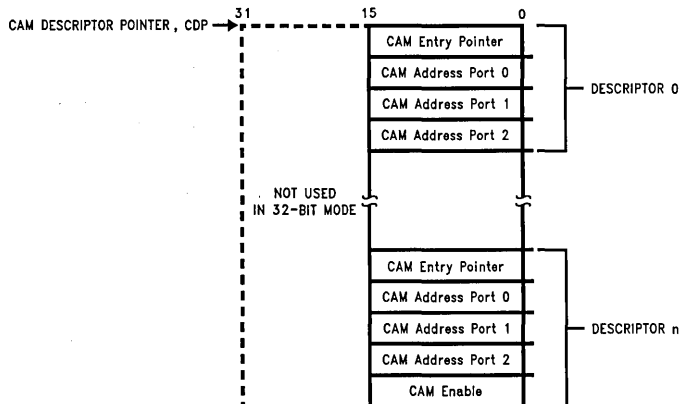

2. Initialize the CDA as described above.

3. Initialize the CAM Descriptor Count with the number of CAM descriptors. Note, only the lower 5 bits are used in this register. The other bits are don't cares. (See Section 6.3.10.)

4. Initialize the CAM Descriptor Pointer to locate the first descriptor in the CDA. This register must be reloaded each time a new Load CAM command is issued.

5. Issue the Load CAM command (LCAM) in the Command register. (See Section 6.3.1.)

If a transmission or reception is in progress, the CAM DMA function will not occur until these operations are complete. When the SONIC-T completes the Load CAM command, the CDP register points to the next location after the CAM enable field and the CDC equals zero. The SONIC-T resets the LCAM bit in the Command register and sets the Load CAM Done (LCD) bit in the ISR.

## 6.0 SONIC-T Registers (Continued)

### 6.2 STATUS/CONTROL REGISTERS

This set of registers is used to convey status/control information to/from the host system and to control the operation of the SONIC-T. These registers are used for loading commands generated from the system, indicating transmit and receive status, buffering data to/from memory, and provid-

ing interrupt control. The registers are selected by asserting chip select to the SONIC-T and providing the necessary address on register address pins RA5-RA0. Tables 6-1, 6-2, and 6-3 show the locations of all SONIC-T registers and where information on the registers can be found in the data sheet.

**TABLE 6-1. User Registers**

**Note 1:** These registers can only be read when the SONIC-T is in reset mode (RST bit in the CR is set). The SONIC-T gives invalid data when these registers are read in non-reset mode.

**Note 2:** This register can only be written to when the SONIC-T is in reset mode. This register is normally only loaded by the Load CAM command.

**Note 3:** The Data Configuration registers, DCR and DCR2, can only be written to when the SONIC-T is in reset mode (RST bit in CR is set). Writing to these registers while not in reset mode does not alter the registers.

**Note 4:** The data written to these registers is inverted before being latched. That is, if a value of FFFFh is written, these registers will contain and read back the value of 0000h. Data is not inverted during a read operation.

**TABLE 6-2. Internal Use Registers (Users should not write to these registers)**

## 6.0 SONIC-T Registers (Continued)

### 6.3 REGISTER DESCRIPTION

#### 6.3.1 Command Register

(RA <5:0> = 0h)

This register (Figure 6-4) is used for issuing commands to the SONIC-T. These commands are issued by setting the corresponding bits for the function. For all bits, except for the RST bit, the SONIC-T resets the bit after the command is completed. With the exception of RST, writing a "0" to any bit has no effect. Before any commands can be issued, the RST bit must first be reset to "0". This means that, if the RST bit is set, two writes to the Command Register are required to issue a command to the SONIC-T; one to clear the RST bit, and one to issue the command.

This register also controls the general purpose 32-bit Watchdog Timer. After the Watchdog Timer register has been loaded, it begins to decrement once the ST bit has been set to "1". An interrupt is issued when the count reaches zero if the Timer Complete interrupt is enabled in the IMR.

During hardware reset, bits 7, 4, and 2 are set to a "1"; all others are cleared. During software reset bits 9, 8, 1, and 0 are cleared and bits 7 and 2 are set to a "1"; all others are unaffected.

r = read only, r/w = read/write

**FIGURE 6-4. Command Register**

Field	Meaning
LCAM	LOAD CAM
RRRA	READ RRA
RST	SOFTWARE RESET
ST	START TIMER
STP	STOP TIMER
RXEN	RECEIVER ENABLE
RXDIS	RECEIVER DISABLE
TXP	TRANSMIT PACKET(S)
HTX	HALT TRANSMISSION

Bit	Description
15-10	<b>Must be 0</b>
9	<p><b>LCAM: LOAD CAM</b> Setting this bit causes the SONIC-T to load the CAM with the descriptor that is pointed to by the CAM Descriptor Pointer register.</p> <p><i>Note:</i> This bit must not be set during transmission (TXP is set). The SONIC-T will lock up if both bits are set simultaneously.</p>
8	<p><b>RRRA: READ RRA</b> Setting this bit causes the SONIC-T to read the next RRA descriptor pointed to by the Resource Read Pointer (RRP) register. Generally this bit is only set during initialization. Setting this bit during normal operation can cause improper receive operation.</p>
7	<p><b>RST: SOFTWARE RESET</b> Setting this bit resets all internal state machines. The CRC generator is disabled and the Tally counters are halted, but not cleared. The SONIC-T becomes operational when this bit is reset to "0". A hardware reset sets this bit to a "1". It must be reset to "0" before the SONIC-T becomes operational.</p>
6	<b>Must be 0</b>
5	<p><b>ST: START TIMER</b> Setting this bit enables the general-purpose watchdog timer to begin counting or to resume counting after it has been halted. This bit is reset when the timer is halted (i.e., STP is set). Setting this bit resets STP.</p>
4	<p><b>STP: STOP TIMER</b> Setting this bit halts the general-purpose watchdog timer and resets the ST bit. The timer resumes when the ST bit is set. This bit powers up as a "1". <i>Note:</i> Simultaneously setting bits ST and STP stops the timer.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.1 Command Register (Continued)

Bit	Description
3	<p><b>RXEN: RECEIVER ENABLE</b></p> <p>Setting this bit enables the receive buffer management engine to begin buffering data to memory. Setting this bit resets the RXDIS bit. Note: If this bit is set while the MAC unit is currently receiving a packet, both RXEN and RXDIS are set until the network goes inactive (i.e., the SONIC-T will not start buffering in the middle of a packet being received). When both RXEN and RXDIS are set, RXEN could be cleared by writing zero to it.</p>
2	<p><b>RXDIS: RECEIVER DISABLE</b></p> <p>Setting this bit disables the receiver from buffering data to memory or the Receive FIFO. If this bit is set during the reception of a packet, the receiver is disabled only after the packet is processed. The RXEN bit is reset when the receiver is disabled. Tally counters remain active regardless of the state of this bit.</p> <p><b>Note:</b> If this bit is set while the SONIC-T is currently receiving a packet, both RXEN and RXDIS are set until the packet is fully received. When both RXEN and RXDIS are set, RXDIS could be cleared by writing zero to it.</p>
1	<p><b>TXP: TRANSMIT PACKET(S)</b></p> <p>Setting this bit causes the SONIC-T to transmit packets which have been set up in the Transmit Descriptor Area (TDA). The SONIC-T loads its appropriate registers from the TDA, then begins transmission. The SONIC-T clears this bit after any of the following conditions have occurred: (1) transmission had completed (i.e., after the SONIC-T has detected EOL = 1), (2) the Halt Transmission command (HTX) has taken effect, or (3) a transmit abort condition has occurred. This condition occurs when any of the following bits in the TCR have been set: EXC, EXD, FU, or BCM. This bit must not be set if a Load CAM operation is in progress (LCAM is set). The SONIC-T will lock up if both bits are set simultaneously.</p>
0	<p><b>HTX: HALT TRANSMISSION</b></p> <p>Setting this bit halts the transmit command after the current transmission has completed. TXP is reset after transmission has halted. The Current Transmit Descriptor Address (CTDA) register points to the last descriptor transmitted. The SONIC-T samples this bit after writing to the Txpkt.status field.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.2 Data Configuration Register

(RA<5:0> = 1h)

This register (*Figure 6-5*) establishes the bus cycle options for reading/writing data to/from 16- or 32-bit memory systems. During a hardware reset, bits 15 and 13 are cleared; all other bits are unaffected. (Because of this, the first thing the driver software does to the SONIC-T should be to set up this register.) All bits are unaffected by a software reset. This register must only be accessed when the SONIC-T is in reset mode (i.e., the RST bit is set in the Command register).

r = read only, r/w = read/write

**FIGURE 6-5. Data Configuration Register**

Field	Meaning
EXBUS	EXTENDED BUS MODE
LBR	LATCHED BUS RETRY
PO0,PO1	PROGRAMMABLE OUTPUTS
SBUS	SYNCHRONOUS BUS MODE
USR0, USR1	USER DEFINABLE PINS
WC0, WC1	WAIT STATE CONTROL
DW	DATA WIDTH SELECT
BMS	BLOCK MODE SELECT FOR DMA
RFT0, RFT1	RECEIVE FIFO THRESHOLD
TFT0, TFT1	TRANSMIT FIFO THRESHOLD

Bit	Description
15	<p><b>EXBUS: EXTENDED BUS MODE</b></p> <p>Setting this bit enables the Extended Bus mode which enables the following:</p> <ol style="list-style-type: none"> <li>1. Extended Programmable Outputs, EXUSR &lt;3:0&gt;: This changes the TXD, LBK, RXC and RXD pins from the external ENDEC interface into four programmable user outputs, EXUSR &lt;3:0&gt; respectively, which are similar to USR &lt;1:0&gt;. These outputs are programmed with bits 15-12 in the DCR2 (see Section 6.3.7). On hardware reset, these four pins will be TRI-STATE and will remain that way until the DCR is changed. If EXBUS is enabled, then these pins will remain TRI-STATE until the SONIC-T becomes a bus master, at which time they will be driven according to the DCR2. If EXBUS is disabled, then these four pins work normally as external ENDEC interface pins.</li> <li>2. Synchronous Termination, STERM: This changes the TXC pin from the External ENDEC interface into a synchronous memory termination input for compatibility with Motorola style processors. This input is only useful when Asynchronous Bus mode is selected (bit 10 below is set to "0") and the Bus Mode is set to Motorola Mode (BMODE = 1). On hardware reset, this pin will be TRI-STATE and will remain that way until the DCR is changed. If EXBUS is enabled, this pin will remain TRI-STATE until the SONIC-T becomes a bus master, at which time it will become the STERM input. If EXBUS is disabled, then this pin works normally as the TXC pin for the external ENDEC interface.</li> <li>3. Asynchronous Bus Retry: Causes <math>\overline{BRT}</math> to be clocked in asynchronously off the falling edge of bus clock. This only applies, however, when the SONIC-T is operating in asynchronous mode (bit 10 below is set to "0"). If EXBUS is not set, XTO (BRT) is sampled synchronously off the rising edge of bus clock.</li> </ol>
14	Must be 0.
13	<p><b>LBR: LATCHED BUS RETRY</b></p> <p>The LBR bit controls the mode of operation of the <math>\overline{BRT}</math> signal (see pin description, Section 2.0). It allows the BUS Retry operation to be latched or unlatched.</p> <p>0: Unlatched mode: The assertion of <math>\overline{BRT}</math> forces the SONIC-T to finish the current DMA operation and get off the bus. The SONIC-T will retry the operation when <math>\overline{BRT}</math> is deasserted.</p> <p>1: Latched mode: The assertion of <math>\overline{BRT}</math> forces the SONIC-T to finish the current DMA operation as above, however, the SONIC-T will not retry until <math>\overline{BRT}</math> is deasserted and the BR bit in the ISR (see Section 6.3.6) has been reset and <math>\overline{BRT}</math> is deasserted. Hence, the mode has been latched on until the BR bit is cleared.</p> <p><b>Note:</b> Unless LBR is set to a "1", <math>\overline{BRT}</math> must remain asserted at least until the SONIC-T has gone idle. See sec. 7.3.6.</p>
12, 11	<p><b>PO1,PO0: PROGRAMMABLE OUTPUTS</b></p> <p>The PO1,PO0 bits individually control the USR1,0 pins respectively when SONIC-T is a bus master (HLDA or <math>\overline{BGACK}</math> is active). When PO1/PO0 are set to a 1 the USR1/USR0 pins are high during bus master operations and when these bits are set to a 0 the USR1/USR0 pins are low during bus master operations.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.2 Data Configuration Register (Continued)

Bit	Description															
10	<p><b>SBUS: SYNCHRONOUS BUS MODE</b></p> <p>The SBUS bit is used to select the mode of system bus operation when SONIC-T is a bus master. This bit selects the internal ready line to be either a synchronous or asynchronous input to SONIC-T during block transfer DMA operations.</p> <p>0: Asynchronous mode. <math>\overline{RDY}_i</math> (BMODE = 0) or <math>\overline{DSACK0}_i</math> (BMODE = 1) are respectively internally synchronized at the falling edge of the bus clock (T2 of the DMA cycle). No setup or hold times need to be met with &lt;S2–S5&gt; respect to this edge to guarantee proper bus operation. The minimum memory cycle time is 3 bus clocks.</p> <p>1: Synchronous mode. <math>\overline{RDY}_i</math> (BMODE = 0) and <math>\overline{DSACK0}_i</math> (BMODE = 1) must respectively meet the setup and &lt;S2–S5&gt; hold times with respect to the rising edge of T1 or T2 to guarantee proper bus operation.</p>															
9, 8	<p><b>USR1,0: USER DEFINABLE PINS</b></p> <p>The USR1,0 bits report the level of the USR1,0 signal pins, respectively, after a chip hardware reset. If the USR1,0 signal pins are at a logical 1 (tied to <math>V_{CC}</math>) during a hardware reset the USR1,0 bits are set to a 1. If the USR1,0 pins are at a logical 0 (tied to ground) during a hardware reset the USR1,0 bits are set to a 0. These bits are latched on the rising edge of <math>\overline{RST}</math>. Once set they remain set/reset until the next hardware reset.</p>															
7, 6	<p><b>WC1,0: WAIT STATE CONTROL</b></p> <p>These encoded bits determine the number of additional bus cycles (T2 states) that are added during each DMA cycle.</p> <table border="1"> <thead> <tr> <th>WC1</th> <th>WC0</th> <th>Bus Cycles Added</th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>0</td> </tr> <tr> <td>0</td> <td>1</td> <td>1</td> </tr> <tr> <td>1</td> <td>0</td> <td>2</td> </tr> <tr> <td>1</td> <td>1</td> <td>3</td> </tr> </tbody> </table>	WC1	WC0	Bus Cycles Added	0	0	0	0	1	1	1	0	2	1	1	3

1	0	12 words or 6 long words (24 bytes)														
1	1	14 words or 7 long words (28 bytes)														

## 6.0 SONIC-T Registers (Continued)

### 6.3.3 Receive Control Register

(RA<5:0> = 2h)

This register is used to filter incoming packets and provide status information of accepted packets (Figure 6-6). Setting any of bits 15–11 to a “1” enables the corresponding receive filter. If none of these bits are set, only packets which match the CAM Address registers are accepted. Bits 10 and 9 control the loopback operations.

After reception, bits 8–0 indicate status information about the accepted packet and are set to “1” when the corresponding condition is true. If the packet is accepted, all bits in the RCR are written into the RXpkt.status field. Bits 8–6 and 3–0 are cleared at the reception of the next packet.

This register is unaffected by a software reset.

**FIGURE 6-6. Receive Control Register**

Field	Meaning
ERR	ACCEPT PACKET WITH ERRORS
RNT	ACCEPT RUNT PACKETS
BRD	ACCEPT BROADCAST PACKETS
PRO	PHYSICAL PROMISCUOUS PACKETS
AMC	ACCEPT ALL MULTICAST PACKETS
LB0, LB1	LOOPBACK CONTROL
MC	MULTICAST PACKET RECEIVED
BC	BROADCAST PACKET RECEIVED
LPKT	LAST PACKET IN RBA
CRS	CARRIER SENSE ACTIVITY
COL	COLLISION ACTIVITY
CRCR	CRC ERROR
FAER	FRAME ALIGNMENT ERROR
LBK	LOOPBACK PACKET RECEIVED
PRX	PACKET RECEIVED OK

Bit	Description
15	<b>ERR: ACCEPT PACKET WITH CRC ERRORS OR COLLISIONS</b> 0: Reject all packets with CRC errors or when a collision occurs. 1: Accept packets with CRC errors and ignore collisions.
14	<b>RNT: ACCEPT RUNT PACKETS</b> 0: Normal address match mode. 1: Accept runt packets (packets less than 64 bytes in length). <i>Note:</i> A hardware reset clears this bit.
13	<b>BRD: ACCEPT BROADCAST PACKETS</b> 0: Normal address match mode. 1: Accept broadcast packets (packets with addresses that match the CAM are also accepted). <i>Note:</i> This bit is cleared upon hardware reset.
12	<b>PRO: PHYSICAL PROMISCUOUS MODE</b> Enable all Physical Address packets to be accepted. 0: normal address match mode. 1: promiscuous mode.
11	<b>AMC: ACCEPT ALL MULTICAST PACKETS</b> 0: normal address match mode. 1: enables all multicast packets to be accepted. Broadcast packets are also accepted regardless of the BRD bit. (Broadcast packets are a subset of multicast packets.)

## 6.0 SONIC-T Registers (Continued)

### 6.3.3 Receive Control Register (Continued)

Bit	Description															
10, 9	<p><b>LB1, LB0: LOOPBACK CONTROL</b>            These encoded bits control loopback operations for MAC loopback, ENDEC loopback and Transceiver lookback. For proper loopback operation, the CAM Address registers and Receive Control register must be initialized to accept the Destination address of the loopback packet (see Section 3.8).</p> <table border="1"> <thead> <tr> <th>LB1</th> <th>LB0</th> <th>Function</th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>no loopback, normal operation</td> </tr> <tr> <td>0</td> <td>1</td> <td>MAC loopback</td> </tr> <tr> <td>1</td> <td>0</td> <td>ENDEC loopback</td> </tr> <tr> <td>1</td> <td>1</td> <td>Transceiver loopback (Bit #6 of the DCR2 must also be set to 1)</td> </tr> </tbody> </table>	LB1	LB0	Function	0	0	no loopback, normal operation	0	1	MAC loopback	1	0	ENDEC loopback	1	1	Transceiver loopback (Bit #6 of the DCR2 must also be set to 1)
LB1	LB0	Function														
0	0	no loopback, normal operation														
0	1	MAC loopback														
1	0	ENDEC loopback														
1	1	Transceiver loopback (Bit #6 of the DCR2 must also be set to 1)														
8	<p><b>MC: MULTICAST PACKET RECEIVED</b>            This bit is set when a packet is received with a Multicast Address.</p>															
7	<p><b>BC: BROADCAST PACKET RECEIVED</b>            This bit is set when a packet is received with a Broadcast Address.</p>															
6	<p><b>LPKT: LAST PACKET IN RBA</b>            This bit is set when the last packet is buffered into a Receive Buffer Area (RBA). The SONIC-T detects this condition when its Remaining Buffer Word Count (RBWC0,1) register is less than or equal to the End Of Buffer Count (EOBC) register. (See Section 5.4.2.)</p>															
5	<p><b>CRS: CARRIER SENSE ACTIVITY</b>            Set when CRS is active. Indicates the presence of network activity.</p>															
4	<p><b>COL: COLLISION ACTIVITY</b>            Indicates that the packet received had a collision occur during reception.</p>															
3	<p><b>CRCR: CRC ERROR</b>            Indicates the packet contains a CRC error. If the packet also contains a Frame Alignment error, FAER will be set instead (see below).</p>															
2	<p><b>FAER: FRAME ALIGNMENT ERROR</b>            Indicates that the incoming packet was not correctly framed on an 8-bit boundary. Note: if no CRC errors have occurred, this bit is not set (i.e., this bit is only set when both a frame alignment and CRC errors occur).</p>															
1	<p><b>LBK: LOOPBACK PACKET RECEIVED</b>            Indicates that the SONIC-T has successfully received a loopback packet.</p>															
0	<p><b>PRX: PACKET RECEIVED OK</b>            Indicates that a packet has been received without CRC, frame alignment, length (run packet) errors or collisions.</p>															

## 6.0 SONIC-T Registers (Continued)

### 6.3.4 Transmit Control Register

(RA <5:0> = 3h)

This register is used to program the SONIC-T's transmit actions and provide status information after a packet has been transmitted (*Figure 6-7*). At the beginning of transmission, bits 15, 14, 13 and 12 from the TXpkt.config field are loaded into the TCR to configure the various transmit modes (see Section 5.5.1.1). When the transmission ends, bits 10–0 indicate status information and are set to a "1" when the corresponding condition is true. These bits, along with the number of collisions information, are written into the TXpkt.status field at the end of transmission (see Section 5.5.1.2). Bits 9 and 5 are cleared after the TXpkt.status field has been written. Bits 10, 7, 6, and 1 are cleared at the commencement of the next transmission while bit 8 is set at this time.

A hardware reset sets bits 8 and 0 to a "1", and bit 1 to a "0". ∴ This register is unaffected by a software reset.

r = read only, r/w = read/write

**FIGURE 6-7. Transmit Control Register**

Field	Meaning
PINT	PROGRAMMABLE INTERRUPT
POWC	PROGRAMMED OUT OF WINDOW COLLISION TIMER
CRCI	CRC INHIBIT
EXDIS	DISABLE EXCESSIVE DEFERRAL TIMER
EXD	EXCESSIVE DEFERRAL
DEF	DEFERRED TRANSMISSION
NCRS	NO CRS
CRSL	CRS LOST
EXC	EXCESSIVE COLLISIONS
OWC	OUT OF WINDOW COLLISION
PMB	PACKET MONITORED BAD
FU	FIFO UNDERRUN
BCM	BYTE COUNT MISMATCH
PTX	PACKET TRANSMITTED OK

Bit	Description
15	<p><b>PINTR: PROGRAMMABLE INTERRUPT</b></p> <p>This bit allows transmit interrupts to be generated under software control. The SONIC-T will issue an interrupt (PINT in the Interrupt Status Register) immediately after reading a TDA and detecting that PINT is set in the TXpkt.config field.</p> <p><b>Note:</b> In order for PINT to operate properly, it must be set and reset in the TXpkt.config field by alternating TDAs. This is necessary because after PINT has been issued in the ISR, PINT in the Transmit Control Register must be cleared before it is set again in order to have the interrupt issued for another packet. The only effective way to do this is to set PINT to a 1 no more often than every other packet.</p>
14	<p><b>POWC: PROGRAM "OUT OF WINDOW COLLISION" TIMER</b></p> <p>This bit programs when the out of window collision timer begins.</p> <p>0: timer begins after the Start of Frame Delimiter (SFD).</p> <p>1: timer begins after the first bit of preamble.</p>
13	<p><b>CRCI: CRC INHIBIT</b></p> <p>0: transmit packet with 4-byte FCS field</p> <p>1: transmit packet without 4-byte FCS field</p>
12	<p><b>EXDIS: DISABLE EXCESSIVE DEFERRAL TIMER:</b></p> <p>0: excessive deferral timer enabled</p> <p>1: excessive deferral timer disabled</p>
11	Must be 0.
10	<p><b>EXD: EXCESSIVE DEFERRAL</b></p> <p>Indicates that the SONIC-T has been deferring for 3.2 ms. The transmission is aborted if the excessive deferral timer is enabled (i.e., EXDIS is reset). This bit can only be set if the excessive deferral timer is enabled.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.4 Transmit Control Register (Continued)

Bit	Description
9	<p><b>DEF: DEFERRED TRANSMISSION</b></p> <p>Indicates that the SONIC-T has deferred its transmission during the first attempt. If subsequent collisions occur, this bit is reset. This bit is cleared after the TXpkt.status field is written in the TDA.</p>
8	<p><b>NCRS: NO CRS</b></p> <p>Indicates that Carrier Sense (CRS) was not present during transmission. CRS is monitored from the beginning of the Start of Frame Delimiter to the last byte transmitted. The transmission will not be aborted. This bit is set at the start of preamble and is reset if CRS is detected. Hence, if CRS is never detected throughout the entire transmission of the packet, this bit will remain set.</p> <p><b>Note:</b> NCRS will always remain set in MAC loopback as long as there is no activity on the RX ±.</p>
7	<p><b>CRSL: CRS LOST</b></p> <p>Indicates that CRS has gone low or has not been present during transmission. CRS is monitored from the beginning of the Start of Frame Delimiter to the last byte transmitted. The transmission will not be aborted.</p> <p><b>Note:</b> if CRS was never present, both NCRS and CRSL will be set simultaneously. Also, CRSL will always be set in MAC loopback.</p>
6	<p><b>EXC: EXCESSIVE COLLISIONS</b></p> <p>Indicates that 16 collisions have occurred. The transmission is aborted.</p>
5	<p><b>OWC: OUT OF WINDOW COLLISION</b></p> <p>Indicates that an illegal collision has occurred after 51.2 μs (one slot time) from either the first bit of preamble or from SFD depending upon the POWC bit. The transmission backs off as in a normal transmission. This bit is cleared after the TXpkt.status field is written in the TDA.</p>
4	Must be 0.
3	<p><b>PMB: PACKET MONITORED BAD</b></p> <p>This bit is set, if after the receive unit has monitored the transmitted packet, the CRC has been calculated as invalid as a result of a Frame Alignment error, or the Source Address does not match any of the CAM address registers.</p> <p><b>Note 1:</b> The SONIC-T's CRC checker is active during transmission.</p> <p><b>Note 2:</b> If CRC has been inhibited for transmissions (CRCI is set), this bit will always be low. This is true regardless of Frame Alignment or Source Address mismatch errors.</p> <p><b>Note 3:</b> If a Receive FIFO overrun has occurred, the transmitted packet is not monitored completely. Thus, if PMB is set along with the RFO bit in the ISR, then PMB has no meaning. The packet must be completely received before PMB has meaning.</p> <p><b>Note 4:</b> This bit is always zero in loopback mode. (True for all three types of loopback mode.)</p>
2	<p><b>FU: FIFO UNDERRUN</b></p> <p>Indicates that the SONIC-T has not been able to access the bus before the FIFO has emptied. This condition occurs from excessive bus latency and/or slow bus clock. The transmission is aborted. (See Section 3.5.2.)</p>
1	<p><b>BCM: BYTE COUNT MISMATCH</b></p> <p>This bit is set when the SONIC-T detects that the TXpkt.pkt_size field is not equal to the sum of the TXpkt.frag_size field(s). Transmission is aborted. This bit will also be set when Excessive Collisions (bit 6 of the transmit control register) occur during transmission.</p>
0	<p><b>PTX: PACKET TRANSMITTED OK</b></p> <p>Indicates that a packet has been transmitted without the following errors:</p> <ul style="list-style-type: none"> <li>—Excessive Collisions (EXC)</li> <li>—Excessive Deferral (EXD)</li> <li>—FIFO Underrun (FU)</li> <li>—Byte Count Mismatch (BCM)</li> </ul>

## 6.0 SONIC-T Registers (Continued)

### 6.3.5 Interrupt Mask Register

(RA<5:0> = 4h)

This register masks the interrupts that can be generated from the ISR (Figure 6-8). Writing a "1" to the bit enables the corresponding interrupt. During a hardware reset, all mask bits are cleared.

15	<b>Must be 0</b>
14	<b>BREN: BUS RETRY OCCURRED enable:</b> 0: disable 1: enables interrupts when a Bus Retry operation is requested.
13	<b>HBLEN: HEARTBEAT LOST enable:</b> 0: disable 1: enables interrupts when a heartbeat lost condition occurs.
12	<b>LCDEN: LOAD CAM DONE INTERRUPT enable:</b> 0: disable 1: enables interrupts when the Load CAM command has finished.
11	<b>PINTEN: PROGRAMMABLE INTERRUPT enable:</b> 0: disable 1: enables programmable interrupts to occur when the PINT bit the TXpkt.config field is set to a "1".
10	<b>PRXEN: PACKET RECEIVED enable:</b> 0: disable 1: enables interrupts for packets accepted.
9	<b>PTXEN: PACKET TRANSMITTED OK enable:</b> 0: disable 1: enables interrupts for transmit completions.
8	<b>TXEREN: TRANSMIT ERROR enable:</b> 0: disable 1: enables interrupts for packets transmitted with error.

## 6.0 SONIC-T Registers (Continued)

### 6.3.5 Interrupt Mask Register (Continued)

Bit	Description
7	<b>TCEN: GENERAL PURPOSE TIMER COMPLETE enable:</b> 0: disable 1: enables interrupts when the general purpose timer has rolled over from 0000 0000h to FFFF FFFFh.
6	<b>RDEEN: RECEIVE DESCRIPTORS EXHAUSTED enable:</b> 0: disable 1: enables interrupts when all receive descriptors in the RDA have been exhausted.
5	<b>RBEEN: RECEIVE BUFFERS EXHAUSTED enable:</b> 0: disable 1: enables interrupts when all resource descriptors in the RRA have been exhausted.
4	<b>RBAEEN: RECEIVE BUFFER AREA EXCEEDED enable:</b> 0: disable 1: enables interrupts when the SONIC-T attempts to buffer data beyond the end of the Receive Buffer Area.
3	<b>CRGEN: CRC TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the CRC tally counter has rolled over from FFFFh to 0000h.
2	<b>FAEEN: FRAME ALIGNMENT ERROR (FAE) TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the FAE tally counter rolled over from FFFFh to 0000h.
1	<b>MPEN: MISSED PACKET (MP) TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the MP tally counter has rolled over from FFFFh to 0000h.
0	<b>RFOEN: RECEIVE FIFO OVERRUN enable:</b> 0: disable 1: enables interrupts when the receive FIFO has overrun.

## 6.0 SONIC-T Registers (Continued)

### 6.3.6 Interrupt Status Register

(RA<5:0> = 5h)

This register (*Figure 6-9*) indicates the source of an interrupt when the INT pin goes active. Enabling the corresponding bits in the IMR allows bits in this register to produce an interrupt. When an interrupt is active, one or more bits in this register are set to a "1". A bit is cleared by writing "1" to it. Writing a "0" to any bit has no effect.

This register is cleared by a hardware reset and unaffected by a software reset.

PINT	PROGRAMMABLE INTERRUPT
PKTRX	PACKET RECEIVED
TXDN	TRANSMISSION DONE
TXER	TRANSMIT ERROR
TC	TIMER COMPLETE
RDE	RECEIVE DISCRIPTORS EXHAUSTED
RBE	RECEIVE BUFFERS EXHAUSTED
RBAE	RECEIVE BUFFER AREA EXCEEDED
CRC	CRC TALLY COUNTER ROLLOVER
FAE	FRAME ALIGNMENT ERROR
MP	MISSED PACKET COUNTER ROLLOVER
RFO	RECEIVE FIFO OVERRUN

Bit	Description
15	<b>Must be 0</b>
14	<p><b>BR: BUS RETRY OCCURRED</b></p> <p>Indicates that a Bus Retry (BRT) operation has occurred. In Latched Bus Retry mode (LBR in the DCR), BR will only be set when the SONIC-T is a bus master. Before the SONIC-T will continue any DMA operations, BR must be cleared. In Unlatched mode, the BR bit should be cleared also, but the SONIC-T will not wait for BR to be cleared before requesting the bus again and continuing its DMA operations. (See Sections 6.3.2 and 7.3.6 for more information on Bus Retry.)</p>
13	<p><b>HBL: CD HEARTBEAT LOST</b></p> <p>If the transceiver fails to provide a collision pulse (heart beat) during the first 6.4 μs of the Interframe Gap after transmission, this bit is set.</p>
12	<p><b>LCD: LOAD CAM DONE</b></p> <p>Indicates that the Load CAM command has finished writing to all programmed locations in the CAM. (See Section 6.1.1.)</p>
11	<p><b>PINT: PROGRAMMED INTERRUPT</b></p> <p>Indicates that upon reading the TXpkt.config field, the SONIC-T has detected the PINT bit to be set. (See Section 6.3.4.)</p>
10	<p><b>PKTRX: PACKET RECEIVED</b></p> <p>Indicates that a packet has been received and been buffered to memory. This bit is set after the RXpkt.seq_no field is written to memory.</p>
9	<p><b>TXDN: TRANSMISSION DONE</b></p> <p>Indicates that either (1) there are no remaining packets to be transmitted in the Transmit Descriptor Area (i.e., the EOL bit has been detected as a "1"), (2) the Halt Transmit command has been given (HTX bit in CR is set to a "1"), or (3) a transmit abort condition has occurred. This condition occurs when any of following bits in the TCR are set: BCM, EXC, FU, or EXD. This bit is set after the TXpkt.status field has been written to.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.6 Interrupt Status Register (Continued)

Bit	Description
8	<p><b>TXER: TRANSMIT ERROR</b></p> <p>Indicates that a packet has been transmitted with at least one of the following errors.</p> <ul style="list-style-type: none"> <li>—Byte count mismatch (BCM)</li> <li>—Excessive collisions (EXC)</li> <li>—FIFO underrun (FU)</li> <li>—Excessive deferral (EXD)</li> </ul> <p>The TXpkt.status field reveals the cause of the error(s).</p>
7	<p><b>TC: GENERAL PURPOSE TIMER COMPLETE</b></p> <p>Indicates that the timer has rolled over from 0000 0000h to FFFF FFFFh. (See Section 6.3.12.)</p>
6	<p><b>RDE: RECEIVE DESCRIPTORS EXHAUSTED</b></p> <p>Indicates that all receive packet descriptors in the RDA have been exhausted. This bit is set when the SONIC-T detects EOL = 1. (See Section 5.4.7.)</p>
5	<p><b>RBE: RECEIVE BUFFER EXHAUSTED</b></p> <p>Indicates that the SONIC-T has detected the Resource Read Pointer (RRP) is equal to the Resource Write Pointer (RWP). This bit is set after the last field is read from the resource area. (See Section 5.4.7.)</p> <p><b>Note 1:</b> This bit will be set as the SONIC-T finishes using the second to last receive buffer and reads the last RRA descriptor. This gives the system an early warning of impending no resources.</p> <p><b>Note 2:</b> The SONIC-T will stop reception of packets when the last RBA has been used and will not continue reception until additional receive buffers have been added (i.e., RWP is incremented beyond RRP) and this bit has been reset.</p> <p><b>Note 3:</b> If additional buffers have been added, resetting this bit causes the SONIC-T to read the next resource descriptor pointed to by the RRP in the Receive Resource Area. Note that resetting this bit under this condition is similar to issuing the Read RRA command (setting the RRRR bit in the Command Register). This bit should never be reset until after the additional resources have been added to the RRA.</p>
4	<p><b>RBAE: RECEIVE BUFFER AREA EXCEEDED</b></p> <p>Indicates that during reception, the SONIC-T has reached the end of the Receive Buffer Area. Reception is aborted and the SONIC-T fetches the next available resource descriptors in the RRA. The buffer space is not re-used and an RDA is not set up for the truncated packet (see Section 5.4.7).</p>
3	<p><b>CRC: CRC TALLY COUNTER ROLLOVER</b></p> <p>Indicates that the tally counter has rolled over from FFFFh to 0000h. (See Section 6.3.11.)</p>
2	<p><b>FAE: FRAME ALIGNMENT ERROR (FAE) TALLY COUNTER ROLLOVER</b></p> <p>Indicates that the FAE tally counter has rolled over from FFFFh to 0000h. (See Section 6.3.11.)</p>
1	<p><b>MP: MISSED PACKET (MP) COUNTER ROLLOVER</b></p> <p>Indicates that the MP tally counter has rolled over from FFFFh to 0000h. (See Section 6.3.11.)</p>
0	<p><b>RFO: RECEIVE FIFO OVERRUN</b></p> <p>Indicates that the SONIC-T has been unable to access the bus before the receive FIFO has filled from the network. This condition is due to excessively long bus latency and/or slow bus clock. Note that FIFO underruns are indicated in the TCR. (See Section 3.5.1.)</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.7 Data Configuration Register 2

(RA<5:0> = 3Fh)

This register (Figure 6-10) is for enabling the extended bus interface options.

A hardware reset will set all bits in this register to "0" except for the Extended Programmable Outputs which are unknown until written to. A software reset will not affect any bits in this register. This register should only be written to when the SONIC-T is in software reset (the  $\overline{\text{RST}}$  bit in the Command Register is set).

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

**FIGURE 6-10. Data Configuration Register 2**

Field	Meaning
EXPO3-0	EXTENDED PROGRAMMABLE OUTPUTS
HD	HEART BEAT DISABLE
JD	TPI JABBER TIMER DISABLE
AUTO	AUI/TPI AUTO SELECTION
XWRAP	TPI TRANSCEIVER LOOPBACK
PH	PROGRAM HOLD
PCM	PACKET COMPRESS WHEN MATCHED
PCNM	PACKET COMPRESS WHEN NOT MATCHED
RJCM	REJECT ON CAM MATCH

Bit	Description
15-12	<p><b>EXPO &lt;3:0&gt; EXTENDED PROGRAMMABLE OUTPUTS</b></p> <p>These bits program the level of the Extended User outputs (EXUSR &lt;3:0&gt;) when the SONIC-T is a bus master. Writing a "1" to any of these bits programs a high level to the corresponding output. Writing a "0" to any of these bits programs a low level to the corresponding output. EXUSR &lt;3:0&gt; are similar to USR &lt;1:0&gt; except that EXUSR &lt;3:0&gt; are only available when the Extended Bus mode is selected (bit 15 in the DCR is set to "1", see Section 6.3.2).</p>
11	<p><b>HD: HEART BEAT DISABLE</b></p> <p>This bit allows the SONIC-T to ignore the heart beat signal.</p> <p>0: Enable heart beat. 1: Disable heart beat.</p>
9	<p><b>JD: TPI JABBER TIMER DISABLE</b></p> <p>This bit allows the user to turn on/off the jabber timer.</p> <p>0: Enable the jabber timer. 1: Disable the jabber timer.</p>
8	<p><b>AUTO: AUI/TPI AUTO SELECTION</b></p> <p>This bit allows the SONIC-T to check for a good link on the TPI and AUI. SONIC-T will first look for a good link on the TPI. If there is no good link on the TPI, SONIC-T will automatically select the AUI. If this bit is enable, the AUI/TPI pin will be ignored.</p> <p>0: Disable AUI/TPI auto selection. 1: Enable AUI/TPI auto selection.</p>
7	Must be zero.
6	<p><b>XWRAP: TPI TRANSCEIVER LOOPBACK</b></p> <p>This bit controls the loopback operation for the TPI transceiver. For proper operation, the CAM Address Registers and Receiver Control Register must be initialized to accept the destination address of the loopback packet (refer to loopback procedure). Also, both bits 9 and 10 of the RCR must be set to 1.</p> <p>0: Disable TPI transceiver loopback. 1: Enable TPI transceiver loopback.</p>
5	Must be zero.
4	<p><b>PH: PROGRAM HOLD</b></p> <p>When this bit is set to "0", the HOLD request output is asserted/deasserted from the falling edge of bus clock. If this bit is set to "1", HOLD will be asserted/deasserted 1/2 clock later on the rising edge of bus clock.</p>
3	Must be zero.

## 6.0 SONIC-T Registers (Continued)

### 6.3.7 Data Configuration Register 2 (Continued)

Bit	Description
2	<p><b>PCM: PACKET COMPRESS WHEN MATCHED</b></p> <p>When this bit is set to a "1" (and the PCNM bit is reset to a "0"), the <math>\overline{\text{PCOMP}}</math> output will be asserted if the destination address of the packet being received matches one of the entries in the CAM (Content Addressable Memory). This bit, along with PCNM, is used with the Management Bus of the DP83950, Repeater Interface Controller (RIC). See the DP83950 datasheet for more details on the RIC Management Bus. This mode is also called the Managed Bridge Mode.</p> <p><b>Note 1:</b> Setting PCNM and PCM to "1" at the same time is not allowed.</p> <p><b>Note 2:</b> If PCNM and PCM are both "0", the <math>\overline{\text{PCOMP}}</math> output will remain TRI-STATE until PCNM or PCM are changed.</p>
1	<p><b>PCNM: COMPRESS WHEN NOT MATCHED</b></p> <p>When this bit is set to a "1" (and the PCM bit is set to "0"), the <math>\overline{\text{PCOMP}}</math> output will be asserted if the destination address of the packet does not match one of the entries in the CAM. See the PCM bit above. This mode is also called the Managed Hub Mode.</p> <p><b>Note:</b> <math>\overline{\text{PCOMP}}</math> will not be asserted if the destination address is a broadcast address. This is true regardless of the state of the BRD bit in the Receive Control Register.</p>
0	<p><b>RJCM: REJECT ON CAM MATCH</b></p> <p>When this bit is set to "1", the SONIC-T will reject a packet on a CAM match. Setting RJCM to "0" causes the SONIC-T to operate normally by accepting packets on a CAM match. Setting this mode is useful for a small bridge with a limited number of nodes attached to it. RJCM only affects the CAM, though. Setting RJCM will not invert the function of the BRD, PRO or AMC bits (to accept broadcast, all physical or multicast packets respectively) in the Receive Control Register (see Section 6.3.3). This means, for example, that it is not possible to set RJCM and BRD to reject all broadcast packets. If RJCM and BRD are set at the same time, however, all broadcast packets will be accepted, but any packets that have a destination address that matches an address in the CAM will be rejected.</p>

## 6.0 SONIC-T Registers (Continued)

### 6.3.8 Transmit Registers

The transmit registers described in this section are part of the User Register set. The UTDA and CTDA must be initialized prior to issuing the transmit command (setting the TXP bit) in the Command register.

**Upper Transmit Descriptor Address Register (UTDA):** This register contains the upper address bits ( $A<31:16>$ ) for accessing the transmit descriptor area (TDA) and is concatenated with the contents of the CTDA when the SONIC-T accesses the TDA in system memory. The TDA can be as large as 32k words or 16k long words and can be located anywhere in system memory. This register is unaffected by a hardware or software reset.

**Current Transmit Descriptor Address Register (CTDA):** The 16-bit CTDA register contains the lower address bits ( $A<15:1>$ ) of the 32-bit transmit descriptor address. During initialization this register must be programmed with the lower address bits of the transmit descriptor. The SONIC-T concatenates the contents of this register with the contents of the UTDA to point to the transmit descriptor. For 32-bit memory systems, bit 1, corresponding to address signal A1, must be set to "0" for alignment to long-word boundaries. Bit 0 of this register is the End of List (EOL) bit and is used to denote the end of the list. This register is unaffected by a hardware or software reset.

### 6.3.9 Receive Registers

The receive registers described in this section are part of the User Register set. A software reset has no effect on these registers and a hardware reset only affects the EOBC and RSC registers. The receive registers must be initialized prior to issuing the receive command (setting the RXEN bit) in the Command register.

**Upper Receive Descriptor Address Register (URDA):** This register contains the upper address bits ( $A<31:16>$ ) for accessing the receive descriptor area (RDA) and is concatenated with the contents of the CRDA when the SONIC-T accesses the RDA in system memory. The RDA can be as large as 32k words or 16k long words and can be located anywhere in system memory. This register is unaffected by a hardware or software reset.

**Current Receive Descriptor Address Register (CRDA):** The CRDA is a 16-bit read/write register used to locate the received packet descriptor block within the RDA. It contains the lower address bits ( $A<15:1>$ ). The SONIC-T concatenates the contents of the CRDA with the contents of the URDA to form the complete 32-bit address. The resulting 32-bit address points to the first field of the descriptor block. For 32-bit memory systems, bit 1, corresponding to address signal A1, must be set to "0" for alignment to long-word boundaries. Bit 0 of this register is the End of List (EOL) bit and is used to denote the end of the list. This register is unaffected by a hardware or software reset.

**End of Buffer Word Count Register (EOBC):** The SONIC-T uses the contents of this register to determine where to place the next packet. At the end of packet reception, the SONIC-T compares the contents of the EOBC register with the contents of the Remaining Buffer Word Count registers ( $RBWC0,1$ ) to determine whether: (1) to place the next packet in the same RBA or (2) to place the next packet in another RBA. If the EOBC is less than or equal to the remaining number of words in the RBA after a packet is received (i.e.,  $EOBC \leq RBWC0,1$ ), the SONIC-T buffers the next packet in the same RBA. If the EOBC is greater than

the remaining number of words in the RBA after the packet is received (i.e.,  $EOBC > RBWC0,1$ ), the Last Packet in RBA bit, LPKT in the Receive Control Register, Section 6.3.3, is set and the SONIC-T fetches the next resource descriptor. Hence, the next packet received will be buffered in a new RBA. A hardware reset sets this register to 02FH (760 words or 1520 bytes). See Sections 5.4.2 and 5.4.4.4 for more information about using EOBC.

**Upper Receive Resource Address Register (URRA):** The URRA is a 16-bit read/write register. It is programmed with the base address of the receive resource area (RRA). This 16-bit upper address value ( $A<31:16>$ ) locates the receive resource area in system memory. SONIC-T uses the URRA register when accessing the receive descriptors within the RRA by concatenating the lower address value from one of four receive resource registers (RSA, REA, RWP, or RRP).

**Resource Start Address Register (RSA):** The RSA is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RSA is programmed with the lower 15 bits ( $A<15:1>$ ) of the starting address of the receive resource area. SONIC-T concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

**Resource End Address Register (REA):** The REA is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The REA is programmed with the lower 15 bits ( $A<15:1>$ ) of the ending address of the receive resource area. SONIC-T concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

**Resource Read Pointer Register (RRP):** The RRP is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RRP is programmed with the lower 15-bit address ( $A<15:1>$ ) of the first field of the next descriptor the SONIC-T will read. SONIC-T concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

**Resource Write Pointer Register (RWP):** The RWP is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RWP is programmed with the lower 15-bit address ( $A<15:1>$ ) of the next available location the system can add a descriptor. SONIC-T concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address. In 32-bit mode, bit 1, corresponding to address signal A1, must be zero to insure the proper equality comparison between this register and the RRP register.

**Receive Sequence Counter Register (RSC):** This is a 16-bit read/write register containing two fields (Figure 6-11). The SONIC-T uses this register to provide status information on the number of packets within a RBA and the number of RBAs. The RSC register contains two 8-bit (modulo 256) counters. After each packet is received the packet sequence number is incremented. The SONIC-T maintains a single sequence number for each RBA. When the SONIC-T uses the next RBA, the packet sequence number is reset to zero and the RBA sequence number is incremented. This register is reset to 0 by a hardware reset or by writing zero to it. A software reset has no affect.

FIGURE 6-11. Receive Sequence Counter Register

## 6.0 SONIC-T Registers (Continued)

### 6.3.10 CAM Registers

The CAM registers described in this section are part of the User Register set. They are used to program the Content Addressable Memory (CAM) entries that provide address filtering of packets. These registers, except for the CAM Enable register, are unaffected by a hardware or software reset.

**CAM Entry Pointer Register (CEP):** The CEP is a 4-bit register used by SONIC-T to select one of the sixteen CAM entries. SONIC-T uses the least significant 4-bits of this register. The value of 0h points to the first CAM entry and the value of Fh points to the last entry.

**CAM Address Port 2, 1, 0 Registers (CAP2, CAP1, CAP0):** Each CAP is a 16-bit read-only register used to access the CAM cells (Figure 6-13). Each CAM cell is 16 bits wide and contains one third of the 48-bit CAM entry (Figure 6-12) which is used by the SONIC-T for address filtering. The CAP2 register is used to access the upper bits (<47:32>), CAP1 the middle bits (<31:16>) and CAP0 the lower bits (<15:0>) of the CAM entry. Given the physical address 60:50:40:30:20:10, which is made up of 6 octets or bytes, where 10h is the least significant byte and 60h is the most significant byte (60h would be the first byte received from the network and 10h would be the last), CAP0 would be loaded with 2010h, CAP1 with 4030h and CAP2 with 6050h.

To read a CAM entry, the user first places the SONIC-T in software reset (set the RST bit in the Command register), programs the CEP register to select one of sixteen CAM entries, then reads CAP2, CAP1, and CAP0 to obtain the complete 48-bit entry. The user can not write to the CAM entries directly. Instead, the user programs the CAM descriptor area in system memory (see Section 6.1.1), then issues the Load CAM command (setting LCAM bit in the Command register). This causes the SONIC-T to read the descriptors from memory and loads the corresponding CAM entry through CAP2-0.

FIGURE 6-12. CAM Entry

FIGURE 6-13. CAM Address Port Registers

**CAM Enable Register (CE):** The CE is a 16-bit read/write register used to mask out or enable individual CAM entries. Each register bit position corresponds to a CAM entry. When a register bit is set to a "1" the corresponding CAM entry is enabled. When "0" the entry is disabled, this register is unaffected by a software reset and cleared to zero (disabling all entries) during a hardware reset. Under normal operations the user does not access this register. Instead the user sets up this register through the last entry in the CAM descriptor area. The SONIC-T loads the CE register during execution of the LCAM Command.

**CAM Descriptor Pointer Register (CDP):** The CDP is a 15-bit read/write register. The LSB is unused and always

reads back as 0. The CDP is programmed with the lower address (A<15:1>) of the first field of the CAM descriptor block in the CAM descriptor area (CDA) of system memory. SONIC-T uses the contents of the CDP register when accessing the CAM descriptors. This register must be programmed by the user before issuing the LCAM command. During execution of the LCAM Command SONIC-T concatenates the contents of this register with the contents of the URRR register to form the complete 32-bit address. During the Load CAM operation this register is incremented to address the fields in the CDA. After the Load Command completes this register points to the next location after the CAM Descriptor Area.

**CAM Descriptor Count Register (CDC):** The CDC is a 5-bit read/write register. It is programmed with the number of CAM descriptor blocks in the CAM descriptor area. This register must be programmed by the user before issuing the LCAM command. SONIC-T uses the value in this register to determine how many entries to place in the CAM during execution of the LCAM command. During LCAM execution SONIC-T decrements this register each time it reads a descriptor block. When the CDC decrements to zero SONIC-T terminates the LCAM execution. Since the CDC register is programmed with the number of CAM descriptor blocks in the CAM Descriptor Area, the value programmed into the CDC register ranges 1 to 16 (1h to 10h).

### 6.3.11 Tally Counters

The SONIC-T provides three 16-bit counters used for monitoring network statistics on the number of CRC errors, Frame Alignment errors, and missed packets. These registers rollover after the count of FFFFh is reached and produce an interrupt if enabled in the Interrupt Mask Register (IMR). These counters are unaffected by the RXEN bit in the CR, but are halted when the RST bit in the CR is set. The data written to these registers is inverted before being latched. This means that if a value of FFFFh is written to these registers by the system, they will contain and read back the value 0000h. Data is not inverted during a read operation. The Tally registers, therefore, are cleared by writing all "1's" to them. A software or hardware reset does not affect the tally counters.

**CRC Tally Counter Register (CRCT):** The CRCT is a 16-bit read/write register. This register is used to keep track of the number of packets received with CRC errors. After a packet is accepted by the address recognition logic, this register is incremented if a CRC error is detected. If the packet also contains a Frame Alignment error, this counter is not incremented.

**FAE Tally Counter Register (FAET):** The FAET is a 16-bit read/write register. This register is used to keep track of the number of packets received with frame alignment errors. After a packet is accepted by the address recognition logic, this register is incremented if a FAE error is detected.

**Missed Packet Tally Counter Register (MPT):** The MPT is a 16-bit read/write register. After a packet is received, this counter is incremented if there is: (1) lack of memory resources to buffer the packet, (2) a FIFO overrun, or (3) a valid packet has been received, but the receiver is disabled (RXDIS is set in the command register).

## 6.0 SONIC-T Registers (Continued)

### 6.3.12 General Purpose Timer

The SONIC-T contains a 32-bit general-purpose Watchdog Timer for timing user-definable events (*Figure 6-14*). This timer is accessed by the user through two 16-bit read/write registers (WT1 and WT0). The lower count value is programmed through the WT0 register and the upper count value is programmed through the WT1 register.

These two registers are concatenated together to form the complete 32-bit timer. This timer, clocked at  $\frac{1}{2}$  the Transmit Clock (TXC) frequency, counts down from its programmed value and generates an interrupt, if it is enabled Interrupt Mask register, when it rolls over from 0000 0000h to FFFF FFFFh. When the counter rolls over it continues decrementing unless explicitly stopped (setting the STP bit). The timer is controlled by the ST (Start Timer) and STP (Stop Timer) bits in the Command register. A hardware or software reset halts, but does not clear, the General Purpose timer.

WT1 (Upper Count Value)		WT0 (Lower Count Value)	

FIGURE 6-14. Watchdog Timer Register

### 6.3.13 Silicon Revision Register

This is a 16-bit read only register. It contains information on the current revision of the SONIC-T. The DP83934BVUL revision register is 0101h.

## 7.0 Bus Interface

SONIC-T features a high speed non-multiplexed address and data bus designed for a wide range of system environments. The data bus can be programmed (via the Data Configuration Register) to a width of either 32- or 16-bits. SONIC-T contains an on-chip DMA and supplies all the necessary signals for DMA operation. With 31 address lines SONIC-T can access a full 2 G-word address space. To accommodate different memory speeds, wait states can be added to the bus cycle by two methods. The memory subsystem can add wait states by simply withholding the appropriate handshake signals or the SONIC-T can be programmed (via the Data Configuration Register) to add wait states.

The SONIC-T is designed to interface to both the National/Intel and Motorola style buses. To facilitate minimum chip

count designs and complete bus compatibility, the user can program the SONIC-T for the following bus modes:

- National/Intel bus operating in synchronous mode
- National/Intel bus operating in asynchronous mode
- Motorola bus operating in synchronous mode
- Motorola bus operating in asynchronous mode

The Bus Mode pin (BMODE) along with the SBUS bit in the Data Configuration Register are used to select the bus mode.

This section illustrates some SONIC-T system interface examples and describes the various SONIC-T bus operations.

### 7.1 PIN CONFIGURATIONS

There are two user selectable pin configurations for SONIC-T to provide the proper interface signals for either the National/Intel or Motorola style buses. The state of the BMODE pin is used to define the pin configuration. Section 1.0 shows the pin configurations for both National/Intel Mode (BMODE = 0, tied to ground) and Motorola Mode (BMODE = 1, tied to  $V_{CC}$ ).

### 7.2 SYSTEM CONFIGURATION

Any device that meets the SONIC-T interface protocol and electrical requirements (timing, threshold, and loading) can be interfaced to SONIC-T. Since two bus protocols are provided, via the BMODE pin, the SONIC-T can interface directly to most microprocessors. *Figure 7-1* shows a typical interface to the National/Intel style bus (BMODE = 0) and *Figure 7-2* shows a typical interface to the Motorola style bus (BMODE = 1).

The BMODE pin also controls byte ordering. When BMODE = 1 big endian byte ordering is selected and when BMODE = 0 little endian byte ordering is selected.

### 7.3 BUS OPERATIONS

There are two types of system bus operations: 1) SONIC-T as a slave, and 2) SONIC-T as a bus master. When SONIC-T is a slave (e.g., a CPU accessing SONIC-T registers) all transfers are non-DMA. When SONIC-T is a bus master (e.g., SONIC-T accessing receive or transmit buffer/descriptor areas) all transfers are block transfers using SONIC-T's on-chip DMA. This section describes the SONIC-T bus operations. Pay special attention to all sections labeled as "Note". These conditions must be met for proper bus operation.

## 7.0 Bus Interface (Continued)

### 7.3.1 Acquiring The Bus

The SONIC-T requests the bus when 1) its FIFO threshold has been reached or 2) when the descriptor areas in memory (i.e., RRA, RDA, CDA, and TDA) are accessed. Note that when the SONIC-T moves from one area in memory to another (e.g., RBA to RDA), it always deasserts its bus request and then requests the bus again when accessing the next area in memory.

The SONIC-T provides two methods to acquire the bus for compatibility with National/Intel or Motorola type microprocessors. These two methods are selected by setting the proper level on the BMODE pin.

Figures 7-3 and 7-4 show the National/Intel (BMODE = 0) and Motorola (BMODE = 1) bus request timing. Descriptions of each mode follows. For both modes, when the SONIC-T relinquishes the bus, there is an extra holding state (Th) for one bus cycle after the last DMA cycle (T2). This assures that the SONIC-T does not contend with another bus master after it has released the bus.

#### BMODE = 0

The National/Intel processors require a 2-way handshake using a HOLD REQUEST/HOLD ACKNOWLEDGE protocol (Figure 7-3). When the SONIC-T needs to access the bus, it issues a HOLD REQUEST (HOLD) to the microprocessor. The microprocessor, responds with a HOLD ACKNOWLEDGE (HLDA) to the SONIC-T. The SONIC-T then begins its memory transfers on the bus. As long as the CPU maintains HLDA active, the SONIC-T continues until it has finished its memory block transfer. The CPU, however, can preempt the SONIC-T from finishing the block transfer by deasserting HLDA before the SONIC-T deasserts HOLD. This allows a higher priority device to preempt the SONIC-T from continuing to use the bus. The SONIC-T will request the bus again later to complete any operation that it was doing at the time of preemption. The HLDA signal is sampled synchronously by the SONIC-T at the rising edge of the BSCK, setup time must be met to ensure proper operation.

As shown in Figure 7-3, the SONIC-T will assert HOLD to either the falling or rising edge of the bus clock (BSCK). The default is for HOLD to be asserted on the falling edge. Setting the PH bit in the DCR2 (see Section 6.3.7) causes HOLD to be asserted 1/2 bus clock later on the rising edge (shown by the dotted line). Before HOLD is asserted, the SONIC-T checks the HLDA line. If HLDA is asserted, HOLD will not be asserted until after HLDA has been deasserted first.

**Note:** If HLDA is driven low to preempt the SONIC-T from the bus while the SONIC-T is accessing the CAM (LCAM command), the SONIC-T will get off the bus but will not deassert HOLD even though the status bit will indicate idle state. If HLDA is driven low while the SONIC-T is accessing descriptor areas (RRA, RDA, TDA), the SONIC-T will be preempted normally (i.e., get off the bus and deassert HOLD) and the HOLD signal will be reasserted again after one bus clock. If HLDA is driven low while the SONIC-T is accessing data areas (RBA, TBA), the SONIC-T will be preempted normally but may not reassert HOLD unless required to do so depending on the threshold condition of the FIFO.

#### BMODE = 1

The Motorola protocol requires a 3-way handshake using a BUS REQUEST, BUS GRANT, and BUS GRANT ACKNOWLEDGE handshake (Figure 7-4). When using this protocol, the SONIC-T requests the bus by lowering BUS REQUEST  $\overline{BR}$ . The CPU responds by issuing BUS GRANT  $\overline{BG}$ . Upon receiving  $\overline{BG}$ , the SONIC-T assures that all devices have relinquished control of the bus before using the bus. The following signals must be deasserted before the SONIC-T acquires the bus:

- $\overline{BGACK}$
- $\overline{AS}$
- $\overline{DSACK0,1}$
- $\overline{STERM}$  (Asynchronous Mode Only)

Deasserting  $\overline{BGACK}$  indicates that the previous master has released the bus. Deasserting  $\overline{AS}$  indicates that the previous master has completed its cycle and deasserting  $\overline{DSACK0,1}$  and  $\overline{STERM}$  indicates that the previous slave has terminated its connection to the previous master. The SONIC-T maintains its mastership of the bus until it deasserts  $\overline{BGACK}$ . It can not be preempted from the bus.

FIGURE 7-3. Bus Request Timing (BMODE = 0)

## 7.0 Bus Interface (Continued)

FIGURE 7-4. Bus Request Timing (BMODE = 1)

TL/F/11719-31

### 7.3.2 Block Transfers

The SONIC-T performs block operations during all bus actions, thereby providing efficient transfers to memory. The block cycle consists of three parts. The first part is the bus acquisition phase, as discussed above, in which the SONIC-T gains access to the bus. Once it has access of the bus, the SONIC-T enters the second phase by transferring data to/from its internal FIFOs or registers from/to memory. The SONIC-T transfers data from its FIFOs in either EXACT BLOCK mode or EMPTY/FILL.

**EXACT BLOCK mode:** In this mode the number of words (or long words) transferred during a block transfer is determined by either the Transmit or Receive FIFO thresholds programmed in the Data Configuration Register.

**EMPTY/FILL mode:** In this mode the DMA completely fills the Transmit FIFO during transmission, or completely empties the Receive FIFO during reception. This allows for greater bus latency.

When the SONIC-T accesses the Descriptor Areas (i.e., RRA, RDA, CDA, and TDA), it transfers data between its registers and memory. All fields which need to be used are accessed in one block operation. Thus, the SONIC-T performs 4 accesses in the RRA (see Section 5.4.4.2), 7 accesses in the RDA (see Section 5.4.6.1), 2, 3, or 6 accesses in the TDA (see Section 5.5.4) and 4 accesses in the CDA.

### 7.3.3 Bus Status

The SONIC-T presents three bits of status information on pins S2-S0 which indicate the type of bus operation the SONIC-T is currently performing (Table 7-1). Bus status is valid when at the falling edge of  $\overline{AS}$  or the rising edge of  $\overline{ADS}$ .

TABLE 7-1. Bus Status

S2	S1	S0	Status
1	1	1	The bus is idle. The SONIC-T is not performing any transfers on the bus.
1	0	1	The Transmit Descriptor Area (TDA) is currently being accessed.
0	0	1	The Transmit Buffer Area (TBA) is currently being read.
0	1	1	The Receive Buffer Area (RBA) is currently being written to. Only data is being written, though, not a Source or Destination address.
0	1	0	The Receive Buffer Area (RBA) is currently being written to. Only the Source or Destination address is being written, though.
1	1	0	The Receive Resource Area (RRA) is currently being read.
1	0	0	The Receive Descriptor Area (RDA) is currently being accessed.
0	0	0	The CAM Descriptor Area (CDA) is currently being accessed.

## 7.0 Bus Interface (Continued)

### 7.3.3.1 Bus Status Transitions

When the SONIC-T acquires the bus, it only transfers data to/from a single area in memory (i.e., TDA, TBA, RDA, RBA, RRA, or CDA). Thus, the bus status pins remain stable for the duration of the block transfer cycle with the following three exceptions: 1) if the SONIC-T is accessed during a block transfer, S2-S0 indicates bus idle during the register access, then returns to the previous status, 2) if the SONIC-T finishes writing the Source Address during a block transfer, S2-S0 changes from [0,1,0] to [0,1,1], or 3) during an RDA access between the RXpkt.seq\_no and RXpkt.link access, and between the RXpkt.link and RXpkt.in\_use access, S2-S0 will respectively indicate idle [1,1,1] for 2 or 1 bus clocks. Status will be valid on the falling edge of  $\overline{AS}$  or rising edge of  $\overline{ADS}$ .

Figure 7-5 illustrates the SONIC-T's transitions through memory during the process of transmission and reception. During transmission, the SONIC-T reads the descriptor information from the TDA and then transmits data of the packet from the TBA. The SONIC-T moves back and forth between the TDA and TBA until all fragments and packets are transmitted. During reception, the SONIC-T takes one of two paths. In the first case (path A), when the SONIC-T detects EOL = 0 from the previous reception, it buffers the accepted packet into the RBA, and then writes the descriptor information to the RDA. If the RBA becomes depleted (i.e., RBWC0,1 < EOBC), it moves to the RRA to read a resource descriptor. In the second case (path B), when the SONIC-T detects EOL = 1 from the previous reception, it rereads the RXpkt.link field to determine if the system has

reset the EOL bit since the last reception. If it has, the SONIC-T buffers the packet as in the first case. Otherwise, it rejects the packet and returns to idle.

### 7.3.4 Bus Mode Compatibility

For compatibility with different microprocessor and bus architectures, the SONIC-T operates in one of two modes (set by the BMODE pin) called the National/Intel or little endian mode (BMODE tied low) and the Motorola or big endian mode (BMODE tied high). The definitions for several pins change depending on the mode the SONIC-T is in. Table 7-2 shows these changes. These modes affect both master and slave bus operations with the SONIC-T.

TABLE 7-2. Bus Mode Compatibility

Pin Name	BMODE = 0 (National/Intel)	BMODE = 1 (Motorola)
$\overline{BR}/\text{HOLD}$	HOLD	$\overline{BR}$
$\overline{BG}/\text{HLDA}$	HLDA	$\overline{BG}$
$\text{MR}\overline{W}/\text{M}\overline{W}\overline{R}$	$\text{M}\overline{W}\overline{R}$	$\text{MR}\overline{W}$
$\text{SR}\overline{W}/\text{S}\overline{W}\overline{R}$	$\text{S}\overline{W}\overline{R}$	$\text{SR}\overline{W}$
$\overline{\text{DSACK0}}/\text{RD}\overline{Y}\text{i}$	$\text{RD}\overline{Y}\text{i}$	$\overline{\text{DSACK0}}$
$\overline{\text{DSACK1}}/\text{RD}\overline{Y}\text{o}$	$\text{RD}\overline{Y}\text{o}$	$\overline{\text{DSACK1}}$
$\overline{\text{AS}}/\text{ADS}$	$\overline{\text{ADS}}$	$\overline{\text{AS}}$
$\overline{\text{INT}}/\text{INT}$	INT	$\overline{\text{INT}}$

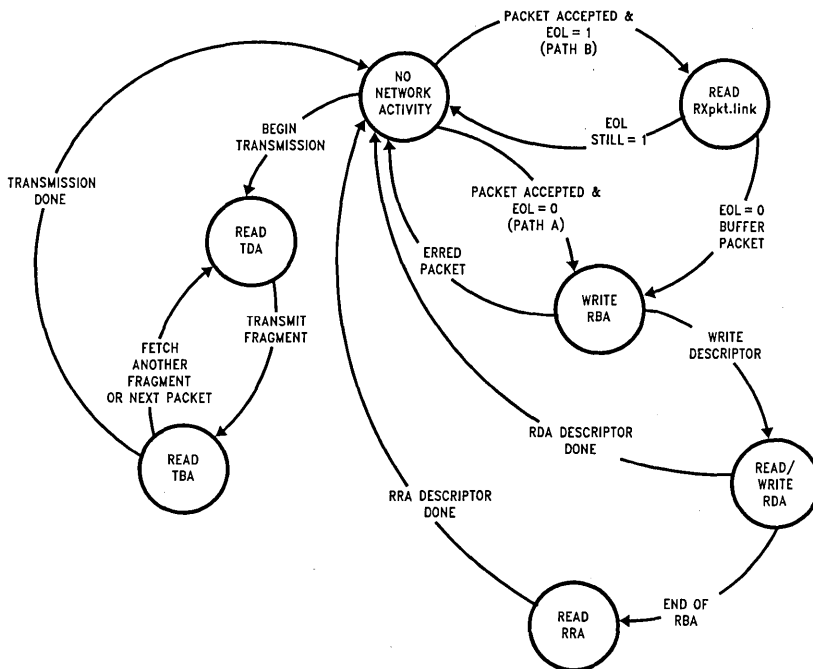

FIGURE 7-5. Bus Status Transitions

TL/F/11719-32

## 7.0 Bus Interface (Continued)

### 7.3.5 Master Mode Bus Cycles

In order to add additional compatibility with different bus architectures, there are two other modes that affect the operation of the bus. These modes are called the synchronous and asynchronous modes and are programmed by setting or resetting the SBUS bit in the Data Configuration Register (DCR). The synchronous and asynchronous modes do not have an effect on slave accesses to the SONIC-T but they do affect the master mode operation. Within the particular bus/processor mode, synchronous and asynchronous modes are very similar. This section discusses all four modes of operation of the SONIC-T (National/Intel vs. Motorola, synchronous vs. asynchronous) when it is a bus master.

In this section, the rising edge of T1 and T2 means the beginning of these states, and the falling edge of T1 and T2 means the middle of these states.

#### 7.3.5.1 Adding Wait States

To accommodate different memory speeds, the SONIC-T provides two methods for adding wait states for its bus operations. Both of these methods can be used singly or in conjunction with each other. A memory cycle is extended by adding additional T2 states. The first method inserts wait-states by withholding the assertion of  $\overline{DSACK0,1}$  or  $\overline{RDYi}$ . The other method allows software to program wait-states. Programming the WC0, WC1 bits in the Data Configuration Register allows 1 to 3 wait-states to be added on each memory cycle. These wait states are inserted between the T1 and T2 bus states and are called T2 (wait) bus states. The SONIC-T will not look at the  $\overline{DSACK0,1}$ ,  $\overline{STERM}$  or  $\overline{RDYi}$  lines until the programmed wait states have passed. Hence, in order to complete a bus operation that

includes programmed wait states, the  $\overline{DSACK0,1}$ ,  $\overline{STERM}$  or  $\overline{RDYi}$  lines must be asserted at their proper times at the end of the cycle during the last T2, not during a programmed wait state. The only exception to this is asynchronous mode where  $\overline{DSACK0,1}$  or  $\overline{RDYi}$  would be asserted during the last programmed wait state, T2 (wait). See the timing for these signals in the timing diagrams for more specific information. Programmed wait states do not affect Slave Mode bus cycles.

#### 7.3.5.2 Memory Cycle for BMODE = 1, Synchronous Mode

On the rising edge of T1, the SONIC-T asserts  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe ( $\overline{MRW}$ ) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC-T deasserts  $\overline{ECS}$  and asserts  $\overline{AS}$ .

In synchronous mode,  $\overline{DSACK0,1}$  are sampled on the rising edge of T2. T2 states will be repeated until  $\overline{DSACK0,1}$  are sampled properly in a low state.  $\overline{DSACK0,1}$  must meet the setup and hold times with respect to the rising edge of bus clock for proper operation.

During read cycles (Figure 7-6) data (D31-D0) is latched at the falling edge of T2 and  $\overline{DS}$  is asserted at the falling edge of T1. For write cycles (Figure 7-7) data is driven on the falling edge of T1. If there are wait states inserted,  $\overline{DS}$  is asserted on the falling edge of T2.  $\overline{DS}$  is not asserted for zero wait state write cycles. The SONIC-T terminates the memory cycle by deasserting  $\overline{AS}$  and  $\overline{DS}$  at the falling edge of T2.

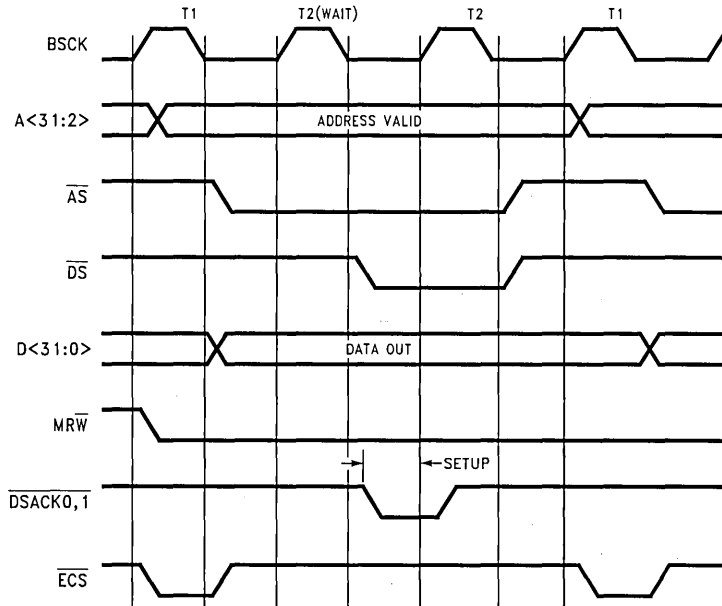

FIGURE 7-6. Memory Read, BMODE = 1, Synchronous (1 Wait-State)

TL/F/11719-33

## 7.0 Bus Interface (Continued)

TL/F/11719-34

FIGURE 7-7. Memory Write, BMODE = 1, Synchronous (1 Wait-State)

### 7.3.5.3 Memory Cycle for BMODE = 1, Asynchronous Mode

On the rising edge of T1, the SONIC-T asserts  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31–A1), bus status (S2–S0) and the direction strobe (MRW) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC-T deasserts  $\overline{ECS}$  and asserts  $\overline{AS}$ .

In asynchronous mode,  $\overline{DSACK0,1}$  are asynchronously sampled on the falling edge of both T1 and T2.  $\overline{DSACK0,1}$  do not need to be synchronized to the bus clock because the chip always resolves these signals to either a high or low state. If a synchronous termination of the bus cycle is required, however,  $\overline{STERM}$  may be used.  $\overline{STERM}$  is sampled on the rising edge of T2 and must meet the setup and hold times with respect to that edge for proper operation. Meeting the setup time for  $\overline{DSACK0,1}$  or  $\overline{STERM}$  guarantees that the SONIC-T will terminate the memory cycle 1.5

bus clocks after  $\overline{DSACK0,1}$  were sampled, or 1 cycle after  $\overline{STERM}$  was sampled. T2 states will be repeated until  $\overline{DSACK0,1}$  or  $\overline{STERM}$  are sampled properly in a low state (see note below).

During read cycles (Figures 7-8 and 7-9), data (D31–D0) is latched at the falling edge of T2 and  $\overline{DS}$  is asserted at the falling edge of T1. For write cycles (Figures 7-10 and 7-11) data is driven on the falling edge of T1. If there are wait states inserted,  $\overline{DS}$  is asserted on the falling edge of the first T2 (wait).  $\overline{DS}$  is not asserted for zero wait state write cycles. The SONIC-T terminates the memory cycle by deasserting  $\overline{AS}$  and  $\overline{DS}$  at the falling edge of T2.

**Note:** If the setup time for  $\overline{DSACK0,1}$  is met during T1, or the setup time for  $\overline{STERM}$  is met during the first T2, the full asynchronous bus cycle will take only 2 bus clocks. This may be an unwanted situation. If so,  $\overline{DSACK0,1}$  and  $\overline{STERM}$  should normally be deasserted during T1 and the start of T2 respectively.

## 7.0 Bus Interface (Continued)

### 7.3.5.4 Memory Cycle for BMODE = 0, Synchronous Mode

On the rising edge of T1, the SONIC-T asserts  $\overline{ADS}$  and  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe ( $\overline{MWR}$ ) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC-T deasserts  $\overline{ECS}$ .  $\overline{ADS}$  is deasserted on the rising edge of T2.

In Synchronous mode,  $\overline{RDYi}$  is sampled on the rising edge at the end of T2 (the rising edge of the next T1). T2 states will be repeated until  $\overline{RDYi}$  is sampled properly. In a low state  $\overline{RDYi}$  must meet the setup and hold times with respect to the rising edge of bus clock for proper operation.

During read cycles (Figure 7-12), data (D31-D0) is latched at the rising edge at the end of T2. For write cycles (Figure 7-13), data is driven on the falling edge of T1 and stays driven until the end of the cycle.

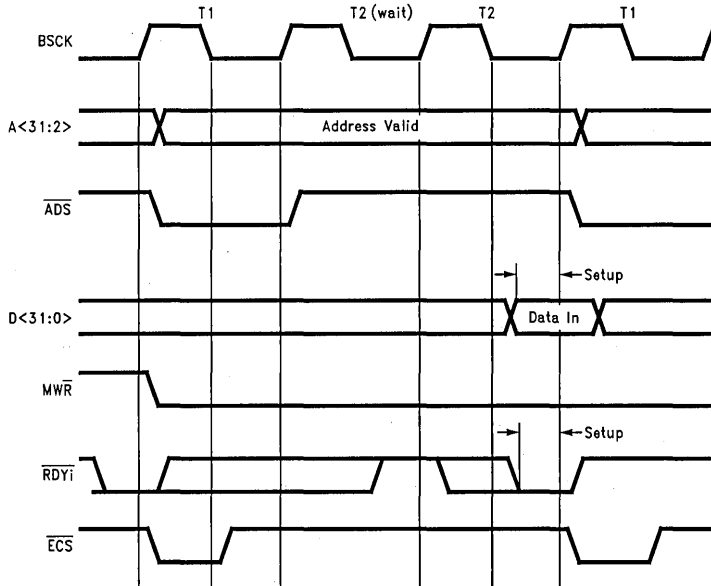

FIGURE 7-12. Memory Read, BMODE = 0, Synchronous (1 Wait-State)

FIGURE 7-13. Memory Write, BMODE = 0, Synchronous (1 Wait-State)

TL/F/11719-40

## 7.0 Bus Interface (Continued)

### 7.3.5.5 Memory Cycle for BMODE = 0, Asynchronous Mode

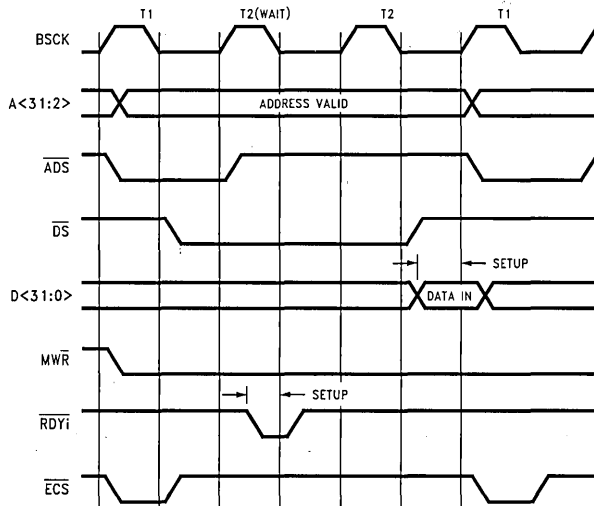

On the rising edge of T1, the SONIC-T asserts  $\overline{ADS}$  and  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe ( $\overline{MWR}$ ) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC-T deasserts  $\overline{ECS}$ .  $\overline{ADS}$  is deasserted on the rising edge of T2.

In Asynchronous mode,  $\overline{RDYi}$  is asynchronously sampled on the falling edge of both T1 and T2.  $\overline{RDYi}$  does not need to be synchronized to the bus clock because the chip always resolves these signals to either a high or low state. Meeting the setup time for  $\overline{RDYi}$  guarantees that the

SONIC-T will terminate the memory cycle 1.5 bus clocks after  $\overline{RDYi}$  was sampled. T2 states will be repeated until  $\overline{RDYi}$  is sampled properly in a low state (see note below).

During read cycles (Figures 7-14 and 7-15), data (D31-D0) is latched at the falling edge of T2 and  $\overline{DS}$  is asserted at the rising edge of T1. For write cycles (Figures 7-16 and 7-17) data is driven on the falling edge of T1. If there are wait states inserted,  $\overline{DS}$  is asserted on the rising edge of the first T2 (wait).  $\overline{DS}$  is not asserted for zero wait state write cycles. The SONIC-T terminates the memory cycle by deasserting  $\overline{DS}$  at the falling edge of T2.

**Note:** If the setup time for  $\overline{RDYi}$  is met during T1, the full asynchronous bus cycle will take only 2 bus clocks. This may be an unwanted situation. If so,  $\overline{RDYi}$  should be deasserted during T1.

## 7.0 Bus Interface (Continued)

### 7.3.6 Bus Exceptions (Bus Retry)

The SONIC-T provides the capability of handling errors during the execution of the bus cycle (Figure 7-18).

The system asserts  $\overline{\text{BRT}}$  (bus retry) to force the SONIC-T to repeat the current memory cycle. When the SONIC-T detects the assertion of  $\overline{\text{BRT}}$ , it completes the memory cycle at the end of T2 and gets off the bus by deasserting  $\overline{\text{BGACK}}$  or HOLD. Then, if Latched Bus Retry mode is not set (LBR in the Data Configuration Register, Section 6.3.2), the SONIC-T requests the bus again to retry the same memory cycle. If Latched Bus Retry is set, though, the SONIC-T will not retry until the BR bit in the ISR (see Section 6.3.6) has been reset and  $\overline{\text{BRT}}$  is deasserted.  $\overline{\text{BRT}}$  has precedence of terminating a memory cycle over  $\overline{\text{DSACK0,1}}$ ,  $\overline{\text{STERM}}$  or  $\overline{\text{RDYi}}$ .

$\overline{\text{BRT}}$  may be sampled synchronously or asynchronously by setting the EXBUS bit in the DCR (see Section 6.3.2). If synchronous Bus Retry is set,  $\overline{\text{BRT}}$  is sampled on the rising edge of T2. If asynchronous Bus Retry is set,  $\overline{\text{BRT}}$  is double synchronized from the falling edge of T1. The asynchronous setup time does not need to be met, but doing so will guarantee that the bus exception will occur in the current bus cycle instead of the next bus cycle. Asynchronous Bus Retry may only be used when the SONIC-T is set to asynchronous mode.

**Note 1:** The deassertion edge of HOLD is dependent on the PH bit in the DCR2 (see Section 6.3.7). Also,  $\overline{\text{BGACK}}$  is driven high for about 0.5 bus clocks before going TRI-STATE.

**Note 2:** If Latched Bus retry is set,  $\overline{\text{BRT}}$  need only satisfy its setup time (the hold time is not important). Otherwise,  $\overline{\text{BRT}}$  must remain asserted until after the Th state.

**Note 3:** If  $\overline{\text{DSACK0,1}}$ ,  $\overline{\text{STERM}}$  or  $\overline{\text{RDYi}}$  remain asserted after  $\overline{\text{BRT}}$ , the next memory cycle, may be adversely affected.

### 7.3.7 Slave Mode Bus Cycle

The SONIC-T's internal registers can be accessed by one of two methods (BMODE = 1 or BMODE = 0). In both methods, the SONIC-T is a slave on the bus. This section describes the SONIC-T's slave mode bus operations.

#### 7.3.7.1 Slave Cycle for BMODE = 1

The system accesses the SONIC-T by driving  $\overline{\text{SAS}}$ ,  $\overline{\text{CS}}$ ,  $\text{SRW}$  and  $\text{RA} < 5:0 >$ . These signals will be sampled each bus cycle, but the SONIC-T will not actually start a slave cycle until  $\overline{\text{CS}}$  has also been asserted.  $\overline{\text{CS}}$  should not be asserted before  $\overline{\text{SAS}}$  is driven low as this will cause improv-

er slave operation. Once  $\overline{\text{SAS}}$  has been driven low, between one and two bus clocks after the assertion of  $\overline{\text{CS}}$ ,  $\overline{\text{SMACK}}$  will be asserted to signify that the SONIC-T has started the slave cycle. Although  $\overline{\text{CS}}$  is an asynchronous input, meeting its setup time (as shown in Figures 7-19 and 7-20) will guarantee that  $\overline{\text{SMACK}}$ , which is asserted off of a falling edge, will be asserted 1 bus clock after the falling edge that  $\overline{\text{CS}}$  is clocked in on. This is assuming that the SONIC-T is not a bus master when  $\overline{\text{CS}}$  was asserted. If the SONIC-T is a bus master, then, when  $\overline{\text{CS}}$  is asserted, the SONIC-T will complete its current master bus cycle and get off the bus temporarily (see Section 7.4.8). In this case,  $\overline{\text{SMACK}}$  will be asserted 5 bus clocks after the falling edge that  $\overline{\text{CS}}$  was clocked in on. This is assuming that there were no wait states in the current master mode access. Wait states will increase the time for  $\overline{\text{SMACK}}$  to go low by the number of wait states in the cycle.

If the slave access is a read cycle (Figure 7-19), then the data will be driven off the same edge as  $\overline{\text{SMACK}}$ . If it is a write cycle (Figure 7-20), then the data will be latched in exactly 2 bus clocks after the assertion of  $\overline{\text{SMACK}}$ . In either case,  $\overline{\text{DSACK0,1}}$  are driven low 2 bus clocks after  $\overline{\text{SMACK}}$  to terminate the slave cycle. For a read cycle, the assertion of  $\overline{\text{DSACK0,1}}$  indicates valid register data and for a write cycle, the assertion indicates that the SONIC-T has latched the data. The SONIC-T deasserts  $\overline{\text{DSACK0,1}}$ ,  $\overline{\text{SMACK}}$  and the data if the cycle is a read cycle at the rising edge of  $\overline{\text{SAS}}$  or  $\overline{\text{CS}}$  depending on which is deasserted first.

**Note 1:** Although the SONIC-T responds as a 32-bit peripheral when it drives  $\overline{\text{DSACK0,1}}$  low, it transfers data only on lines D < 15:0 >.

**Note 2:** For multiple register accesses,  $\overline{\text{CS}}$  can be held low and  $\overline{\text{SAS}}$  can be used to delimit the slave cycle (this is the only case where  $\overline{\text{CS}}$  may be asserted before  $\overline{\text{SAS}}$ ). In this case,  $\overline{\text{SMACK}}$  will be driven low due to  $\overline{\text{SAS}}$  going low since  $\overline{\text{CS}}$  has already been asserted. Notice that this means  $\overline{\text{SMACK}}$  will not stay asserted low during the entire time  $\overline{\text{CS}}$  is low (as is the case for  $\overline{\text{MREQ}}$ , Section 7.3.8).

**Note 3:** If memory request ( $\overline{\text{MREQ}}$ ) follows a chip select ( $\overline{\text{CS}}$ ), it must be asserted at least 2 bus clocks after  $\overline{\text{CS}}$  is deasserted. Both  $\overline{\text{CS}}$  and  $\overline{\text{MREQ}}$  must not be asserted concurrently.

**Note 4:** When  $\overline{\text{CS}}$  is deasserted, it must remain deasserted for at least one bus clock.

**Note 5:** The way in which  $\overline{\text{SMACK}}$  is asserted due to  $\overline{\text{CS}}$  is not the same as the way in which  $\overline{\text{SMACK}}$  is asserted due to  $\overline{\text{MREQ}}$ . The assertion of  $\overline{\text{SMACK}}$  is dependent upon both  $\overline{\text{CS}}$  and  $\overline{\text{SAS}}$  being low, not just  $\overline{\text{CS}}$ . This is not the same as the case for  $\overline{\text{MREQ}}$  (see Section 7.3.8). The assertion of  $\overline{\text{SMACK}}$  in these two cases should not be confused.

TL/F/11719-46

FIGURE 7-20. Register Write, BMODE = 1

TL/F/11719-47

## 7.0 Bus Interface (Continued)

### 7.3.7.2 Slave Cycle for BMODE = 0

The system accesses the SONIC-T by driving  $\overline{SAS}$ ,  $\overline{CS}$ ,  $\overline{SWR}$  and  $RA<5:0>$ . These signals will be sampled each bus cycle, but the SONIC-T will not actually start a slave cycle until  $\overline{CS}$  has been sampled low and  $\overline{SAS}$  has been sampled high.  $\overline{CS}$  should not be asserted low before the falling edge of  $\overline{SAS}$  as this will cause improper slave operation.  $\overline{CS}$  may be asserted low, however, before the rising edge of  $\overline{SAS}$ . In this case, it is suggested that  $\overline{SAS}$  be driven high within one bus clock after the falling edge of  $\overline{CS}$ . Between one and two bus clocks after the assertion of  $\overline{CS}$ , once  $\overline{SAS}$  has been driven high,  $\overline{SMACK}$  will be driven low to signify that the SONIC-T has started the slave cycle. Although  $\overline{CS}$  is an asynchronous input, meeting its setup time (as shown in Figures 7-21 and 7-22) will guarantee that  $\overline{SMACK}$ , which is asserted off a falling edge, will be asserted 1 bus clock after the falling edge that  $\overline{CS}$  was clocked in on. This is assuming that the SONIC-T is not a bus master when  $\overline{CS}$  is asserted. If the SONIC-T is a bus master, then, when  $\overline{CS}$  is asserted, the SONIC-T will complete its current master bus cycle and get off the bus temporarily (see Section 7.3.8). In this case,  $\overline{SMACK}$  will be asserted 5 bus clocks after the falling edge that  $\overline{CS}$  was clocked in on. This is assuming that there were no wait states in the current master mode access. Wait states will increase the time for  $\overline{SMACK}$  to go low by the number of wait states in the cycle.

If the slave access is a read cycle (Figure 7-21), then the data will be driven off the same edge as  $\overline{SMACK}$ . If it is a write cycle (Figure 7-22), then the data will be latched in exactly 2 bus clocks after the assertion of  $\overline{SMACK}$ . In either case,  $\overline{RDY0}$  is driven low 2.5 bus clocks after  $\overline{SMACK}$  to terminate the slave cycle. For a read cycle, the assertion of  $\overline{RDY0}$  indicates valid register data and for a write cycle, the assertion indicates that the SONIC-T has latched the data. The SONIC-T deasserts  $\overline{RDY0}$ ,  $\overline{SMACK}$  and the data if the cycle is a read cycle at the falling edge of  $\overline{SAS}$  or the rising edge of  $\overline{CS}$  depending on which is first.

**Note 1:** The SONIC-T transfers data only on lines  $D<15:0>$  during slave mode accesses.

**Note 2:** For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle (this is the only case where  $\overline{CS}$  may be asserted before  $\overline{SAS}$ ). In this case,  $\overline{SMACK}$  will be driven low due to  $\overline{SAS}$  going high since  $\overline{CS}$  has already been asserted. Notice that this means  $\overline{SMACK}$  will not stay asserted low during the entire time  $\overline{CS}$  is low (as is the case for  $\overline{MREQ}$ , Section 7.3.8).

**Note 3:** If memory request ( $\overline{MREQ}$ ) follows a chip select  $\overline{CS}$ , it must be asserted at least 2 bus clocks after  $\overline{CS}$  is deasserted. Both  $\overline{CS}$  and  $\overline{MREQ}$  must not be asserted concurrently.

**Note 4:** When  $\overline{CS}$  is deasserted, it must remain deasserted for at least one bus clock.

**Note 5:** The way in which  $\overline{SMACK}$  is asserted due to  $\overline{CS}$  is not the same as the way in which  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ . The assertion of  $\overline{SMACK}$  is dependent upon both  $\overline{CS}$  and  $\overline{SAS}$  being low, not just  $\overline{CS}$ . This is not the same as the case for  $\overline{MREQ}$  (see Section 7.3.8). The assertion of  $\overline{SMACK}$  in these two cases should not be confused.

FIGURE 7-22. Register Write, BMODE = 0

TL/F/11719-49

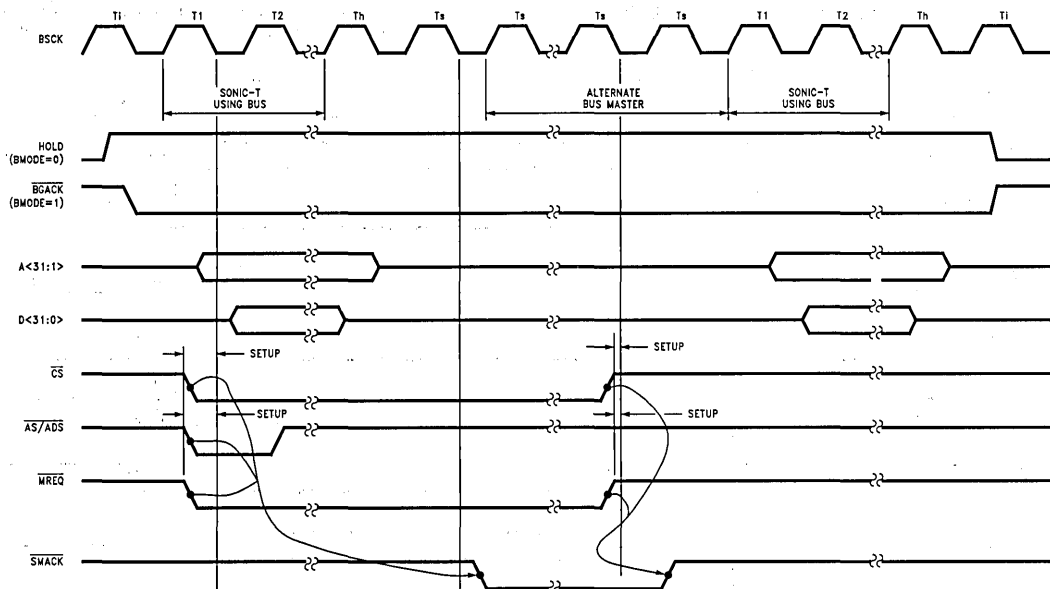

FIGURE 7-23. On-Chip Memory Arbitrer

TL/F/11719-50

## 7.0 Bus Interface (Continued)

### 7.3.8 On-Chip Memory Arbiter

For applications which share the buffer memory area with the host system (shared-memory applications), the SONIC-T provides a fast on-chip memory arbiter for efficiently resolving accesses between the SONIC-T and the host system (Figure 7-23). The host system indicates its intentions to use the shared-memory by asserting Memory Request (MREQ). The SONIC-T will allow the host system to use the shared memory by acknowledging the host system's request with Slave and Memory Acknowledge SMACK. Once SMACK is asserted, the host system may use the shared memory freely. The host system gives up the shared memory by deasserting MREQ.

MREQ is clocked in on the falling edge of bus clock and is double synchronized internally to the rising edge. SMACK is asserted on the falling edge of a Ts bus cycle. If the SONIC-T is not currently accessing the memory, SMACK is asserted immediately after MREQ was clocked in. If, however, the SONIC-T is accessing the shared memory, it finishes its current memory transfer and then issues SMACK. SMACK will be asserted 1 or 5 bus clocks, respectively, after MREQ is clocked in. Since MREQ is double synchronized, it is not necessary to meet its setup time. Meeting the setup time for MREQ will, however, guarantee that SMACK is asserted in the next or fifth bus clock after the current bus clock. SMACK will deassert within one bus clock after MREQ is deasserted. The SONIC-T will then finish its master operation if it was using the bus previously.

If the host system needs to access the SONIC-T's registers instead of shared memory, CS would be asserted instead of MREQ. Accessing the SONIC-T's registers works almost exactly the same as accessing the shared memory except that the SONIC-T goes into a slave cycle instead of going idle. See Section 7.3.7 for more information about how register accesses work.

**Note 1:** The successive assertion of CS and MREQ must be separated by at least two bus clocks. Both CS and MREQ must not be asserted concurrently.

**Note 2:** The number of bus clocks between MREQ being asserted and the assertion of SMACK when the SONIC-T is in Master Mode is 5 bus clocks assuming there were no wait states in the Master Mode access. Wait states will increase the time for SMACK to go low by the number of wait states in the cycle (the time will be 5 + the number of wait states).

**Note 3:** The way in which SMACK is asserted is due to CS is not the same as the way in which SMACK is asserted due to MREQ. SMACK goes low as a direct result of the assertion of MREQ, whereas, for CS, SAS must also be driven low (BMODE = 1) or high (BMODE = 0) before SMACK will be asserted. This means that when SMACK is asserted due to MREQ, SMACK will remain asserted until MREQ is deasserted. Multiple memory accesses can be made to the shared memory without SMACK ever going high. When SMACK is asserted due to CS, however, SMACK will only remain low as long as SAS is also low (BMODE = 1) or high (BMODE = 0). SMACK will not remain low throughout multiple register accesses to the SONIC-T because SAS must toggle for each register access. This is an important difference to consider when designing shared memory designs.

### 7.3.9 Chip Reset

The SONIC-T has two reset modes; a hardware reset and a software reset. The SONIC-T can be hardware reset by asserting the RESET pin or software reset by setting the RST bit in the Command Register (Section 6.3.1). The two reset modes are not interchangeable since each mode performs a different function.

After power-on, the SONIC-T must be hardware reset before it will become operational. This is done by asserting RESET for a minimum of 10 transmit clocks (10 ethernet transmit clock periods, TXC). If the bus clock (BSCK) period is greater than the transmit clock period, RESET should be asserted for 10 bus clocks instead of 10 transmit clocks. A hardware reset places the SONIC-T in the following state. (The registers affected are listed in parentheses. See Table 7-3 and Section 6.3 for more specific information about the registers and how they are affected by a hardware reset. Only those registers listed below and in Table 7-3 are affected by a hardware reset.)

1. Receiver and Transmitter are disabled (CR).
2. The General Purpose timer is halted (CR).
3. All interrupts are masked out (IMR).
4. The NCRS and PTX status bits in the Transmit Control Register (TCR) are set.
5. The End Of Byte Count (EOBC) register is set to 02F8h (760 words).
6. Packet and buffer sequence number counters are set to zero.
7. All CAM entries are disabled. The broadcast address is also disabled (CAM Enable Register and the RCR).
8. Loopback operation is disabled (RCR).
9. The latched bus retry is set to the unlatched mode (DCR).
10. All interrupt status bits are reset (ISR).
11. The Extended Bus Mode is disabled (DCR).
12. HOLD will be asserted/deasserted from the falling clock edge (DCR2).

**TABLE 7-3. Internal Register Content after Reset**

Register	Contents after Reset	
	Hardware Reset	Software Reset
Command	0094h	0094h/00A4h
Data Configuration (DCR and DCR2)	*	unchanged
Interrupt Mask	0000h	unchanged
Interrupt Status	0000h	unchanged
Transmit Control	0101h	unchanged
Receive Control	**	unchanged
End Of Buffer Count	02F8h	unchanged
Sequence Counters	0000h	unchanged
CAM Enable	0000h	unchanged

\*Bits 15 and 13 of the DCR and bits 4 through 0 of the DCR2 are reset to a 0 during a hardware reset. Bits 15–12 of the DCR2 are unknown until written to. All other bits in these two registers are unchanged.

\*\*Bits LB1, LB0 and BRD are reset to a 0 during hardware reset. All other bits are unchanged.

### 7.0 Bus Interface (Continued)

- 13. PCOMP will not be asserted (DCR2).
- 14. Packets will be accepted (not rejected) on CAM match (DCR2).

A software reset immediately terminates DMA operations and future interrupts. The chip is put into an idle state where registers can be accessed, but the SONIC-T will not be active in any other way. The registers are affected by a software reset as shown in Table 7-3 (only the Command Register is changed).

### 8.0 Network Interfacing

The SONIC-T contains an on-chip ENDEC that performs the network interfacing between the AUI (Attachment Unit Inter-

face) and the SONIC-T's MAC unit. A pin selectable option allows the internal ENDEC to be disabled and the MAC/ENDEC signals to be supplied to the user for connection to an external ENDEC. If the EXT pin is tied to ground (EXT=0) the internal ENDEC is selected and if EXT is tied to V<sub>CC</sub> (EXT=1) the external ENDEC option is selected.

**Internal ENDEC:** When the internal ENDEC is used (EXT=0) the interface signals between the ENDEC and MAC unit are internally connected. While these signals are used internally by the SONIC-T they are also provided as an output to the user (Figure 8-1).

The internal ENDEC allows for a 2-chip solution for the complete Ethernet interface. Figure 8-2 shows a typical diagram of the Thin Ethernet and AUI network interface.

TL/F/11719-51

FIGURE 8-1. MAC and Internal ENDEC Interface Signals

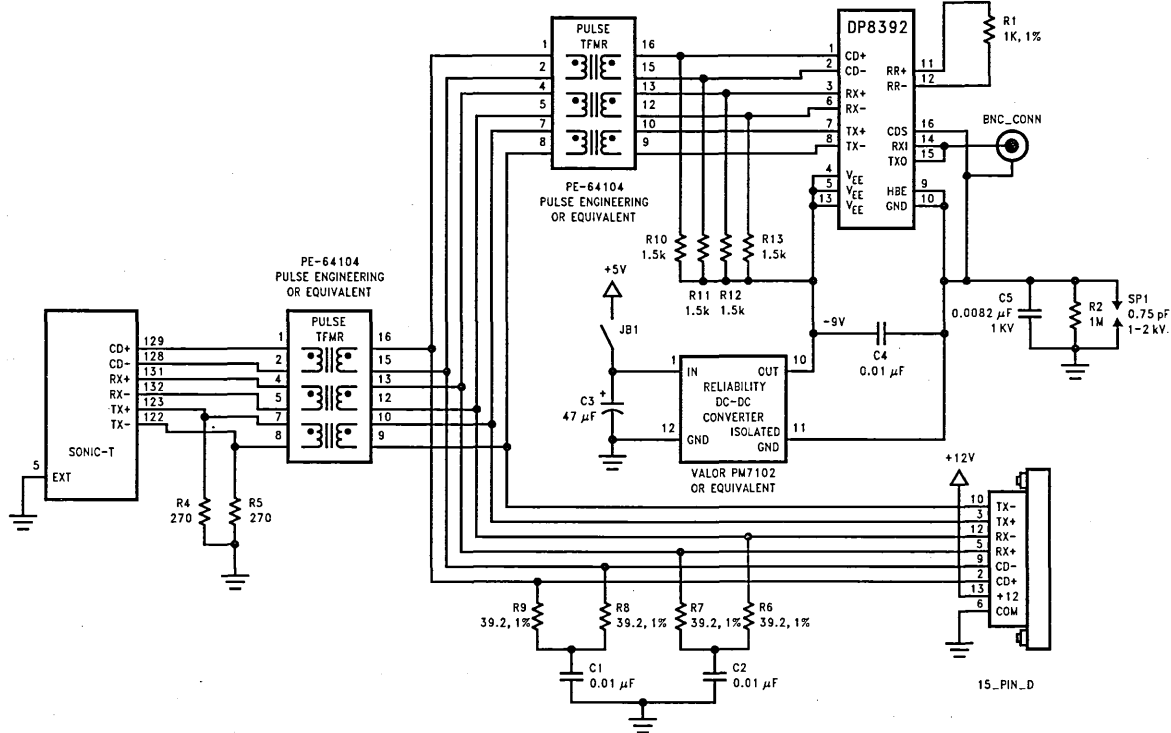

FIGURE 8-2. Network Interface Example (EXT = 0)

TL/F/11719-52

## 8.0 Network Interfacing (Continued)

**External ENDEC:** When EXT = 1 the internal ENDEC is bypassed and the signals are provided directly to the user. Since SONIC-T's on-chip ENDEC is the same as National's DP83910 Serial Network Interface (SNI) the interface considerations discussed in this section would also apply to using this device in the external ENDEC mode.

### 8.1 MANCHESTER ENCODER AND DIFFERENTIAL DRIVER

The ENDEC unit's encoder begins operation when the MAC section begins sending the serial data stream. It converts NRZ data from the MAC section to Manchester data for the differential drivers (TX±). In Manchester encoding, the first half of the bit cell contains the complementary data and the second half contains the true data (Figure 8-3). A transition always occurs at the middle of the bit cell. As long as the MAC continues sending data, the ENDEC section remains in operation. At the end of transmission, the last transition is always positive, occurring at the center of the bit cell if the last bit is a one, or at the end of the bit cell if the last bit is a zero.

The differential transmit pair drives up to 50 meters of twisted pair AUI cable. These outputs are source followers which require two 270Ω pull-down resistors to ground. In addition, a pulse transformer is required between the transmit pair output and the AUI interface.

The driver provides full-step mode for compatibility with Ethernet and IEEE 802.3, so that TX+ and TX- are equal in the idle state.

FIGURE 8.3. Manchester Encoded Data Stream

#### 8.1.1 Manchester Decoder

The decoder consists of a differential receiver and a phase lock loop (PLL) to separate the Manchester encoded data stream into clock signals and NRZ data. The differential input must be externally terminated with two 39Ω resistors connected in series. In addition, a pulse transformer is required between the receive input pair and the AUI interface.

To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with a magnitude less than -175 mV. Signals more negative than -300 mV are decoded.

Once the input exceeds the squelch requirements, the decoder begins operation. The decoder may tolerate bit jitter up to 18 ns in the received data. The decoder detects the end of a frame within one and a half bit times after the last bit of data.

#### 8.1.2 Collision Translator

When the Ethernet transceiver (DP8392 CTI) detects a collision, it generates a 10 MHz signal to the differential collision inputs (CD+ and CD-) of the SONIC-T. When SONIC-T

detects these inputs active, its Collision translator converts the 10 MHz signal to an active collision signal to the MAC section. This signal causes SONIC-T to abort its current transmission and reschedule another transmission attempt.

The collision differential inputs are terminated the same way as the differential receive inputs and a pulse transformer is required between the collision input pair and the AUI interface. The squelch circuitry is also similar, rejecting pulses with magnitudes less than -175 mV.

#### 8.1.3 Oscillator Inputs

The oscillator inputs to the SONIC-T (OSCIN and OSCOUT) can be driven with a parallel resonant crystal or an external clock. In either case the oscillator inputs must be driven with a 20 MHz signal. The signal is divided by 2 to generate the 10 MHz transmit clock (TXC) for the MAC unit. The oscillator also provides internal clock signals for the encoding and decoding circuits.

##### 8.1.3.1 External Crystal

According to the IEEE 802.3 standard, the transmit clock (TXC) must be accurate to 0.01%. This means that the oscillator circuit, which includes the crystal and other parts involved must be accurate to 0.01% after the clock has been divided in half. Hence, when using a crystal, it is necessary to consider all aspects of the crystal circuit. An example of a recommended crystal circuit is shown in Figure 8-4 and suggested oscillator specifications are shown in Table 8-1. The load capacitors in Figure 8-4, C1 and C2, should be no greater than 36 pF each, including all stray capacitance (see note 2). The resistor, R1, may be required in order to minimize frequency drift due to changes in V<sub>CC</sub>. If R1 is required, its value must be carefully selected since R1 decreases the loop gain. If R1 is made too large, the loop gain will be greatly reduced and the crystal will not oscillate. If R1 is made too small, normal variations in V<sub>CC</sub> may cause the oscillation frequency to drift out of specification. As a first rule of thumb, the value of R1 should be made equal to five times the motional resistance of the crystal. The motional resistance of 20 MHz crystals is usually in the range of 10Ω to 30Ω. This implies that reasonable values for R1 should be in the range of 50Ω to 150Ω. The decision of whether or not to include R1 should be based upon measured variations of crystal frequency as each of the circuit parameters are varied.

FIGURE 8-4. Crystal Connection to the SONIC-T  
(see text)

**Note 1:** The OSCOUT pin is not guaranteed to provide a TTL compatible logic output, and should not be used to drive any external logic. If additional logic needs to be driven, then an external oscillator should be used as described in the following section.

**Note 2:** The frequency marked on the crystal is usually measured with a fixed load capacitance specified in the crystal's data sheet. The actual load capacitance used should be the specified value minus the stray capacitance.

## 8.0 Network Interfacing (Continued)

**TABLE 8-1. Crystal Specifications**

Resonant frequency	20 MHz
Tolerance (see text)	±0.01% at 25°C
Accuracy	±0.005% (50 ppm) at 0 to 70°C
Fundamental Mode Series Resistance	≤25Ω
Specified Load Capacitance	≤18 pF
Type	AT cut
Circuit	Parallel Resonance

### 8.1.3.2 Clock Oscillator Module

The SONIC-T also allows an external clock oscillator to be used. The connection configuration is shown in *Figure 8-5*. This connection requires an oscillator with the following specifications:

1. TTL or CMOS output with a 0.01% frequency tolerance
2. 40%–60% duty cycle
3. One CMOS load output drive

These specifications assume that no other circuitry is driven. In this configuration the OSCOUT pin must be left open.

TL/F/11719-55

**FIGURE 8-5. Oscillator Module Connection to the SONIC-T**

### 8.1.3.3 PCB Layout Considerations

Care should be taken when connecting a crystal. Stray capacitance (e.g., from PC board traces and plated through-holes around the OSCIN and OSCOUT pins) can shift the crystal's frequency out of range, causing the transmitted frequency to exceed the 0.01% tolerance specified by IEEE. The layout considerations for using an external crystal are rather straightforward. The oscillator layout should locate all components close to the OSCIN and OSCOUT pins and

should use short traces that avoid excess capacitance and inductance. A solid ground should be used to connect the ground legs of the two capacitors.

When connecting an external oscillator, the only considerations are to keep the oscillator module as close to the SONIC-T as possible to reduce stray capacitance and inductance and to give the module a clean  $V_{CC}$  and a solid ground.

### 8.1.4 Power Supply Considerations

In general, power supply routing and design for the SONIC-T need only follow standard practices. In some situations, however, additional care may be necessary in the layout of the analog supply. Specifically special care may be needed for the  $TXV_{CC}$ ,  $RXV_{CC}$ ,  $PLL_{VCC}$ ,  $OSCV_{CC}$ ,  $RXTV_{CC}$  and  $TPV_{CC}$  power supplies and the  $TXGND$ ,  $RXGND$ ,  $PLL_{GND}$ ,  $OSCGND$ ,  $TPGND$  and  $ANGND$ . In most cases the analog and digital power supplies can be interconnected. However, to ensure optimum performance of the SONIC-T's analog functions, power supply noise should be minimized. To reduce analog supply noise, any of several techniques can be used.

1. Route analog supplies as a separate set of traces or planes from the digital supplies with their own decoupling capacitors.
2. Provide noise filtering on the analog supply pins by inserting a low pass filter. Alternatively, a ferrite bead could be used to reduce high frequency power supply noise.
3. Utilize a separate regulator to generate the analog supply.

## 8.2 TWISTED PAIR INTERFACE MODULE

**Transmitter Considerations:** The transmitter consists of four signals, the true and complement Manchester encoded data ( $TXO_{\pm}$ ) and these signals delayed by 50 ns ( $TXOd_{\pm}$ ).

These four signals are resistively combined (*Figure 8-6*),  $TXO_{+}$  with  $TXOd_{-}$  and  $TXO_{-}$  with  $TXOd_{+}$ , in a configuration referred to as pre-emphasis. This digital pre-emphasis is required to compensate for the low-pass filter effects of the twisted pair cable, which cause greater attenuation to the 10 MHz (50 ns) pulses of the Manchester encoded waveform than the 5 MHz (100 ns) pulses.

TL/F/11719-56

**FIGURE 8-6. External Circuitry to Connect the SONIC-T to Twisted Pair Cable**

## 9.0 AC and DC Specifications

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to 7.0V
DC Input Voltage ( $V_{IN}$ )	-0.5V to $V_{CC} + 0.5V$
DC Output Voltage ( $V_{OUT}$ )	-0.5V to $V_{CC} + 0.5V$

Storage Temperature Range ( $T_{STG}$ )	-65°C to 150°C
Power Dissipation (PD)	500 mW
Lead Temp. (TL) (Soldering, 10 sec.)	260°C
ESD Rating ( $R_{ZAP} = 1.5k, C_{ZAP} = 120 pF$ )	1.5 kV

### DC Specifications $T_A = 0^\circ\text{C}$ to $70^\circ\text{C}$ , $V_{CC} = 5V \pm 5\%$ unless otherwise specified

Symbol	Parameter	Conditions	Min	Max	Units
$V_{OH}$	Minimum High Level Output Voltage	$I_{OH} = -8 \text{ mA}$	3.0		V
$V_{OL}$	Maximum Low Level Output Voltage	$I_{OL} = 8 \text{ mA}$		0.5	V
$V_{IH}$	Minimum High Level Input Voltage		2.0		V
$V_{IL}$	Maximum Low Level Input Voltage			0.8	V
$I_{IN}$	Input Current	$V_{IN} = V_{CC}$ or GND	-10	10	$\mu\text{A}$
$I_{OZ}$	TRI-STATE Output Leakage Current	$V_{OUT} = V_{CC}$ or GND	-10	10	$\mu\text{A}$
$I_{CC}$	Average Operating Supply Current	$I_{OUT} = 0 \text{ mA}$ , Freq = $f_{max}$		140	mA

#### AUI INTERFACE PINS (TX $\pm$ , RX $\pm$ , and CD $\pm$ )

$V_{OD}$	Diff. Output Voltage (TX $\pm$ )	78 $\Omega$ Termination, and 270 $\Omega$ from Each to GND	$\pm 550$	$\pm 1200$	mV
$V_{OB}$	Diff. Output Voltage Imbalance (TX $\pm$ ) (Guaranteed by Design. Not Tested.)	78 $\Omega$ Termination, and 270 $\Omega$ from Each to GND	Typical: 40 mV		
$V_U$	Undershoot Voltage (TX $\pm$ ) (Guaranteed by Design. Not Tested.)	78 $\Omega$ Termination, and 270 $\Omega$ from Each to GND	Typical: 80 mV		
$V_{DS}$	Diff. Squelch Threshold (RX $\pm$ and CD $\pm$ )		-175	-300	mV

#### TPI INTERFACE PINS

$R_{TOL}$	TXOd $\pm$ , TXO $\pm$ Low Level Output Resistance	$I_{OL} = 25 \text{ mA}$		15	$\Omega$
$R_{TOH}$	TXOd $\pm$ , TXO $\pm$ High Level Output Resistance	$I_{OL} = -25 \text{ mA}$		15	$\Omega$
$V_{SRON1}$	Receive Threshold Turn-On Voltage 10BASE-T Mode	LOWSQL = 1	$\pm 300$	$\pm 585$	mV
$V_{SRON2}$	Receive Threshold Turn-On Voltage Reduce Threshold		$\pm 175$	$\pm 300$	mV
$V_{SROFF}$	Receive Threshold Turn-Off Voltage		$\pm 175$	$\pm 300$	mV
$V_{DIFF}$	Differential Mode Input Voltage Range	$V_{CC} = 5.0V$ (Guaranteed by Design, Not Tested)	-3.1	+3.1	V

#### OSCILLATOR PINS (OSCOU and OSCIN)

$V_{IH}$	OSCIN Input High Voltage	OSCIN is Connected to an Oscillator and OSCOUT is Open	2.0		V
$V_{IL}$	OSCIN Input Low Voltage	OSCIN is Connected to an Oscillator and OSCOUT is Open		0.8	V
$I_{OSC2}$	OSCIN Input Leakage Current	OSCIN is Connected to an Oscillator and OSCOUT is Open $V_{IN} = V_{CC}$ or GND	-100	100	$\mu\text{A}$

## 9.0 AC and DC Specifications (Continued)

### AC Characteristics

#### BUS CLOCK TIMING

TL/F/11719-57

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T1	Bus Clock Low Time	22		18		ns
T2	Bus Clock High Time	22		18		ns
T3	Bus Clock Cycle Time	50	100	40	100	ns

#### POWER-ON RESET

TL/F/11719-58

#### NON POWER-ON RESET

TL/F/11719-59

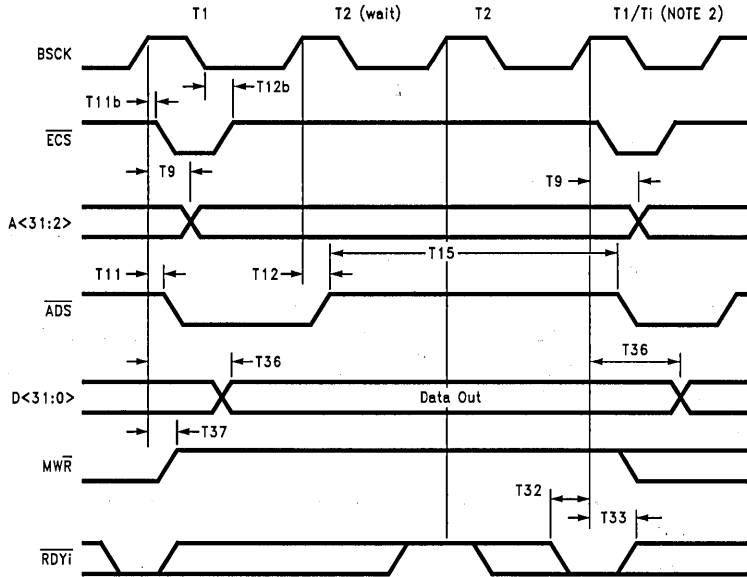

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T4	USR<1:0> Setup to RST	7		6		ns
T5	USR<1:0> Hold from RST	9		8		ns
T6	Power-On Reset Low (Notes 1, 2)	10		10		TXC
T8	Reset Pulse Width (Notes 1, 2)	10		10		TXC

**Note 1:** The reset time is determined by the slower of BSCK or TXC. If BSCK > TXC, T6 and T8 equal 10 TXCs. If BSCK < TXC, T6 and T8 equal 10 BSCKs (T3).

**Note 2:** These specifications are not tested.

### 9.0 AC and DC Specifications (Continued)

MEMORY WRITE, BMODE = 0, SYNCHRONOUS MODE (one wait-state shown)

TL/F/11719-60

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T9	BSCCK to Address Valid/Hold Time	2	26	3	24	ns
T11	BSCCK to $\overline{\text{ADS}}$ Low		26		24	ns
T11b	BSCCK to $\overline{\text{ECS}}$ Low		19		17	ns
T12	BSCCK to $\overline{\text{ADS}}$ High		24		22	ns
T12b	BSCCK to $\overline{\text{ECS}}$ High		29		27	ns
T15	$\overline{\text{ADS}}$ High Width	45		35		ns
T32	$\overline{\text{RDYi}}$ Setup to BSCCK	19		17		ns
T33	$\overline{\text{RDYi}}$ Hold from BSCCK	5		3		ns
T36	BSCCK to Memory Write Data Valid/Hold Time (Note 2)	3	50	3	48	ns
T37	BSCCK to $\overline{\text{MWR}}$ (Write) Valid (Note 1)		24		22	ns

**Note 1:** For successive read operations,  $\overline{\text{MWR}}$  remains high.

**Note 2:** One idle clock cycle (T1) will be inserted between the last write cycle and the following read cycle in RDA and TDA operation. Note that the data bus will become TRI-STATE from the rising edge of the clock after the idle cycle (see T52 for BSCCK to data TRI-STATE timing).

### 9.0 AC and DC Specifications (Continued)

MEMORY READ, BMODE = 0, SYNCHRONOUS MODE (one wait-state shown)

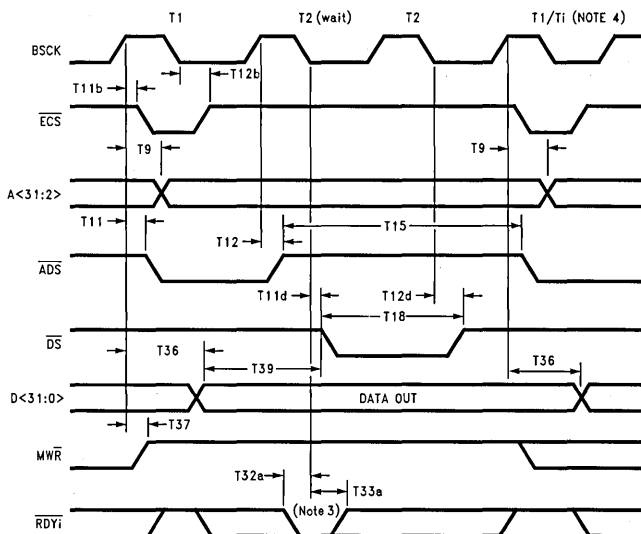

TL/F/11719-61

T32	$\overline{RDYi}$ Setup Time to BSCCK	19		17		ns
T33	$\overline{RDYi}$ Hold Time to BSCCK	5		3		ns

Note 1: For successive read operations,  $\overline{MWR}$  remains low.

## 9.0 AC and DC Specifications (Continued)

### MEMORY WRITE, BMODE = 0, ASYNCHRONOUS MODE

TL/F/11719-62

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T9	BSCCK to Address Valid/Hold Time	3	26	3	24	ns
T11	BSCCK to $\overline{\text{ADS}}$ Low		26		24	ns
T11b	BSCCK to $\overline{\text{ECS}}$ Low		19		17	ns
T11d	BSCCK to $\overline{\text{DS}}$ Low		17		15	ns
T12	BSCCK to $\overline{\text{ADS}}$ High		24		22	ns
T12b	BSCCK to $\overline{\text{ECS}}$ High		29		27	ns
T12d	BSCCK to $\overline{\text{DS}}$ High		17		15	ns
T15	$\overline{\text{ADS}}$ High Width	45		35		ns
T18	Write Data Strobe Low Width (Note 2)	40		30		ns
T32a	$\overline{\text{RDYi}}$ Asynchronous Setup to BSCCK (Note 3)	5		4		ns
T33a	$\overline{\text{RDYi}}$ Asynchronous Hold from BSCCK	5		5		ns
T36	BSCCK to Memory Write Data Valid/Hold Time (Note 4)	3	50	3	48	ns
T37	BSCCK to $\overline{\text{MWR}}$ (Write) Valid (Note 1)		24		22	ns
T39	Write Data Valid to $\overline{\text{DS}}$ Low	34		21		ns

**Note 1:** For successive read operations,  $\overline{\text{MWR}}$  remains high.

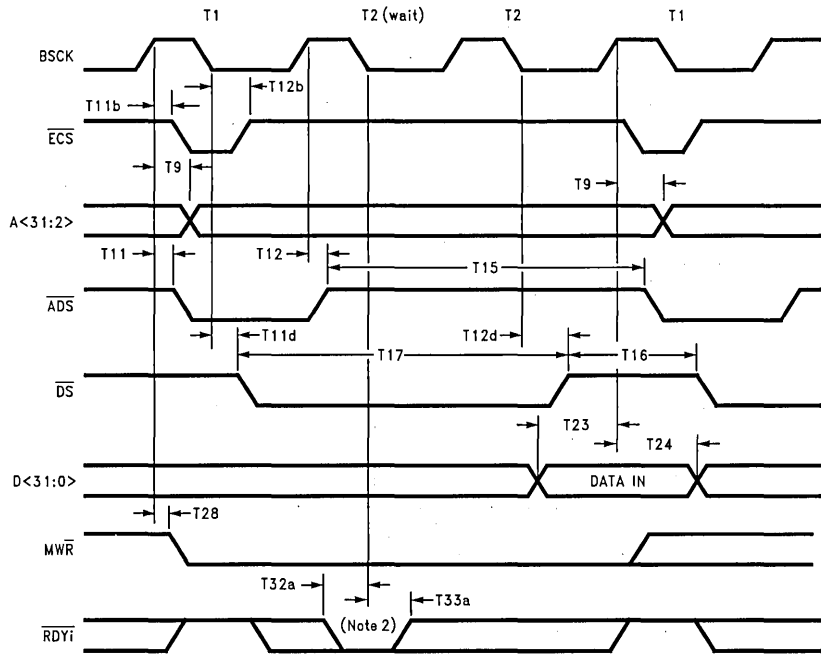

**Note 2:**  $\overline{\text{DS}}$  will only be asserted if the bus cycle has at least one wait state inserted.

**Note 3:** This setup time assures that the SONIC-T terminates the memory cycle on the next bus clock (BSCCK).  $\overline{\text{RDYi}}$  does not need to be synchronized to the bus clock, though, since it is an asynchronous input in this case.  $\overline{\text{RDYi}}$  is sampled during the falling edge of BSCCK. If the SONIC-T samples  $\overline{\text{RDYi}}$  low during the T1 cycle, the SONIC-T will finish the current access in a total of two bus clocks instead of three, which would be the case if  $\overline{\text{RDYi}}$  had been sampled low during T2 (wait). (This is assuming that programmable wait states are set to 0.)

**Note 4:** One idle clock cycle (Ti) will be inserted between the last write cycle and the following read cycle in RDA and TDA operation. Note that the data bus will become TRI-STATE from the rising edge of the clock after the idle cycle (see T52 for BSCCK to data TRI-STATE timing).

T12a	BCK to $\overline{AS}$ High		17		15	ns
T12c	BCK to $\overline{ECS}$ High		19		17	ns
T13a	BCK to $\overline{DS}$ Low		16		14	ns
T13b	BCK to $\overline{DS}$ High		16		14	ns
T14	$\overline{AS}$ Low Width	44		34		ns
T15a	$\overline{AS}$ High Width	45		35		ns
T18	Write Data Strobe Low Width (Note 3)	40		30		ns
T19	Address Hold Time from $\overline{AS}$	18		14		ns
T20	Data Hold Time from $\overline{AS}$	20		16		ns
T22	Address Valid to $\overline{AS}$	9		6		ns
T30	$\overline{DSACK0,1}$ Setup to BCK (Note 2)	5		4		ns
T30a	$\overline{STERM}$ Setup to BCK (Note 2)	5		4		ns
T31	$\overline{DSACK0,1}$ Hold from BCK	9		8		ns
T31a	$\overline{STERM}$ Hold from BCK	8		7		ns
T36	BCK to Memory Write Data Valid (Note 4)	3	50	3	48	ns
T37a	BCK to $\overline{MRW}$ (Write) Valid (Note 1)		26		24	ns
T39	Write Data Valid to Data Strobe Low	34		21		ns

**Note 1:** For successive write operations,  $\overline{MRW}$  remains low.

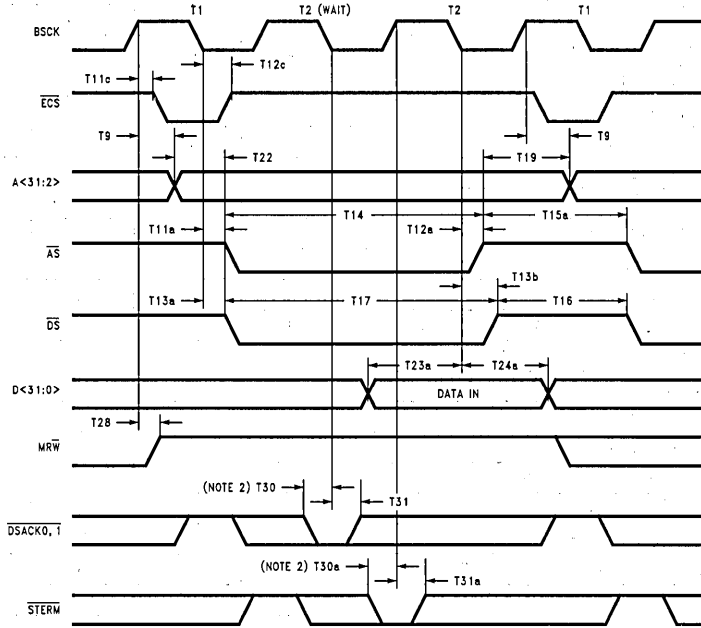

**Note 2:** Meeting the setup time for  $\overline{DSACK0,1}$  or  $\overline{STERM}$  guarantees that the SONIC-T will terminate the memory cycle 11/2 bus clocks after  $\overline{DSACK0,1}$  were sampled, or 1 cycle after  $\overline{STERM}$  was sampled. T2 states will be repeated until  $\overline{DSACK0,1}$  or  $\overline{STERM}$  are sampled properly in a low state. If the SONIC-T samples  $\overline{DSACK0,1}$  or  $\overline{STERM}$  low during the T1 or first T2 state respectively, the SONIC-T will finish the current access in a total of two bus clocks instead of three (assuming that programmable wait states are set to 0).  $\overline{DSACK0,1}$  are asynchronously sampled and  $\overline{STERM}$  is synchronously sampled.

**Note 3:**  $\overline{DS}$  will only be asserted if the bus cycle has at least one wait state inserted.

**Note 4:** One idle clock cycle (T1) will be inserted between the last write cycle and the following read cycle in RDA and TDA operation. Note that the data bus will become TRI-STATE from the rising edge of the clock after the idle cycle (see T52 for BCK to data TRI-STATE timing).

T14	$\overline{AS}$ Low Width	44		34		ns
T15a	$\overline{AS}$ High Width	45		35		ns
T16	Read Data Strobe High Width	45		35		ns
T17	Read Data Strobe Low Width	40		30		ns
T19	Address Hold Time from $\overline{AS}$	18		14		ns
T22	Address Valid to $\overline{AS}$	9		6		ns
T23a	Read Data Setup Time to BSCK	6		5		ns
T24a	Read Data Hold Time from BSCK	5		5		ns
T28	BSCK to $\overline{MRW}$ (Read) Valid (Note 1)		26		24	ns
T30	$\overline{DSACK0,1}$ Setup to BSCK (Note 2)	5		4		ns
T30a	$\overline{STERM}$ Setup to BSCK (Note 2)	5		4		ns
T31	$\overline{DSACK0,1}$ Hold from BSCK	9		8		ns
T31a	$\overline{STERM}$ Hold from BSCK	8		7		ns

**Note 1:** For successive read operations,  $\overline{MRW}$  remains high.

**Note 2:** Meeting the setup time for  $\overline{DSACK0,1}$  or  $\overline{STERM}$  guarantees that the SONIC-T will terminate the memory cycle 1.5 bus clocks after  $\overline{DSACK0,1}$  were sampled, or 1 cycle after  $\overline{STERM}$  was sampled. T2 states will be repeated until  $\overline{DSACK0,1}$  or  $\overline{STERM}$  are sampled properly in a low state. If the SONIC-T samples  $\overline{DSACK0,1}$  or  $\overline{STERM}$  low during the T1 or first T2 state respectively, the SONIC-T will finish the current access in a total of two bus clocks instead of three (assuming that programmable wait states are set to 0).  $\overline{DSACK0,1}$  are asynchronously sampled and  $\overline{STERM}$  is synchronously sampled.

## 9.0 AC and DC Specifications (Continued)

### BUS REQUEST TIMING, BMODE = 0

TL/F/11719-68

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T43	BSCCK to HOLD High (Note 2)		18	16		ns
T44	BSCCK to HOLD Low (Note 2)		19	17		ns
T45	HLDA Asynchronous Setup Time to BSCCK	7		6		ns
T46	HLDA Synchronous Deassert Setup Time (Note 1)	7		6		ns
T51	BSCCK to Address, $\overline{ADS}$ , $\overline{MWR}$ , $\overline{DS}$ , $\overline{ECS}$ , $USR<1:0>$ and $EXUSR<3:0>$ TRI-STATE (Note 4)		37	35		ns
T52	BSCCK to Data TRI-STATE		39	37		ns
T53	BSCCK to $USR<1:0>$ or $EXUSR<3:0>$ Valid		34	32		ns
T55	BSCCK to Bus Status Valid		29	27		ns
T55b	$S<2:0>$ Hold from BSCCK	3		3		ns

**Note 1:** A block transfer by the SONIC-T can be pre-empted from the bus by deasserting HLDA provided HLDA is asserted T46 before the rising edge of the last T2 in the current access.

**Note 2:** The assertion edge for HOLD is dependent upon the PH bit in the DCR2. The default situation is shown with a solid line in the timing diagram. T43 and T44 apply for both modes. Also, if HLDA is asserted when the SONIC-T wants to acquire the bus, HOLD will not be asserted until HLDA has been deasserted first.

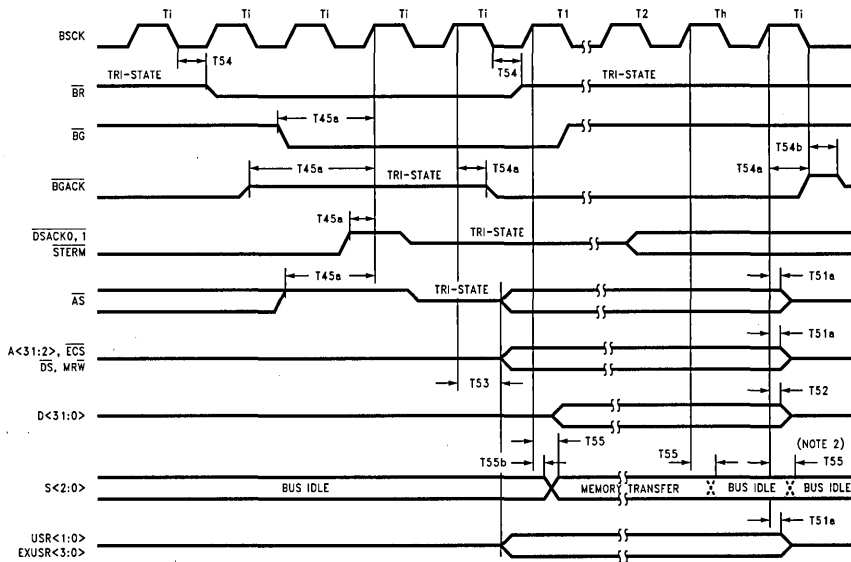

**Note 3:**  $S<2:0>$  will indicate IDLE at the end of T2 if the last operation is a read operation, or at the end of Th if the last operation is a write operation.

**Note 4:** This timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

## 9.0 AC and DC Specifications (Continued)

### BUS REQUEST TIMING, BMODE = 1

TL/F/11719-69

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T45a	$\overline{BG}$ , $\overline{AS}$ , $\overline{BGACK}$ , $\overline{DSACK0,1}$ , and $\overline{STERM}$ Asynchronous Setup Time to BSCK (Note 1)	7		6		ns
T51a	BSCK to Address, $\overline{AS}$ , $\overline{MRW}$ , $\overline{DS}$ , $\overline{ECS}$ , $USR<1:0>$ and $EXUSR<3:0>$ TRI-STATE		37		35	ns
T52	BSCK to Data TRI-STATE		34		32	ns
T53	BSCK to Address, $\overline{AS}$ , $\overline{MRW}$ , $\overline{DS}$ , $\overline{ECS}$ , $USR<1:0>$ and $EXUSR<3:0>$ Active (Note 1)		34		32	ns
T54	BSCK Low to $\overline{BR}$ Low/TRI-STATE		26		24	ns
T54a	BSCK High to $\overline{BGACK}$ Low/High		24		22	ns
T54b	High to $\overline{BGACK}$ TRI-STATE		19		17	ns
T55	BSCK to Bus Status Valid		29		27	ns
T55b	$S<2:0>$ Hold from BSCK	3		3		ns

**Note 1:**  $\overline{BGACK}$  is asserted one bus clock after all the signals ( $\overline{AS}$ ,  $\overline{DSACK0,1}$ ,  $\overline{BGACK}$ ,  $\overline{STERM}$  (Extended bus mode), and  $\overline{BG}$ ) meet the T45a setup time (see Section 5.4.1 for more information). The address bus,  $\overline{AS}$ ,  $\overline{DS}$ ,  $\overline{ECS}$ ,  $\overline{MRW}$ ,  $USR<1:0>$ , and  $EXUSR<3:0>$  will also be driven active on the same clock.

**Note 2:**  $S<2:0>$  will indicate IDLE at the end of T2 if the last operation is a read operation, or at the end of Th if the last operation is a write operation.

## 9.0 AC and DC Specifications (Continued)

### BUS RETRY

TL/F/11719-70

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T41	Bus Retry Synchronous Setup Time to BSCk (Note 3)	5		4		ns
T41a	Bus Retry Asynchronous Setup Time to BSCk (Note 3)	6		5		ns
T42	Bus Retry Hold Time from BSCk (Note 2)	7		6		ns

**Note 1:** Depending upon the mode, the SONIC-T will assert and deassert HOLD from the rising or falling edge of BSCk.

**Note 2:** Unless Latched Bus Retry mode is set (LBR in the Data Configuration Register, Section 4.3.2), BRT must remain asserted until after the Th state. If Latched Bus Retry mode is used, BRT does not need to satisfy T42.

**Note 3:** T41 is for synchronous bus retry and T41a is for asynchronous bus retry (see Section 4.3.2, bit 15, Extended Bus Mode). Since T41a is an asynchronous setup time, it is not necessary to meet it, but doing so will guarantee that the bus exception occurs in the current memory transfer, not the next.

## 9.0 AC and DC Specifications (Continued)

### MEMORY ARBITRATION/S�AVE ACCESS

TL/F/11719-71

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T56	$\overline{CS}$ Low Asynchronous Setup to BSCCK (Note 2)	8		7		ns
T58	$\overline{MREQ}$ Low Asynchronous Setup to BSCCK (Note 2)	8		7		ns
T60	$\overline{MREQ}$ or $\overline{CS}$ Valid to $\overline{SMACK}$ Low (Notes 3, 4)	1	5	1	5	bcyc
T80	$\overline{MREQ}$ to $\overline{SMACK}$ High		18		16	ns
T81	BSCCK to $\overline{SMACK}$ Low		22		20	ns

**Note 1:** Both  $\overline{CS}$  and  $\overline{MREQ}$  must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting and asserting edges of these signals.

**Note 2:** It is not necessary to meet the setup times for  $\overline{MREQ}$  or  $\overline{CS}$  since these signals are asynchronously sampled. Meeting the setup time for these signals, however, makes it possible to use T60 to determine exactly when  $\overline{SMACK}$  will be asserted.

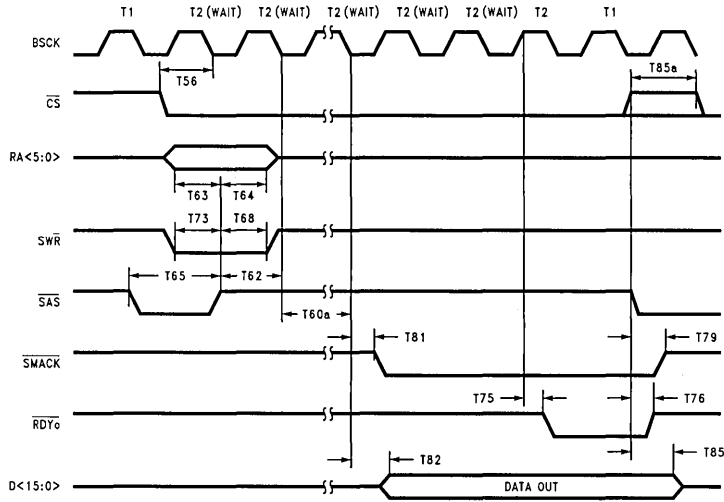

**Note 3:** T60 could range from 1 bus clock minimum to 5 bus clock maximum depending on what state machine the SONIC-T is when the  $\overline{CS}$  or  $\overline{MREQ}$  signal is asserted. This timing is not tested, but is guaranteed by design. This specification assumes that  $\overline{CS}$  or  $\overline{MREQ}$  is asserted before the falling edge that these signals are asynchronously clocked in on (see T56 and T58).  $\overline{SAS}$  must have been asserted for this timing to be correct. See  $\overline{SAS}$  and  $\overline{CS}$  timing in the Register Read, and Register Write timing specifications.

**Note 4:** bcyc = bus clock cycle time (T3).

**Note 5:** The way in which  $\overline{SMACK}$  is asserted due to  $\overline{CS}$  is not the same as the way in which  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ .  $\overline{SMACK}$  goes low as a direct result of the assertion of  $\overline{MREQ}$ , whereas, for  $\overline{CS}$ ,  $\overline{SAS}$  must also be driven low (BMODE = 1) or high (BMODE = 0) before  $\overline{SMACK}$  will be asserted. This means that when  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ ,  $\overline{SMACK}$  will remain asserted until  $\overline{MREQ}$  is deasserted. Multiple memory accesses can be made to the shared memory without  $\overline{SMACK}$  ever going high. When  $\overline{SMACK}$  is asserted due to  $\overline{CS}$ , however,  $\overline{SMACK}$  will only remain low as long as  $\overline{SAS}$  is also low (BMODE = 1) or high (BMODE = 0).  $\overline{SMACK}$  will not remain low throughout multiple register accesses to the SONIC-T because  $\overline{SAS}$  must toggle for each register access. This is an important difference to consider when designing shared memory designs.

## 9.0 AC and DC Specifications (Continued)

### REGISTER READ, BMODE = 0 (Note 1)

TL/F/11719-88

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T56	$\overline{CS}$ Asynchronous Setup to BSCk (Notes 4, 6)	8		7		ns
T60a	$\overline{CS}$ and $\overline{SAS}$ to $\overline{SMACK}$ Low (Notes 3, 5, 6)	0	4	0	4	bcyc
T62	$\overline{SAS}$ Asynchronous Setup to BSCk (Notes 4, 6)	7		6		ns
T63	Register Address Setup Time to $\overline{SAS}$	7		6		ns
T64	Register Address Hold Time from $\overline{SAS}$	8		7		ns
T65	$\overline{SAS}$ Minimum Low Width (Notes 4, 6)	20		17		ns
T68	$\overline{SWR}$ (Read) Hold from $\overline{SAS}$	8		7		ns
T73	$\overline{SWR}$ (Read) Setup to $\overline{SAS}$	7		6		ns
T75	BSCk to $\overline{RDY0}$ Low		20		18	ns
T76	$\overline{SAS}$ or $\overline{CS}$ to $\overline{RDY0}$ High (Note 2)		34		32	ns
T79	$\overline{SAS}$ or $\overline{CS}$ to $\overline{SMACK}$ High (Note 2)		18		16	ns
T81	BSCk to $\overline{SMACK}$ Low		22		20	ns
T82	BSCk to Register Data Valid		44		42	ns
T85	$\overline{SAS}$ or $\overline{CS}$ to Data TRI-STATE (Notes 2, 7)		34		32	ns
T85a	Minimum $\overline{CS}$ Deassert Time (Note 3)	1		1		bcyc

**Note 1:** This figure shows a slave access to the SONIC-T. The BSCk states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** If  $\overline{CS}$  is deasserted before the falling edge of  $\overline{SAS}$ , T76, T79 and T85 are referenced from the rising edge of  $\overline{CS}$ .

**Note 3:** bcyc = bus clock cycle time (T3).

**Note 4:** It is not necessary to meet the setup time for  $\overline{CS}$  (T56) and the setup time for  $\overline{SAS}$  (T62) since these signals are asynchronously sampled. Meeting these setup times for these signals, however, makes it possible to use T60a to determine exactly when  $\overline{SMACK}$  will be asserted. For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle. In this case,  $\overline{SMACK}$  will be driven low by the SONIC-T after T60a when T62 is met. T85a must be met to ensure proper slave operation once  $\overline{CS}$  is deasserted.

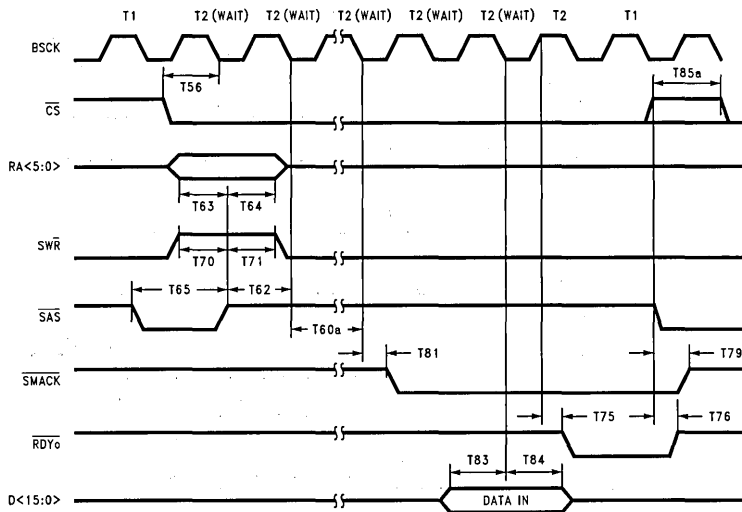

**Note 5:** The smaller value for T60a refers to when the SONIC-T is accessed during an Idle condition and the other value refers to when the SONIC-T is accessed during non-idle conditions. These values are not tested, but are guaranteed by design.

**Note 6:**  $\overline{SAS}$  may be asserted low anytime before or simultaneous to the falling edge of  $\overline{CS}$ . Register address and slave read/write signals are latched on the rising edge of the  $\overline{SAS}$ , and if T62 is met,  $\overline{SMACK}$  will be asserted by the SONIC-T after T60a. If T62 is not met, SONIC-T will sample  $\overline{SAS}$  again on the next falling edge of the clock, and  $\overline{SMACK}$  will not be asserted until  $\overline{SAS}$  is deasserted.

**Note 7:** This timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

## 9.0 AC and DC Specifications (Continued)

### REGISTER WRITE, BMODE = 0 (Note 1)

TL/F/11719-89

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T56	$\overline{CS}$ Asynchronous Setup to BSCCK (Notes 4, 6)	8		7		ns
T60a	$\overline{CS}$ and $\overline{SAS}$ to $\overline{SMACK}$ Low (Notes 3, 5, 6)	0	4	0	4	bcyc
T62	$\overline{SAS}$ Asynchronous Setup to BSCCK (Notes 4, 6)	7		6		ns
T63	Register Address Setup Time to $\overline{SAS}$	7		6		ns
T64	Register Address Hold Time from $\overline{SAS}$	8		7		ns
T65	Minimum $\overline{SAS}$ Low Width (Notes 4, 6)	20		17		ns
T70	$\overline{SWR}$ (Write) Setup to $\overline{SAS}$	7		6		ns
T71	$\overline{SWR}$ (Write) Hold from $\overline{SAS}$	8		7		ns
T75	BSCCK to $\overline{RDY<0>}$ Low		20		18	ns
T76	$\overline{SAS}$ or $\overline{CS}$ to $\overline{RDY<0>}$ High (Note 2)		34		32	ns
T79	$\overline{SAS}$ or $\overline{CS}$ to $\overline{SMACK}$ High (Note 2)		18		16	ns
T81	BSCCK to $\overline{SMACK}$ Low		22		20	ns
T83	Register Write Data Setup to BSCCK	8		7		ns
T84	Register Write Data Hold from BSCCK	14		12		ns
T85a	Minimum $\overline{CS}$ Deassert Time (Note 3)	1		1		bcyc

**Note 1:** This figure shows a slave access to the SONIC-T. The BSCCK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** If  $\overline{CS}$  is deasserted before the falling edge of  $\overline{SAS}$ , T76, T79 and T85 are referenced from the rising edge of  $\overline{CS}$ .

**Note 3:** bcyc = bus clock cycle time (T3).

**Note 4:** It is not necessary to meet the setup time for  $\overline{CS}$  (T56) and the setup time for  $\overline{SAS}$  (T62) since these signals are asynchronously sampled. Meeting these setup times for these signals, however, makes it possible to use T60a to determine exactly when  $\overline{SMACK}$  will be asserted. For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle. In this case,  $\overline{SMACK}$  will be driven low by the SONIC-T after T60a when T62 is met. T85a must be met to ensure proper slave operation once  $\overline{CS}$  is deasserted.

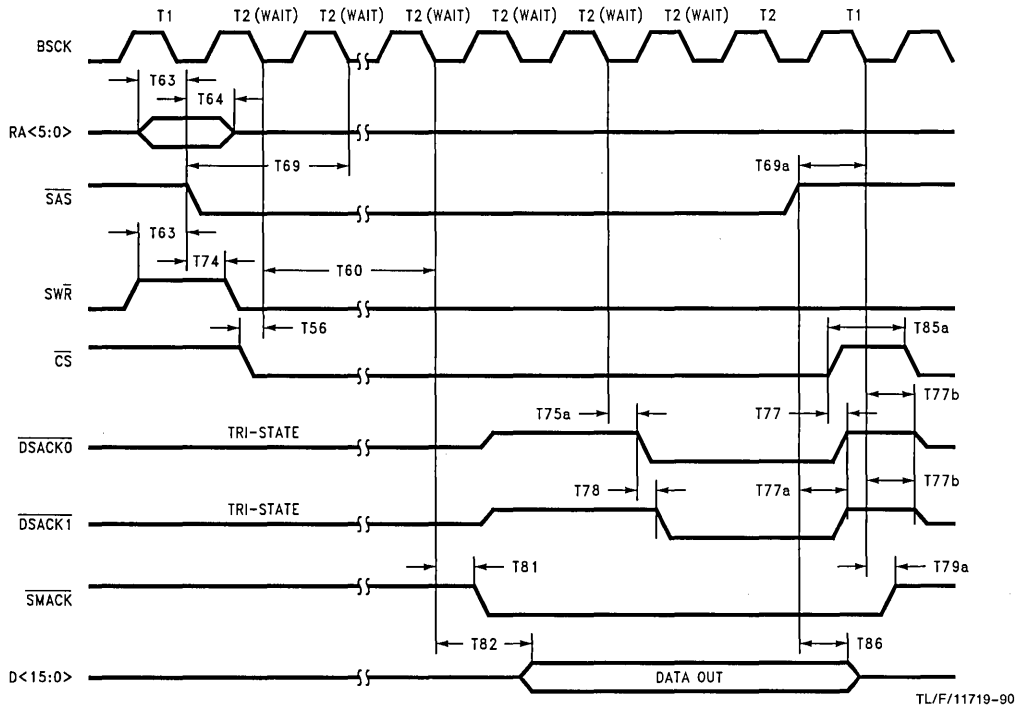

**Note 5:** The smaller value for T60a refers to when the SONIC-T is accessed during an Idle condition and the other value refers to when the SONIC-T is accessed during non-idle conditions. These values are not tested, but are guaranteed by design.

**Note 6:**  $\overline{SAS}$  may be asserted low anytime before or simultaneous to the falling edge of  $\overline{CS}$ . Register address and slave read/write signals are latched on the rising edge of the  $\overline{SAS}$ , and if T62 is met,  $\overline{SMACK}$  will be asserted by the SONIC-T after T60a. If T62 is not met, SONIC-T will sample  $\overline{SAS}$  again on the next falling edge of the clock, and  $\overline{SMACK}$  will not be asserted until  $\overline{SAS}$  is deasserted.

### 9.0 AC and DC Specifications (Continued)

REGISTER READ, BMODE = 1 (Note 1)

## 9.0 AC and DC Specifications (Continued)

Number	Parameter	20 MHz		25 MHz		Units
		Min	Max	Min	Max	
T56	$\overline{CS}$ Asynchronous Setup to BSCK (Notes 3, 4)	8		7		ns
T60	$\overline{CS}$ Valid to $\overline{SMACK}$ Low (Notes 2, 3, 4)	1	5	1	5	bcyc
T63	Register Address Setup to $\overline{SAS}$	6		5		ns
T64	Register Address Hold from $\overline{SAS}$	8		7		ns
T67	SRW (Read) Setup to $\overline{SAS}$	4		3		ns
T69	$\overline{SAS}$ Asynchronous Setup to BSCK (Notes 3, 4)	7		6		ns
T69a	$\overline{SAS}$ Asynchronous Setup to BSCK (Notes 3, 5)	5		4		ns
T74	SRW (Read) Hold from $\overline{SAS}$	8		7		ns
T75a	BSCK to $\overline{DSACK0,1}$ Low		20		18	ns
T77	$\overline{CS}$ to $\overline{DSACK0,1}$ High (Note 5)		20		18	ns
T77a	$\overline{SAS}$ to $\overline{DSACK0,1}$ High (Note 5)		31		29	ns
T77b	BSCK to $\overline{DSACK0,1}$ TRI-STATE (Note 5)		19		17	ns
T78	Skew between $\overline{DSACK0,1}$		3		3	ns
T79a	BSCK to $\overline{SMACK}$ High (Note 5)		19		17	ns
T81	BSCK to $\overline{SMACK}$ Low		22		20	ns
T82	BSCK to Register Data Valid		44		42	ns
T85a	Minimum $\overline{CS}$ Deassert Time (Notes 2, 3)	1		1		bcyc
T86	$\overline{SAS}$ to Register Data TRI-STATE (Note 6)		42		40	ns

**Note 1:** This figure shows a slave access to the SONIC-T when the SONIC-T is idle, or rather not in master mode. If the SONIC-T is a bus master, there will be some differences as noted in the Memory Arbitration/Slave Access diagram. The BSCK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** bcyc = bus clock cycle time (T3).

**Note 3:** It is not necessary to meet the setup time for  $\overline{CS}$  and  $\overline{SAS}$  (T56 and T69) since these signals are asynchronously sampled. Meeting the setup time for these signals, however, makes it possible to use T60 to determine when  $\overline{SMACK}$  will be asserted.  $\overline{SAS}$  may be asserted anytime before the next falling edge of the clock that the  $\overline{CS}$  is sampled on (as shown by specification T69). For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle (T69a must be met in order to terminate and start another cycle). In this case,  $\overline{SMACK}$  will be asserted as soon as T69 timing is met.

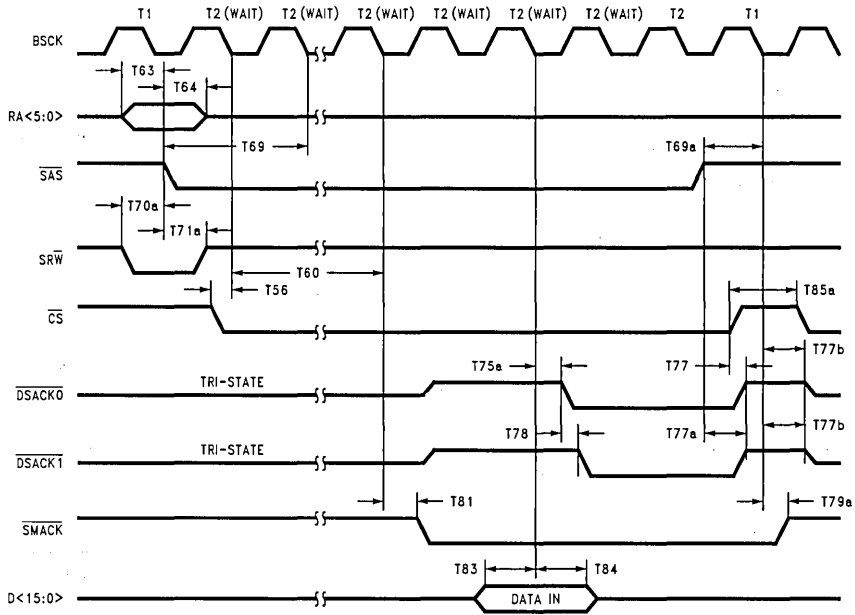

**Note 4:** T60 could range from 1 bus clock minimum to 5 bus clock maximum depending on what state machine the SONIC-T is in when the  $\overline{CS}$  signal is asserted. This timing is not tested, but is guaranteed by design. This specification assumes that both T56 is met for  $\overline{CS}$  and T69 is met for  $\overline{SAS}$ . T60 specification also assumes that there were no wait states in the current master mode access (if  $\overline{CS}$  is asserted when SONIC-T is in Master Mode). If there were wait states, then it would increase to T60 further.

**Note 5:** It is not necessary to meet the setup time for  $\overline{SAS}$  (T69a) since this signal is asynchronously sampled. Meeting the setup time for this signal, however, will ensure  $\overline{DSACK0,1}$  becomes TRI-STATE (T77b) and  $\overline{SMACK}$  goes high (T79) at the falling edge of T1. Both  $\overline{CS}$  and  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to deassert but only  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to become TRI-STATE.

**Note 6:** The timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

T75b	BSCCK to $\overline{DSACK0,1}$ Low		22		20	ns
T77	$\overline{CS}$ to $\overline{DSACK0,1}$ High (Note 5)		20		18	ns
T77a	$\overline{SAS}$ to $\overline{DSACK0,1}$ High (Note 5)		31		29	ns
T77b	BSCCK to $\overline{DSACK0,1}$ TRI-STATE (Note 5)		19		17	ns
T78	Skew between $\overline{DSACK0,1}$		3		3	ns
T79a	BSCCK to $\overline{SMACK}$ High (Note 5)		19		17	ns
T81	BSCCK to $\overline{SMACK}$ Low		22		20	ns
T83	Register Write Data Setup to BSCCK	8		7		ns
T84	Register Write Data Hold from BSCCK	14		12		ns
T85a	Minimum $\overline{CS}$ Deassert Time (Notes 2, 3)	1		1		bcyc

**Note 1:** This figure shows a slave access to the SONIC-T when the SONIC-T is idle, or rather not in master mode. If the SONIC-T is a bus master, there will be some differences as noted in the Memory Arbitration/Slave Access diagram. The BSCCK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** bcyc = bus clock cycle time (T3).

## 9.0 AC and DC Specifications (Continued)

**Note 3:** It is not necessary to meet the setup time for  $\overline{CS}$  and  $\overline{SAS}$  (T56 and T69) since these signals are asynchronously sampled. Meeting the setup time for these signals, however, makes it possible to use T60 to determine when  $\overline{SMACK}$  will be asserted.  $\overline{SAS}$  may be asserted anytime before the next falling edge of the clock that the  $\overline{CS}$  is sampled on (as shown by specification T69). For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle (T69a must be met in order to terminate and start another cycle). In this case,  $\overline{SMACK}$  will be asserted as soon as T69 timing is met.

**Note 4:** T60 could range from 1 bus clock minimum to 5 bus clock maximum depending on what state machine the SONIC-T is in when the  $\overline{CS}$  signal is asserted. This timing is not tested, but is guaranteed by design. This specification assumes that both T56 is met for  $\overline{CS}$  and T69 is met for  $\overline{SAS}$ . T60 specification also assumes that there were no wait states in the current master mode access (if  $\overline{CS}$  is asserted when SONIC-T is in Master Mode). If there were wait states, then it would increase the T60 further.

**Note 5:** It is not necessary to meet the setup time for  $\overline{SAS}$  (T69a) since this signal is asynchronously sampled. Meeting the setup time for this signal, however, will ensure  $\overline{DSACK0,1}$  becomes TRI-STATE (77b) and  $\overline{SMACK}$  goes high (T79) at the falling edge of T1. Both  $\overline{CS}$  and  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to deassert but only  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to become TRI-STATE.

### ENDEC TRANSMIT TIMING

TL/F/11719-76

Number	Parameter	Min	Max	Units
T87	Transmit Clock High Time (Note 1)	40		ns

T89	Transmit Clock Cycle Time (Note 1)	99.99	100.01	ns
T95	Transmit Output Delay (Note 1)		55	ns
T96	Transmit Output Fall Time (80% to 20%, Note 1)		7	ns
T97	Transmit Output Rise Time (20% to 80%, Note 1)		7	ns
T98	Transmit Output Jitter (Not Shown)	0.5 Typ		ns
T100	Transmit Output High before Idle (Half Step)	200		ns
T101	Transmit Output Idle Time (Half Step)		8000	ns

**Note 1:** This specification is provided for information only and is not tested.

## 9.0 AC and DC Specifications (Continued)

### ENDEC RECEIVE TIMING (INTERNAL ENDEC MODE)

TL/F/11719-77

### ENDEC COLLISION TIMING

TL/F/11719-78

Number	Parameter	Min	Max	Units
T102	Receive Clock Duty Cycle Time (Note 1)	40	60	ns
T105	Carrier Sense on Time		70	ns
T106	Data Acquisition Time		700	ns
T107	Receive Data Output Delay		150	ns
T108	Receive Data Valid from RXC		10	ns
T109	Receive Data Stable Valid Time	90		ns
T112	Carrier Sense Off Delay		250	ns
T113	Minimum Number of RXCs after CRS Low (Note 3)	5		rcyc
T114	Collision Turn On Time		55	ns
T115	Collision Turn Off Time		250	ns

**Note 1:** This parameter is measured at the 50% point of each clock edge.

**Note 2:** When CRSi goes low, it remains low for a minimum of 2 receive clocks (RXC).

**Note 3:** rcyc = receive clocks.

## 9.0 AC and DC Specifications (Continued)

### ENDEC-MAC SERIAL TIMING FOR RECEPTION (EXTERNAL ENDEC MODE)

TL/F/11719-92

Number	Parameter	Min	Max	Units
T118	Receive Clock High Time	40		ns
T119	Receive Clock Low Time	40		ns
T120	Receive Clock Cycle Time	90	110	ns
T121	RXD Setup to RXC	20		ns
T122	RXD Hold from RXC	15		ns
T124	Maximum Allowed Dribble Bits		6	Bits
T125	Receive Recovery Time (Note 2)			
T126	RXC to Carrier Sense Low (Notes 1, 3)		1	rcyc

**Note 1:** tcyc = transmit clocks, rcyc = receive clocks, bcyc = T3.

**Note 2:** This parameter refers to longest time (not including wait-states) the SONIC™ requires to perform its end of receive processing and be ready for the next start of frame delimiter. This time is 4 + 36 ccyc bcyc. This is guaranteed by design and is not tested.

**Note 3:** To ensure proper receive operation, a minimum of 5 RXCs after CRS low are required.

### ENDEC-MAC SERIAL TIMING FOR TRANSMIT (NO COLLISION)

TL/F/11719-86

Number	Parameter	Min	Max	Units
T127	Transmit Clock High Time	40		ns
T128	Transmit Clock Low Time	40		ns
T129	Transmit Clock Cycle Time	90	110	ns
T130	TXC to TXE High		40	ns
T131	TXC to TXD Valid		40	ns
T132	TXD Hold Time from TXC	0		ns
T133	TXC to TXE Low		40	ns
T134	TXE Low to Start of CD Heartbeat (Note 1)		64	tcyc
T135	Collision Detect Width (Note 1)	2		tcyc

**Note 1:** tcyc = transmit clock.

Symbol	Parameter	Min	Max	Units
$t_{lp}$	Time between Link Output Pulses	8	24	ms
$t_{lpw}$	Link Integrity Output Pulse Width	80	130	ns

### TPI TRANSMIT TIMING (End of Packet)

TL/F/11719-82

Symbol	Parameter	Min	Max	Units
$t_{del}$	Pre-Emphasis Output Delay (TX0± to TX0±) (Note 1)	46	54	ns
$t_{off}$	Transmit Hold Time at End of Packet (TX0±) (Note 1)	250		ns
$t_{offd}$	Transmit Hold Time at End of Packet (TX0d±) (Note 1)	200		ns

**Note 1:** This parameter is guaranteed by design and is not tested.

## 10.0 AC Timing Test Conditions

All specifications are valid only if the mandatory isolation is employed and all differential signals are taken to be at the AUI side of the pulse transformer.

Input Pulse Levels (TTL/CMOS)	GND to 3.0V
Input Rise and Fall Times (TTL/CMOS)	5 ns
Input and Output Reference Levels (TTL/CMOS)	1.5V
Input Pulse Levels (Diff.)	-350 mV to -1315 mV
Input and Output Reference Levels (Diff.)	50% Point of the Differential
TRI-STATE Reference Levels	Float ( $\Delta V$ ) $\pm 0.5V$

### OUTPUT LOAD (See Figure below)

TL/F/11719-83

**Note 1:** 50 pF, includes scope and jig capacitance.

**Note 2:** S1 = Open for timing test for push pull outputs.

S1 =  $V_{CC}$  for  $V_{OL}$  test.

S1 = GND for  $V_{OH}$  test.

S1 =  $V_{CC}$  for High Impedance to active low and active low to High Impedance measurements.

S1 = GND for High Impedance to active high and active High to High Impedance measurements.

## Pin Capacitance $T_A = 25^\circ C, f = 1 \text{ MHz}$

Symbol	Parameter	Typ	Units
$C_{IN}$	Input Capacitance	7	pF
$C_{OUT}$	Output Capacitance	7	pF

### DERATING FACTOR

Output timing is measured with a purely capacitive load of 50 pF. The following correction factor can be used for other loads:  $C_L \geq 50 \text{ pF} = 0.05 \text{ ns/pF}$ .

### AUI Transmit Test Load

TL/F/11719-84

**Note:** In the above diagram, the TX+ and TX- signals are taken from the AUI side of the isolation (pulse transformer). The pulse transformer used for all testing is a 100  $\mu H \pm 0.1\%$  Pulse Engineering PE64103.

# DP83932C-20/25/33 MHz SONIC™ Systems-Oriented Network Interface Controller

## General Description

The SONIC (Systems-Oriented Network Interface Controller) is a second-generation Ethernet Controller designed to meet the demands of today's high-speed 32- and 16-bit systems. Its system interface operates with a high speed DMA that typically consumes less than 3% of the bus bandwidth (25 MHz bus clock). Selectable bus modes provide both big and little endian byte ordering and a clean interface to standard microprocessors. The linked-list buffer management system of SONIC offers maximum flexibility in a variety of environments from PC-oriented adapters to high-speed motherboard designs. Furthermore, the SONIC integrates a fully-compatible IEEE 802.3 Encoder/Decoder (ENDEC) allowing for a simple 2-chip solution for Ethernet when the SONIC is paired with the DP8392 Coaxial Transceiver Interface or a 10BASE-T transceiver.

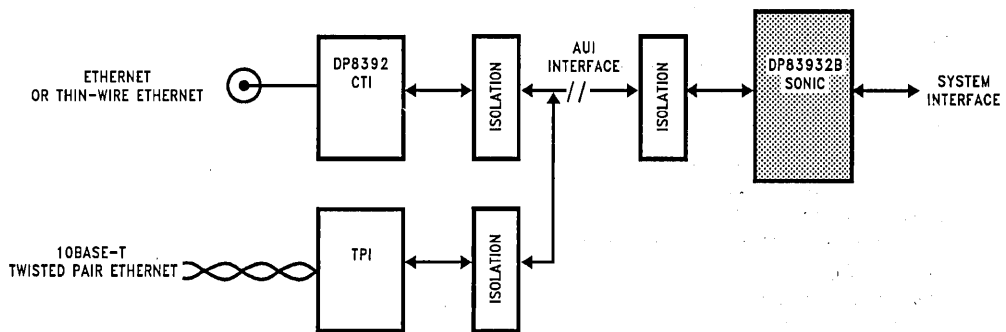

For increased performance, the SONIC implements a unique buffer management scheme to efficiently process, receive and transmit packets in system memory. No intermediate packet copy is necessary. The receive buffer management uses three areas in memory for (1) allocating additional resources, (2) indicating status information, and (3) buffering packet data. During reception, the SONIC stores packets in the buffer area, then indicates receive status and control information in the descriptor area. The system allocates more memory resources to the SONIC by adding descriptors to the memory resource area. The transmit buffer

management uses two areas in memory: one for indicating status and control information and the other for fetching packet data. The system can create a transmit queue allowing multiple packets to be transmitted from a single transmit command. The packet data can reside on any arbitrary byte boundary and can exist in several non-contiguous locations.

## Features

- 32-bit non-multiplexed address and data bus
- High-speed, interruptible DMA
- Linked-list buffer management maximizes flexibility
- Two independent 32-byte transmit and receive FIFOs
- Bus compatibility for all standard microprocessors
- Supports big and little endian formats
- Integrated IEEE 802.3 ENDEC
- Complete address filtering for up to 16 physical and/or multicast addresses
- 32-bit general-purpose timer
- Full-duplex loopback diagnostics
- Fabricated in low-power CMOS
- 132 PQFP package
- Full network management facilities support the 802.3 layer management standard
- Integrated support for bridge and repeater applications

## 1.0 Functional Description

The SONIC (*Figure 1-1*) consists of an encoder/decoder (ENDEC) unit, media access control (MAC) unit, separate receive and transmit FIFOs, a system buffer management engine, and a user programmable system bus interface unit on a single chip. SONIC is highly pipelined providing maximum system level performance. This section provides a functional overview of SONIC.

### 1.1 IEEE 802.3 ENDEC UNIT

The ENDEC (Encoder/Decoder) unit is the interface between the Ethernet transceiver and the MAC unit. It provides the Manchester data encoding and decoding functions for IEEE 802.3 Ethernet/Thin-Ethernet type local area networks. The ENDEC operations of SONIC are identical to the DP83910A CMOS Serial Network Interface device. During transmission, the ENDEC unit combines non-return-zero (NRZ) data from the MAC section and clock pulses into Manchester data and sends the converted data differentially to the transceiver. Conversely, during reception, an analog PLL decodes the Manchester data to NRZ format and receive clock. The ENDEC unit is a functionally complete Manchester encoder/decoder incorporating a balanced driver and receiver, on-board crystal oscillator, collision signal translator, and a diagnostic loopback. The features include:

- Compatible with Ethernet I and II, IEEE 802.3 10base5 and 10base2
- 10Mb/s Manchester encoding/decoding with receive clock recovery
- Requires no precision components
- Loopback capability for diagnostics
- Externally selectable half or full step modes of operation at transmit output
- Squelch circuitry at the receive and collision inputs reject noise
- Connects to the transceiver (AUI) cable via external pulse transformer

### 1.1.1 ENDEC Operation

The primary function of the ENDEC unit (*Figure 1-2*) is to perform the encoding and decoding necessary for compatibility between the differential pair Manchester encoded data of the transceiver and the Non-Return-to-Zero (NRZ) serial data of the MAC unit data line. In addition to encoding and decoding the data stream, the ENDEC also supplies all the necessary special signals (e.g., collision detect, carrier sense, and clocks) to the MAC unit. The signals provided to the MAC unit from the on-chip ENDEC are also provided as outputs to the user.

#### Manchester Encoder and Differential Output Driver:

During transmission to the network, the ENDEC unit translates the NRZ serial data from the MAC unit into differential pair Manchester encoded data on the Coaxial Transceiver Interface (e.g., National's DP8392) transmit pair. To perform this operation the NRZ bit stream from the MAC unit is passed through the Manchester encoder block of the ENDEC unit. Once the bit stream is encoded, it is transmitted out differentially to the transmit differential pair through the transmit driver.

**Manchester Decoder:** During reception from the network, the differential receive data from the transceiver (e.g., the DP8392) is converted from Manchester encoded data into NRZ serial data and a receive clock, which are sent to the receive data and clock inputs of the MAC unit. To perform this operation the signal, once received by the differential receiver, is passed to the phase locked loop (PLL) decoder block. The PLL decodes the data and generates a data receive clock and a NRZ serial data stream to the MAC unit.

**Special Signals:** In addition to performing the Manchester encoding and decoding function, the ENDEC unit provides control and clocking signals to the MAC unit. The ENDEC sends a carrier sense (CRS) signal that indicates to the MAC unit that data is present from the network on the ENDEC's receive differential pair. The MAC unit is also provided with a collision detection signal (COL) that informs the MAC unit that a collision is taking place somewhere on

FIGURE 1-1. SONIC Block Diagram

TL/F/10492-1

FIGURE 1-2. Block Diagram of Ethernet ENDEC

1-640

## 1.0 Functional Description (Continued)

the network. The ENDEC section detects this when its collision receiver detects a 10 MHz signal on the differential collision input pair. The ENDEC also provides both the receive and transmit clocks to the MAC unit. The transmit clock is one half of the oscillator input. The receive clock is extracted from the input data by the PLL.

**Oscillator:** The oscillator generates the 10 MHz transmit clock signal for network timing. The oscillator is controlled by a parallel resonant crystal or by an external clock (see Section 6.1.3). The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock (TXC) for the MAC section. The oscillator provides an internal clock signal for the encoding and decoding circuits.

**Loopback Functions:** The SONIC provides three loopback modes. These modes allow loopback testing at the MAC, ENDEC and external transceiver level (see Section 1.7 for details). It is important to note that when the SONIC is transmitting, the transmitted packet will always be looped back by the external transceiver. The SONIC takes advantage of this to monitor the transmitted packet. See the explanation of the Receive State Machine in Section 1.2.1 for more information about monitoring transmitted packets.

### 1.1.2 Selecting An External ENDEC

An option is provided on SONIC to disable the on-chip ENDEC unit and use an external ENDEC. The internal IEEE 802.3 ENDEC can be bypassed by connecting the EXT pin to V<sub>CC</sub> (EXT = 1). In this mode the MAC signals are redirected, allowing an external ENDEC to be used. See Section 5.2 for the alternate pin definitions.

## 1.2 MAC UNIT

The MAC (Media Access Control) unit performs the media access control functions for transmitting and receiving packets over Ethernet. During transmission, the MAC unit frames information from the transmit FIFO and supplies serialized data to the ENDEC unit. During reception, the incoming information from the ENDEC unit is deserialized, the frame checked for valid reception, and the data is transferred to the receive FIFO. Control and status registers on the SONIC govern the operation of the MAC unit.

### 1.2.1 MAC Receive Section

The receive section (*Figure 1-3*) controls the MAC receive operations during reception, loopback, and transmission. During reception, the deserializer goes active after detecting the one byte SFD (Start of Frame Delimiter) pattern (Section 2.1) consisting of a "10101011" sequence. It then frames the incoming bits into octet boundaries and transfers the

data to the 32-byte receive FIFO. Concurrently the address comparator compares the Destination Address Field to the addresses stored in the chip's CAM address registers (Content Addressable Memory cells). If a match occurs, the deserializer passes the remainder of the packet to the receive FIFO. The packet is decapsulated when the carrier sense input pin (CRS) goes inactive. At the end of reception the receive section checks the following:

- Frame alignment errors
- CRC errors
- Length errors (runt packets)

The appropriate status is indicated in the Receive Control register (Section 4.3.3). In loopback operations, the receive section operates the same as during normal reception.

During transmission, the receive section remains active to allow monitoring of the self-received packet. The CRC checker operates as normal, and the Source Address field is compared with the CAM address entries. Status of the CRC check and the source address comparison is indicated by the PMB bit in the Transmit Control register (Section 4.3.4). No data is written to the receive FIFO during transmit operations.

The receive section consists of the following blocks detailed below.

**Receive State Machine (RSM):** The RSM insures the proper sequencing for normal reception and self-reception during transmission. When the network is inactive, the RSM remains in an idle state continually monitoring for network activity. If the network becomes active, the RSM allows the deserializer to write data into the receive FIFO. During this state, the following conditions may prevent the complete reception of the packet.

- FIFO Overrun—The receive FIFO has been completely filled before the SONIC could buffer the data to memory.
- CAM Address Mismatch—The packet is rejected because of a mismatch between the destination address of the packet and the address in the CAM.
- Memory Resource Error—There are no more resources (buffers) available for buffering the incoming packets.
- Collision or Other Error—A collision occurred on the network or some other error, such as a CRC error, occurred (this is true if the SONIC has been told to reject packets on a collision, or reject packets with errors).

If these conditions do not occur, the RSM processes the packet indicating the appropriate status in the Receive Control register.

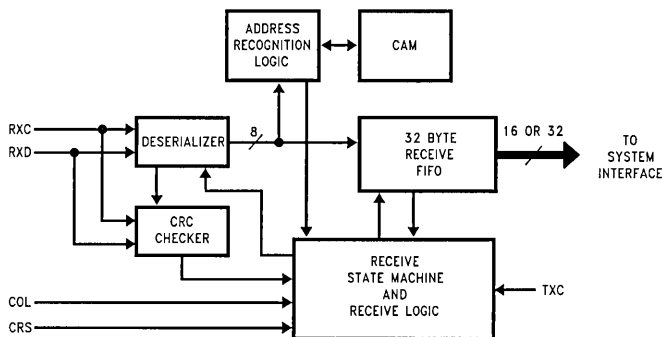

FIGURE 1-3. MAC Receiver

TL/F/10492-4

## 1.0 Functional Description (Continued)

During transmission of a packet from the SONIC, the external transceiver will always loop the packet back to the SONIC. The SONIC will use this to monitor the packet as it is being transmitted. The CRC and source address of the looped back packet are checked with the CRC and source address that were transmitted. If they do not match, an error bit is set in the status of the transmitted packet (see Packet Monitored Bad, PMB, in the Transmit Control Register, Section 4.3.4). Data is not written to the receive FIFO during this monitoring process unless Transceiver Loopback mode has been selected (see Section 1.7).

**Receive Logic:** The receive logic contains the command, control, and status registers that govern the operations of the receive section. It generates the control signals for writing data to the receive FIFO, processes error signals obtained from the CRC checker and the deserializer, activates the "packet reject" signal to the RSM for rejecting packets, and posts the applicable status in the Receive Control register.

**Deserializer:** This section deserializes the serial input data stream and furnishes a byte clock for the address comparator and receive logic. It also synchronizes the CRC checker to begin operation (after SFD is detected), and checks for proper frame alignment with respect to CRS going inactive at the end of reception.

**Address Comparator:** The address comparator latches the Destination Address (during reception or loopback) or Source Address (during transmission) and determines whether the address matches one of the entries in the CAM (Content Addressable Memory).

**CRC Checker:** The CRC checker calculates the 4-byte Frame Check Sequence (FCS) field from the incoming data stream and compares it with the last 4-bytes of the received packet. The CRC checker is active for both normal reception and self-reception during transmission.

**Content Addressable Memory (CAM):** The CAM contains 16 user programmable entries and 1 pre-programmed Broadcast address entry for complete filtering of received packets. The CAM can be loaded with any combination of Physical and Multicast Addresses (Section 2.2). See Section 4.1 for the procedure on loading the CAM registers.

### 1.2.2 MAC Transmit Section

The transmit section (Figure 1-4) is responsible for reading data from the transmit FIFO and transmitting a serial data

stream onto the network in conformance with the IEEE 802.3 CSMA/CD standard. The Transmit Section consists of the following blocks.

**Transmit State Machine (TSM):** The TSM controls the functions of the serializer, preamble generator, and JAM generator. It determines the proper sequence of events that the transmitter follows under various network conditions. If no collision occurs, the transmitter prefixes a 7 byte preamble and 1 byte Start of Frame Delimiter (SFD) consisting of a "10101011" sequence at the beginning of each packet, then sends the serialized data. At the end of the packet, an optional 4-byte CRC pattern is appended. If a collision occurs, the transmitter switches from transmitting data to sending a 4-byte Jam pattern to notify all nodes that a collision has occurred. Should the collision occur during the preamble, the transmitter waits for it to complete before jamming. After the transmission has completed, the transmitter writes status in the Transmit Control register (Section 4.3.4).

**Protocol State Machine:** The protocol state machine assures that the SONIC obeys the CSMA/CD protocol. Before transmitting, this state machine monitors the carrier sense and collision signals for network activity. If another node(s) is currently transmitting, the SONIC defers until the network is quiet, then transmits after its Interframe Gap Timer (9.6  $\mu$ s) has expired. The Interframe Gap time is divided into two portions. During the first 6.4  $\mu$ s, network activity restarts the Interframe Gap timer. Beyond this time, however, network activity is ignored and the state machine waits the remaining 3.2  $\mu$ s before transmitting. If the SONIC experiences a collision during a transmission, the SONIC switches from transmitting data to a 4-byte JAM pattern (4 bytes of all 1's), before ceasing to transmit. The SONIC then waits a random number of slot times (51.2  $\mu$ s) determined by the *Truncated Binary Exponential Backoff Algorithm* before reattempting another transmission. In this algorithm, the number of slot times to delay before the nth retransmission is chosen to be a random integer  $r$  in the range of:

$$0 \leq r \leq 2^k$$

$$\text{where } k = \min(n, 10)$$

If a collision occurs on the 16th transmit attempt, the SONIC aborts transmitting the packet and reports an "Excessive Collisions" error in the Transmit Control register.

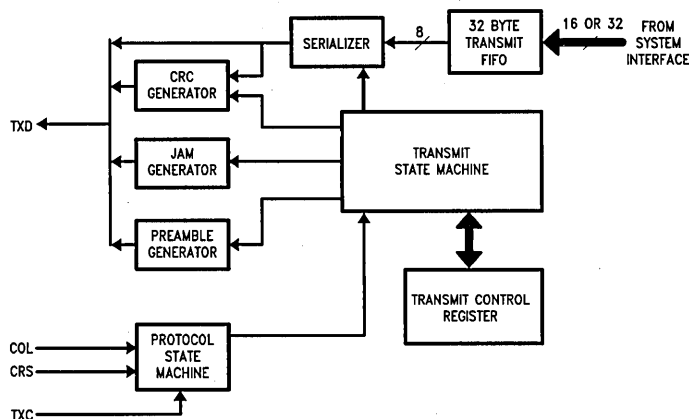

FIGURE 1-4. MAC Transmitter

## 1.0 Functional Description (Continued)

**Serializer:** After data has been written into the 32-byte transmit FIFO, the serializer reads byte wide data from the FIFO and sends a NRZ data stream to the Manchester encoder. The rate at which data is transmitted is determined by the transmit clock (TXC). The serialized data is transmitted after the SFD.

**Preamble Generator:** The preamble generator prefixes a 7 byte alternating "1,0" pattern and a 1 byte "10101011" SFD pattern at the beginning of each packet. This allows receiving nodes to synchronize to the incoming data. The preamble is always transmitted in its entirety even in the event of a collision. This assures that the minimum collision fragment is 96 bits (64 bits of normal preamble, and 4 bytes, or rather 32 bits, of the JAM pattern).

**CRC Generator:** The CRC generator calculates the 4-byte FCS field from the transmitted serial data stream. If enabled, the 4-byte FCS field is appended to the end of the transmitted packet (Section 2.6).

For bridging or switched ethernet applications the CRC Generator can be inhibited by setting bit 13 in the Transmit Control Register (Section 4.3.4). This feature is used when an ethernet segment has already received a packet with a CRC appended and needs to forward it to another ethernet segment.

**Jam Generator:** The Jam generator produces a 4-byte pattern of all 1's to assure that all nodes on the network sense the collision. When a collision occurs, the SONIC stops transmitting data and enables the Jam generator. If a collision occurs during the preamble, the SONIC finishes transmitting the preamble before enabling the Jam generator (see Preamble Generator above).

### 1.3 DATA WIDTH AND BYTE ORDERING

The SONIC can be programmed to operate with either 32-bit or 16-bit wide memory. The data width is configured during initialization by programming the DW bit in the Data Configuration Register (DCR, Section 4.3.2). If the 16-bit data path is selected, data is driven on pins D15-D0. The SONIC also provides both Little Endian and Big Endian

byte-ordering capability for compatibility with National/Intel or Motorola microprocessors respectively by selecting the proper level on the BMODE pin. The byte ordering is depicted below.

**Little Endian mode (National/Intel, BMODE = 0):** The byte orientation for received and transmitted data in the Receive Buffer Area (RBA) and Transmit Buffer Area (TBA) of system memory is as follows:

**Big Endian mode (Motorola, BMODE = 1):** The byte orientation for received and transmitted data in the RBA and TBA is as follows:

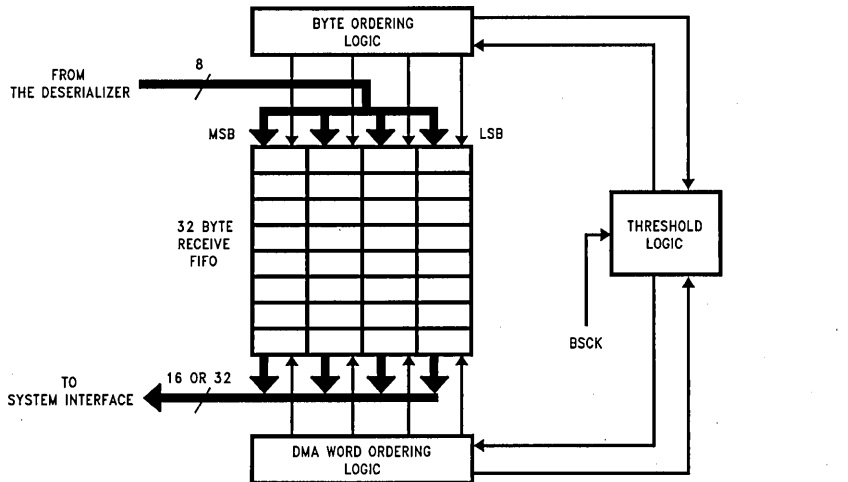

FIGURE 1-5. Receive FIFO

TL/F/10492-6

## 1.0 Functional Description (Continued)

### 1.4 FIFO AND CONTROL LOGIC

The SONIC incorporates two independent 32-byte FIFOs for transferring data to/from the system interface and from/to the network. The FIFOs, providing temporary storage of data, free the host system from the real-time demands on the network.

The way in which the FIFOs are emptied and filled is controlled by the FIFO threshold values and the Block Mode Select bits (BMS, Section 4.3.2). The threshold values determine how full or empty the FIFOs can be before the SONIC will request the bus to get more data from memory or buffer more data to memory. When block mode is set, the number of bytes transferred is set by the threshold value. For example, if the threshold for the receive FIFO is 4 words, then the SONIC will always transfer 4 words from the receive FIFO to memory. If empty/fill mode is set, however, the number of bytes transferred is the number required to fill the transmit FIFO or empty the receive FIFO. More specific information about how the threshold affects reception and transmission of packets is discussed in Sections 1.4.1 and 1.4.2 below.

#### 1.4.1 Receive FIFO

To accommodate the different transfer rates, the receive FIFO (*Figure 1-5*) serves as a buffer between the 8-bit network (deserializer) interface and the 16/32-bit system interface. The FIFO is arranged as a 4-byte wide by 8 deep memory array (8 long words, or 32 bytes) controlled by three sections of logic. During reception, the Byte Ordering logic directs the byte stream from the deserializer into the FIFO using one of four write pointers. Depending on the selected byte-ordering mode, data is written either least significant byte first or most significant byte first to accommodate little or big endian byte-ordering formats respectively.

As data enters the FIFO, the Threshold Logic monitors the number of bytes written in from the deserializer. The programmable threshold (RFT1,0 in the Data Configuration Register) determines the number of words (or long words) written into the FIFO from the MAC unit before a DMA request for system memory occurs. When the threshold is reached, the Threshold Logic enables the Buffer Management Engine to read a programmed number of 16- or 32-bit words (depending upon the selected data width) from the FIFO and transfers them to the system interface (the system memory) using DMA. The threshold is reached when the number of bytes in the receive FIFO is greater than the value of the threshold. For example, if the threshold is 4 words (8 bytes), then the Threshold Logic will not cause the Buffer Management Engine to write to memory until there are more than 8 bytes in the FIFO.

The Buffer Management Engine reads either the upper or lower half (16 bits) of the FIFO in 16-bit mode or reads the complete long word (32 bits) in 32-bit mode. If, after the transfer is complete, the number of bytes in the FIFO is less than the threshold, then the SONIC is done. This is always the case when the SONIC is in empty/fill mode. If, however, for some reason (e.g. latency on the bus) the number of bytes in the FIFO is still greater than the threshold value, the Threshold Logic will cause the Buffer Management Engine to do a DMA request to write to memory again. This later case is usually only possible when the SONIC is in block mode.

When in block mode, each time the SONIC requests the bus, only a number of bytes equal to the threshold value will be transferred. The Threshold Logic continues to monitor

the number of bytes written in from the deserializer and enables the Buffer Management Engine every time the threshold has been reached. This process continues until the end of the packet.

Once the end of the packet has been reached, the serializer will fill out the last word (16-bit mode) or long word (32-bit mode) if the last byte did not end on a word or long word boundary respectively. The fill byte will be 0FFh. Immediately after the last byte (or fill byte) in the FIFO, the received packets status will be written into the FIFO. The entire packet, including any fill bytes and the received packet status will be buffered to memory. When a packet is buffered to memory by the Buffer Management Engine, it is always taken from the FIFO in words or long words and buffered to memory on word (16-bit mode) or long word (32-bit mode) boundaries. Data from a packet cannot be buffered on odd byte boundaries for 16-bit mode, and odd word boundaries for 32-bit mode (see Section 3.3). For more information on the receive packet buffering process, see Section 3.4.

#### 1.4.2 Transmit FIFO

Similar to the Receive FIFO, the Transmit FIFO (*Figure 1-6*) serves as a buffer between the 16/32-bit system interface and the network (serializer) interface. The Transmit FIFO is also arranged as a 4 byte by 8 deep memory array (8 long words or 32 bytes) controlled by three sections of logic. Before transmission can begin, the Buffer Management Engine fetches a programmed number of 16- or 32-bit words from memory and transfers them to the FIFO. The Buffer Management Engine writes either the upper or lower half (16 bits) into the FIFO for 16-bit mode or writes the complete long word (32 bits) during 32-bit mode.

The Threshold logic monitors the number of bytes as they are written into the FIFO. When the threshold has been reached, the Transmit Byte Ordering state machine begins reading bytes from the FIFO to produce a continuous byte stream for the serializer. The threshold is met when the number of bytes in the FIFO is greater than the value of the threshold. For example, if the transmit threshold is 4 words (8 bytes), the Transmit Byte Ordering state machine will not begin reading bytes from the FIFO until there are 9 or more bytes in the buffer. The Buffer Management Engine continues replenishing the FIFO until the end of the packet. It does this by making multiple DMA requests to the system interface. Whenever the number of bytes in the FIFO is equal to or less than the threshold value, the Buffer Management Engine will do a DMA request. If block mode is set, then after each request has been granted by the system, the Buffer Management Engine will transfer a number of bytes equal to the threshold value into the FIFO. If empty/fill mode is set, the FIFO will be completely filled in one DMA request.

Since data may be organized in big or little endian byte ordering format, the Transmit Byte Ordering state machine uses one of four read pointers to locate the proper byte within the 4 byte wide FIFO. It also determines the valid number of bytes in the FIFO. For packets which begin or end at odd bytes in the FIFO, the Buffer Management Engine writes extraneous bytes into the FIFO. The Transmit Byte Ordering state machine detects these bytes and only transfers the valid bytes to the serializer. The Buffer Management Engine can read data from memory on any byte boundary (see Section 3.3). See Section 3.5 for more information on transmit buffering.

## 1.0 Functional Description (Continued)

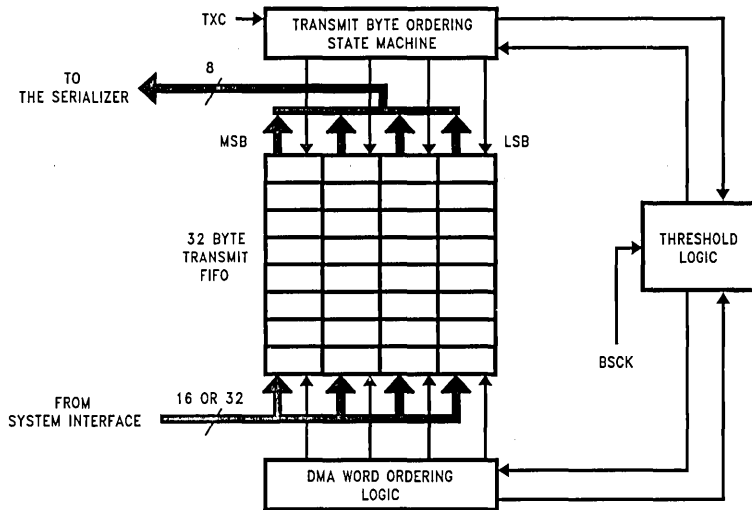

FIGURE 1-6. Transmit FIFO

### 1.5 STATUS AND CONFIGURATION REGISTERS

The SONIC contains a set of status/control registers for conveying status and control information to/from the host system. The SONIC uses these registers for loading commands generated from the system, indicating transmit and receive status, buffering data to/from memory, and providing interrupt control. Each register is 16 bits in length. See Section 4.0 for a description of the registers.

### 1.6 BUS INTERFACE

The system interface (Figure 1-7) consists of the pins necessary for interfacing to a variety of buses. It includes the I/O drivers for the data and address lines, bus access control for standard microprocessors, ready logic for synchronous or asynchronous systems, slave access control, interrupt control, and shared-memory access control. The functional signal groups are shown in Figure 1-7. See Section 5.0 for a complete description of the SONIC bus interface.

### 1.7 LOOPBACK AND DIAGNOSTICS

The SONIC furnishes three loopback modes for self-testing from the controller interface to the transceiver interface. The loopback function is provided to allow self-testing of the chip's internal transmit and receive operations. During loopback, transmitted packets are routed back to the receive section of the SONIC where they are filtered by the address recognition logic and buffered to memory if accepted. Transmit and receive status and interrupts remain active during loopback. This means that when using loopback, it is as if the packet was transmitted and received by two separate chips that are connected to the same bus and memory.

**MAC Loopback:** Transmitted data is looped back at the MAC. Data is not sent from the MAC to either the internal ENDEC or an external ENDEC (the external ENDEC interface pins will not be driven), hence, data is not transmitted from the chip. Even though the ENDEC is not used in MAC loopback, the ENDEC clock (an oscillator or crystal for the

internal ENDEC or TXC for an external ENDEC) must be driven. Network activity, such as a collision, does not affect MAC loopback. CSMA/CD MAC protocol is not completely followed in MAC loopback.

**ENDEC Loopback:** Transmitted data is looped back at the ENDEC. If the internal ENDEC is used, data is switched from the transmit section of the ENDEC to the receive section (Figure 1-2). Data is not transmitted from the chip and the collision lines,  $CD \pm$ , are ignored, hence, network activity does not affect ENDEC loopback. The LBK signal from the MAC tells the internal ENDEC to go into loopback mode. If an external ENDEC is used, it should operate in loopback mode when the LBK signal is asserted. CSMA/CD MAC protocol is followed even though data is not transmitted from the chip.

**Transceiver Loopback:** Transmitted data is looped back at the external transceiver (which is always the case regardless of the SONIC's loopback mode). CSMA/CD MAC protocol is followed since data will be transmitted from the chip. This means that transceiver loopback is affected by network activity. In normal operations, the SONIC only monitors the packet that is looped back by the transceiver, but does not fill the receive FIFO and buffer the packet.

#### 1.7.1 Loopback Procedure

The following procedure describes the loopback operation.

1. Initialize the Transmit and Receive Area as described in Sections 3.4 and 3.5.
2. Load one of the CAM address registers (see Section 4.1), with the Destination Address of the packet if you are verifying the SONIC's address recognition capability.
3. Load one of the CAM address registers with the Source Address of the packet if it is different than the Destination Address to avoid getting a Packet Monitored Bad (PMB) error in the Transmit status (see Section 4.3.4).

### 1.0 Functional Description (Continued)

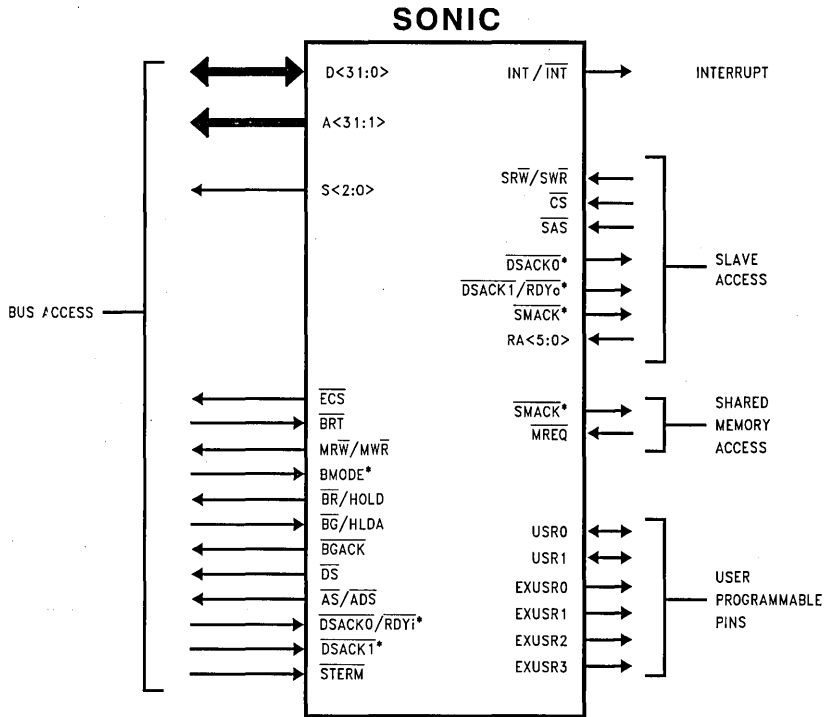

4. Program the Receive Control register with the desired receive filter and the loopback mode (LB1, LB0).
5. Issue the transmit command (TXP) and enable the receiver (RXEN) in the Command register.

The SONIC completes the loopback operation after the packet has been completely received (or rejected if there is an address mismatch). The Transmit Control and Receive Control registers treat the loopback packet as in normal operation and indicate status accordingly. Interrupts are also generated if enabled in the Interrupt Mask register.

**Note:** For MAC Loopback, only one packet may be queued for proper operation. This restriction occurs because the transmit MAC section, which does not generate an Interframe Gap time (IFG) between transmitted packets, does not allow the receive MAC section to update receive status. There are no restrictions for the other loopback modes.

### 1.8 NETWORK MANAGEMENT FUNCTIONS

The SONIC fully supports the Layer Management IEEE 802.3 standard to allow a node to monitor the overall performance of the network. These statistics are available on a per packet basis at the end of reception or transmission. In addition, the SONIC provides three tally counters to tabulate CRC errors, Frame Alignment errors, and missed packets. Table 1-1 shows the statistics indicated by the SONIC.

TL/F/10492-8

\*Note: DSACK0,1 are used for both Bus and Slave Access Control and are bidirectional. SMACK is used for both Slave access and shared memory access. The BMODE pin selects between National/Intel or Motorola type buses.

Alignment Errors	FAET RCR	All FAE
Frame Lost Due to Internal MAC Receive Error	MPT ISR	All RFO

**Note:** The number of collisions and the contents of the Transmit Control register are posted in the TXpkt.status field (see Section 3.5.1.2). The contents of the Receive Control register are posted in the RXpkt.status field (see Section 3.4.3).

## 2.0 Transmit/Receive IEEE 802.3 Frame Format

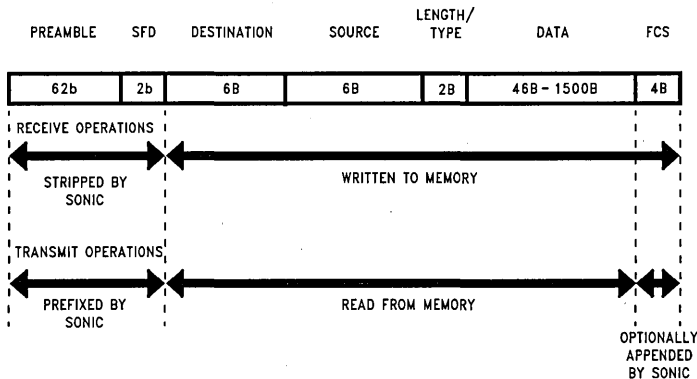

A standard IEEE 802.3 packet (*Figure 2-1*) consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data and Frame Check Sequence (FCS). The typical format is shown in *Figure 2-1*. The packets are Manchester encoded and decoded by the ENDEC unit and transferred serially to/from the MAC unit using NRZ data with a clock. All fields are of fixed length except for the data field. The SONIC generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

### 2.1 PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted, each packet contains 62 bits of an alternating 1,0 preamble. Some of this preamble may be lost as the packet travels through the network. Byte alignment is performed when the Start of Frame Delimiter (SFD) pattern, consisting of two consecutive 1's, is detected.

### 2.2 DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted pack-

**Note:** B = bytes  
b = bits

**FIGURE 2-1. IEEE 802.3 Packet Structure**

TL/F/10492-9

## 2.0 Transmit/Receive IEEE 802.3 Frame Format (Continued)

ets from reaching a node. There are three types of address formats supported by the SONIC: Physical, Multicast, and Broadcast.

**Physical Address:** The physical address is a unique address that corresponds only to a single node. All physical addresses have the LSB of the first byte of the address set to "0". These addresses are compared to the internally stored CAM (Content Addressable Memory) address entries. All bits in the destination address must match an entry in the CAM in order for the SONIC to accept the packet.

**Multicast Address:** Multicast addresses, which have the LSB of the first byte of the address set to "1", are treated similarly as Physical addresses, i.e., they must match an entry in the CAM. This allows perfect filtering of Multicast packets and eliminates the need for a hashing algorithm for mapping Multicast packets.

**Broadcast Address:** If the address consists of all 1's, it is a Broadcast address, indicating that the packet is intended for all nodes.

The SONIC also provides a promiscuous mode which allows reception of all physical address packets. Physical, Multicast, Broadcast, and promiscuous address modes can be selected via the Receive Control register.

### 2.3 SOURCE ADDRESS

The source address is the physical address of the sending node. Source addresses cannot be multicast or broadcast addresses. This field must be passed to the SONIC's transmit buffer from the system software. During transmission, the SONIC compares the Source address with its internal CAM address entries before monitoring the CRC of the self-received packet. If the source address of the packet transmitted does not match a value in the CAM, the packet monitored bad flag (PMB) will be set in the transmit status field of the transmit descriptor (see Sections 3.5.1.2 and 4.3.4). The SONIC does not provide Source Address insertion. However, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. (See Section 3.5.1.)

### 2.4 LENGTH/TYPE FIELD

For IEEE 802.3 type packets, this field indicates the number of bytes that are contained in the data field of the packet. For Ethernet I and II networks, this field indicates the type of packet. The SONIC does not operate on this field.

### 2.5 DATA FIELD

The data field has a variable octet length ranging from 46 to 1500 bytes as defined by the Ethernet specification. Messages longer than 1500 bytes need to be broken into multiple packets for IEEE 802.3 networks. Data fields shorter than 46 bytes require appending a pad to bring the complete frame length to 64 bytes. If the data field is padded, the number of valid bytes are indicated in the length field. The SONIC does not append pad bytes for short packets during transmission, nor check for oversize packets during reception. However, the user's driver software can easily append the pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes (see Section 3.5.1). While the Ethernet specification defines the maximum number of bytes in the data field the SONIC can transmit and receive packets up to 64k bytes in length.

### 2.6 FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of error-free packets. During reception, an error-free packet results in a specific pattern in the CRC

generator. The AUTODIN II ( $X^{32} + X^{26} + X^{23} + X^{22} + X^{16} + X^{12} + X^{11} + X^{10} + X^8 + X^7 + X^5 + X^4 + X^2 + X^1 + 1$ ) polynomial is used for the CRC calculations. The SONIC may optionally append the CRC sequence during transmission, and checks the CRC both during normal reception and self-reception during a transmission (see Section 1.2.1).

### 2.7 MAC (MEDIA ACCESS CONTROL) CONFORMANCE

The SONIC is designed to be compliant to the IEEE 802.3 MAC Conformance specification. The SONIC implements most MAC functions in silicon and provides hooks for the user software to handle the remaining functions. The MAC Conformance specifications are summarized in Table 2-1.

**TABLE 2-1. MAC Conformance Specifications**

Conformance Test Name	Support By		
	SONIC	User Driver Software	Notes
Minimum Frame Size	X		
Maximum Frame Size	X	X	1
Address Generation	X	X	2
Address Recognition	X		
Pad Length Generation	X	X	3
Start Of Frame Delimiter	X		
Length Field	X

Back-to-Back Frames	X		
Flow Control	X		
Attempt Limit	X		
Jam Size (after SFD)	X		
Jam Size (in Preamble)	X		

**Note 1:** The SONIC provides the byte count of the entire packet in the RXpkt.byte\_count (see Section 3.4.3). The user's driver software may perform further filtering of the packet based upon the byte count.

**Note 2:** The SONIC does not provide Source Address insertion; however, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. See Section 3.5.1.

**Note 3:** The SONIC does not provide Pad generation; however, the user's driver software can easily append the Pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes. See Section 3.5.1.

### 3.0 Buffer Management

#### 3.1 BUFFER MANAGEMENT OVERVIEW

The SONIC's buffer management scheme is based on separate buffers and descriptors (*Figures 3-2 and 3-11*). Packets that are received or transmitted are placed in buffers called the Receive Buffer Area (RBA) and the Transmit Buffer Area (TBA). The system keeps track of packets in these buffers using the information in the Receive Descriptor Area (RDA) and the Transmit Descriptor Area (TDA). A single (TDA) points to a single TBA, but multiple RDAs can point to a single RBA (one RDA per packet in the buffer). The Receive Resource Area (RRA), which is another form of descriptor, is used to keep track of the actual buffer.

When packets are transmitted, the system sets up the packets in one or more TBAs with a TDA pointing to each TBA. There can only be one packet per TBA/TDA pair. A single TBA, however, may be made up of several fragments of data dispersed in memory. There is one TDA pointing to each TBA which specifies information about the buffer's size, location in memory, number of fragments and status after transmission. The TDAs are linked together in a linked list. The system causes the SONIC to transmit the packets by passing the first TDA to the SONIC and issuing the transmit command.

Before a packet can be received, an RDA and RBA must be set up by the system. RDA's are made up as a linked list similar to TDAs. An RDA is not linked to a particular RBA, though. Instead, an RDA is linked specifically to a packet after it has been buffered into an RBA. More than one packet can be buffered into the same RBA, but each packet gets its own RDA. A received packet can not be scattered into fragments. The system only needs to tell the SONIC where the first RDA and where the RBAs are. Since an RDA never specifically points to an RBA, the RRA is used to keep track of the RBAs. The RRA is a circular queue of pointers and buffer sizes (not a linked list). When the SONIC receives a packet, it is buffered into a RBA with a corresponding and unique RDA that is written to so that it points to and describes the new packet. If the RBA does not have enough space to buffer the next packet, a new RBA is obtained from the RRA.

#### 3.2 DESCRIPTOR AREAS

Descriptors are the basis of the buffer management scheme used by the SONIC. A RDA points to a received packet within a RBA, RRA points to a RBA and a TDA points to a TBA which contains a packet to be transmitted. The conventions and registers used to describe these descriptors are discussed in the next three sections.

##### 3.2.1 Naming Convention for Descriptors

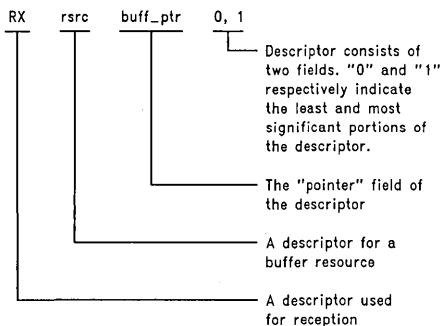

The fields which make up the descriptors are named in a consistent manner to assist in remembering the usage of each descriptor. Each descriptor name consists of three components in the following format.

[RX/TX][descriptor name].[field]

The first two capital letters indicate whether the descriptor is used for transmission (TX) or reception (RX), and is then followed by the descriptor name having one of two names.

rsrc = Resource descriptor  
pkt = Packet descriptor

The last component consists of a field name to distinguish it from the other fields of a descriptor. The field name is separated from the descriptor name by a period ("."). An example of a descriptor is shown below.

TL/F/10492-86

##### 3.2.2 Abbreviations

The abbreviations in Table 3.1 are used to describe the SONIC registers and data structures in memory. The "0" and "1" in the abbreviations indicate the least and most significant portions of the registers or descriptors. Table 3-1 lists the naming convention abbreviations for descriptors.

##### 3.2.3 Buffer Management Base Addresses

The SONIC uses three areas in memory to store descriptor information: the Transmit Descriptor Area (TDA), Receive Descriptor Area (RDA), and the Receive Resource Area (RRA). The SONIC accesses these areas by concatenating a 16-bit base address register with a 16-bit offset register. The base address register supplies a fixed upper 16 bits of address and the offset registers provide the lower 16 bits of address. The base address registers are the Upper Transmit Descriptor Address (UTDA), Upper Receive Descriptor Address (URDA), and the Upper Receive Resource Address (URRA) registers. The corresponding offset registers are shown below.

Upper Address Registers	Offset Registers
URRA	RSA, REA, RWP, RRP
URDA	GRDA
UTDA	CTDA

See Table 3-1 for definition of register mnemonics.

*Figure 3-1* shows an example of the Transmit Descriptor Area and the Receive Descriptor Area being located by the UTDA and URDA registers. The descriptor areas, RDA, TDA, and RRA are allowed to have the same base address. i.e., URRA=URDA=UTDA. Care, however, must be taken to prevent these areas from overwriting each other.

### 3.0 Buffer Management (Continued)

#### 3.3 DESCRIPTOR DATA ALIGNMENT

All fields used by descriptors (RXpkt.xxx, RXsrc.xxx, and TXpkt.xxx) are word quantities (16-bit) and must be aligned to word boundaries (A0=0) for 16-bit memory and to long word boundaries (A1,A0=0,0) for 32-bit memory. The Receive Buffer Area (RBA) must also be aligned to a word boundary in 16-bit mode and a long word boundary in 32-bit mode. The fragments in the Transmit Buffer Area (TBA), however, may be aligned on any arbitrary byte boundary.

#### 3.4 RECEIVE BUFFER MANAGEMENT

The Receive Buffer Management operates on three areas in memory into which data, status, and control information are written during reception (Figure 3-2). These three areas must be initialized (Section 3.4.4) before enabling the receiver (setting the RXEN bit in the Command register). The receive resource area (RRA) contains descriptors that locate receive buffer areas in system memory. These descriptors are denoted by R1, R2, etc. in Figure 3-2. Packets (denoted by P1, P2, etc.) can then be buffered into the corresponding RBAs. Depending on the size of each buffer area and the size of the packet(s), multiple or single packets are buffered into each RBA. The receive descriptor area (RDA) contains status and control information for each packet (D1, D2, etc. in Figure 3-2) corresponding to each received packet (D1 goes with P1, D2 with P2, etc.).

When a packet arrives, the address recognition logic checks the address for a Physical, Multicast, or Broadcast match and if the packet is accepted, the SONIC buffers the packet contiguously into the selected Receive Buffer Area (RBA). Because of the previous end-of-packet processing, the SONIC assures that the complete packet is written into a single contiguous block. When the packet ends, the SONIC writes the receive status, byte count, and location of the packet into the Receive Descriptor Area (RDA). The SONIC then updates its pointers to locate the next available descriptor and checks the remaining words available in the RBA. If sufficient space remains, the SONIC buffers the next packet immediately after the previous packet. If the current buffer is out of space the SONIC fetches a Resource descriptor from the Receive Resource Area (RRA) acquiring an additional buffer that has been previously allocated by the system.

#### 3.4.1 Receive Resource Area (RRA)

As buffer memory is consumed by the SONIC for storing data, the Receive Resource Area (RRA) provides a mechanism that allows the system to allocate additional buffer space for the SONIC. The system loads this area with resource descriptors that the SONIC, in turn, reads as its current buffer space is used up. Each resource descriptor consists of a 32-bit buffer pointer locating the starting point of the RBA and a 32-bit Word Count that indicates the size of the buffer in words (2 bytes per word). The buffer pointer and word count are contiguously located using the format shown in Figure 3-3 with each component composed of 16-bit fields. The SONIC stores this information internally and concatenates the corresponding fields to create 32-bit long words for the buffer pointer and word count. Note that in 32-bit mode the upper word (D<31:16>) is not used by the SONIC. This area may be used for other purposes since the SONIC never writes into the RRA.

The SONIC organizes the RRA as a circular queue for efficient processing of descriptors. Four registers define the RRA. The first two, the Resource Start Area (RSA) and the Resource End Area (REA) registers, determine the starting and ending locations of the RRA, and the other two registers update the RRA. The system adds descriptors at the address specified by the Resource Write Pointer (RWP), and the SONIC reads the next descriptor designated by the Resource Read Pointer (RRP). The RRP is advanced 4 words in 16-bit mode (4 long words in 32-bit mode) after the SONIC finishes reading the RRA and automatically wraps around to the beginning of the RRA once the end has been reached. When a descriptor in the RRA is read, the RXsrc.buf\_pt0,1 is loaded into the CRBA0,1 registers and the RXsrc.buf\_wc0,1 is loaded into the RBWC0,1 registers.

The alignment of the RRA is confined to either word or long word boundaries, depending upon the data width mode. In 16-bit mode, the RRA must be aligned to a word boundary (A0 is always zero) and in 32-bit mode, the RRA is aligned to a long word boundary (A0 and A1 are always zero).

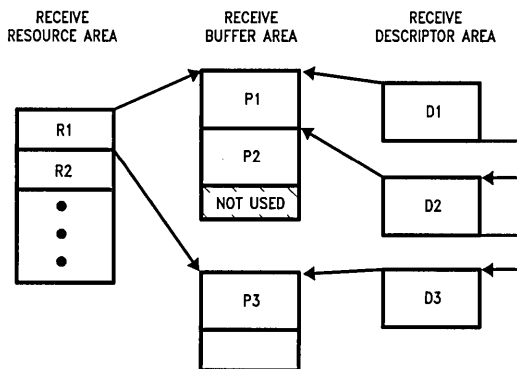

FIGURE 3-2. Overview of Receive Buffer Management

TL/F/10492-11

### 3.0 Buffer Management (Continued)

#### 3.4.2 Receive Buffer Area (RBA)

The SONIC stores the actual data of a received packet in the RBA. The RBAs are designated by the resource descriptors in the RRA as described above. The `RXsrc.buf_wc0,1` fields of the RRA indicate the length of the RBA. When the SONIC gets a RBA from the RRA, the `RXsrc.buf_wc0,1` values are loaded into the Remaining Buffer Word Count registers (`RBWC0,1`). These registers keep track of how much space (in words) is left in the buffer. When a packet is buffered in a RBA, it is buffered contiguously (the SONIC will not scatter a packet into multiple buffers or fragments). Therefore, if there is not enough space left in a RBA after buffering a packet to buffer at least one more maximum sized packet (the maximum legal sized packet expected to be received from the network), a new buffer must be acquired. The End of Buffer Count (EOBC) register is used to tell the SONIC the maximum packet size that the SONIC will need to buffer.

##### 3.4.2.1 End of Buffer Count (EOBC)

The EOBC is a boundary in the RBA based from the bottom of the buffer. The value written into the EOBC is the maximum expected size (in words) of the network packet that the SONIC will have to buffer. This word count creates a line in the RBA that, when crossed, causes the SONIC to fetch a new RBA resource from the RRA.

**Note:** The EOBC is a word count, not a byte count. Also, the value programmed into EOBC must be a double word (32-bit) quantity when the SONIC is in 32-bit mode (e.g. in 32-bit mode, EOBC should be set to 758 words, not 759 words even though the maximum size of an IEEE 802.3 packet is 759 words).

##### 3.4.2.2 Buffering the Last Packet In an RBA

At the start of reception, the SONIC stores the packet beginning at the Current Receive Buffer Address (`CRBA0,1`) and continues until the reception is complete. Concurrent with reception, the SONIC decrements the Remaining Buffer Word Count (`RBWC0,1`) by one in 16-bit mode or by two in 32-bit mode. At the end of reception, if the packet has crossed the EOBC boundary, the SONIC knows that the next packet might not fit in the RBA. This check is done by comparing the `RBWC0,1` registers with the EOBC. If `RBWC0,1` is less than the EOBC (the last packet buffered has crossed the EOBC boundary), the SONIC fetches the next resource descriptor in the RRA. If `RBWC0,1` is greater than or equal to the EOBC (the EOBC boundary has not been crossed) the next packet reception continues at the present location pointed to by `CRBA0,1` in the same RBA. *Figure 3-4* illustrates the SONIC's actions for (1)  $RBWC0,1 \geq EOBC$  and (2)  $RBWC0,1 < EOBC$ . See Section 3.4.4.4 for specific information about setting the EOBC.

**Note:** It is important that the EOBC boundary be "crossed." In other words, case #1 in *Figure 3-4* must exist before case #2 exists. If case #2 occurs without case #1 having occurred first, the test for  $RBWC0,1 < EOBC$  will not work properly and the SONIC will not fetch a new buffer. The result of this will be a buffer overflow (RBAE in the Interrupt Status Register, Section 4.3.6).

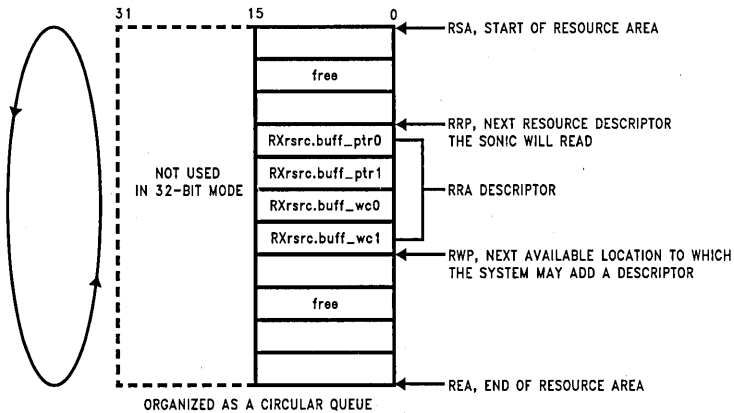

FIGURE 3-3. Receive Resource Area Format

TL/F/10492-12

TL/F/10492-13

Case #1: SONIC buffers next packet in same RBA.  
Case #2: SONIC detects an exhausted RBA and will buffer the next packet in another RBA.

FIGURE 3-4. Receive Buffer Area

### 3.0 Buffer Management (Continued)

#### 3.4.3 Receive Descriptor Area (RDA)

After the SONIC buffers a packet to memory, it writes 6 words of status and control information into the RDA, reads the link field to the next receive descriptor, and writes to the in-use field of the current descriptor. In 32-bit mode, the upper word, D<31:16>, is not used. This unused area in memory should not be used for other purposes, since the SONIC may still write into these locations. Each receive descriptor consists of the following sections (*Figure 3-5*).

TL/F/10492-14

**FIGURE 3-5. Receive Descriptor Format**

**receive status:** indicates status of the received packet. The SONIC writes the Receive Control register into this field. *Figure 3-6* shows the receive status format. This field is loaded from the contents of the Receive Control register. Note that ERR, RNT, BRD, PRO, and AMC are configuration bits and are programmed during initialization. See Section 4.3.3 for the description of the Receive Control register.

**FIGURE 3-6. Receive Status Format**

**byte count:** gives the length of the complete packet from the start of Destination Address to the end of FCS.

**packet pointer:** a 32-bit pointer that locates the packet in the RBA. The SONIC writes the contents of the CRBA0,1 registers into this field.

**sequence numbers:** this field displays the contents of two 8-bit counters (modulo 256) that sequence the RBAs used and the packets buffered. These counters assist the system in determining when an RBA has been completely processed. The sequence numbers allow the system to tally the packets that have been processed within a particular RBA. There are two sequence numbers that describe a packet: the RBA Sequence Number and the Packet Sequence Number. When a packet is buffered to memory, the SONIC maintains a single RBA Sequence Number for all packets in an RBA and sequences the Packet Number for succeeding packets in the RBA. When the SONIC uses the next RBA, it increments the RBA Sequence Number and clears the Packet Sequence Number. The RBA's sequence counter is not incremented when the read RRA command is issued in the Command register. The format of the Receive Sequence Numbers are shown in *Figure 3-7*. These counters are reset during hardware reset or by writing zero to them.

**FIGURE 3-7. Receive Sequence Number Format**

**receive link field:** a 15-bit pointer (A15-A1) that locates the next receive descriptor. The LSB of this field is the End Of List (EOL) bit, and indicates the last descriptor in the list. (Initialized by the system.)

**In use field:** this field provides a handshake between the system and the SONIC to indicate the ownership of the descriptor. When the system avails a descriptor to the SONIC, it writes a non-zero value into this field. The SONIC, in turn, sets this field to all "0's" when it has finished processing the descriptor. (That is, when the CRDA register has advanced to the next receive descriptor.) Generally, the SONIC releases control after writing the status and control information into the RDA. If, however, the SONIC has reached the last descriptor in the list, it maintains ownership of the descriptor until the system has appended additional descriptors to the list. The SONIC then relinquishes control after receiving the next packet. (See Section 3.4.6.1 for details on when the SONIC writes to this field). The receive packet descriptor format is shown in *Figure 3-5*.

#### 3.4.4 Receive Buffer Management Initialization

The Receive Resource, Descriptor, and Buffer areas (RRA, RDA, RBA) in memory and the appropriate SONIC registers must be properly initialized before the SONIC begins buffering packets. This section describes the initialization process.

##### 3.4.4.1 Initializing The Descriptor Page

All descriptor areas (RRA, RDA, and TDA) used by the SONIC reside within areas up to 32k (word) or 16k (long word) pages. This page may be placed anywhere within the 32-bit address range by loading the upper 16 address lines into the UTDA, URDA, and URRR registers.

##### 3.4.4.2 Initializing The RRA

The initialization of the RRA consists of loading the four SONIC RRA registers and writing the resource descriptor information to memory.

The RRA registers are loaded with the following values.

**Resource Start Area (RSA) register:** The RSA is loaded with the lower 16-bit address of the beginning of the RRA.

**Resource End Area (REA) register:** The REA is loaded with the lower 16-bit address of the end of the RRA. The end of the RRA is defined as the address of the last RXrsrc.ptr0 field in the RRA plus 4 words in 16-bit mode or 4 long words in 32-bit mode (*Figure 3-3*).

**Resource Read Pointer (RRP) register:** The RRP is loaded with the lower 16-bit address of the first resource descriptor the SONIC reads.

**Resource Write Pointer (RWP) register:** The RWP is loaded with the lower 16-bit address of the next vacant location where a resource descriptor will be placed by the system.

**Note:** The RWP register must only point to either (1) the RXrsrc.ptr0 field of one of the RRA Descriptors, (2) the memory address that the RSA points to (the start of the RRA), or (3) the memory address that the REA points to (the end of the RRA). When the RWP = RRP comparison is made, it is performed after the complete RRA descriptor has been read and not during the fetch. Failure to set the RWP to any of the above values prevents the RWP = RRP comparison from ever becoming true.

### 3.0 Buffer Management (Continued)

All RRA registers are concatenated with the URRRA register for generating the full 32-bit address.

The resource descriptors that the system writes to the RRA consists of four fields: (1) RXrsrc.buff\_ptr0, (2) RXrsrc.buff\_ptr1, (3) RXrsrc.buff\_wc0, and (4) RXrsrc.buff\_wc1. The fields must be contiguous (they cannot straddle the end points) and are written in the order shown in Figure 3-8. The "0" and "1" in the descriptors denote the least and most significant portions for the Buffer Pointer and Word Count. The first two fields supply the 32-bit starting location of the Receive Buffer Area (RBA), and the second two define the number of 16-bit words that the RBA occupies.

Note that two restrictions apply to the Buffer Pointer and Word Count. First, in 32-bit mode, since the SONIC always writes long words, an even count must be written to RXrsrc.buff\_wc0. Second, the Buffer Pointer must either be pointing to a word boundary in 16-bit mode (A0=0) or a long word boundary in 32-bit mode (A0,A1=0,0). Note also that the descriptors must be properly aligned in the RRA as discussed in Section 3.3.

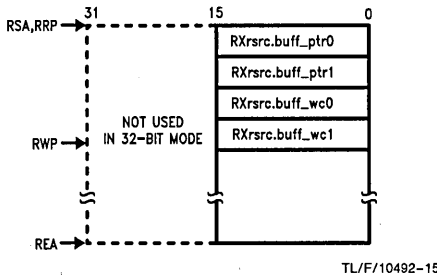

FIGURE 3-8. RRA Initialization

TL/F/10492-15

After configuring the RRA, the RRA Read command (setting RRA bit in the Command register) may be given. This command causes the SONIC to read the RRA descriptor in a single block operation, and load the following registers (see Section 4.2 for register mnemonics):

- CRBA0 register ← RXrsrc.buff\_ptr0
- CRBA1 register ← RXrsrc.buff\_ptr1
- RBWC0 register ← RXrsrc.buff\_wc0
- RBWC1 register ← RXrsrc.buff\_wc1

When the command has completed, the RRA bit in the Command register is reset to "0". Generally this command is only issued during initialization. At all other times, the RRA is automatically read as the SONIC finishes using an RBA.

#### 3.4.4.3 Initializing The RDA

To accept multiple packets from the network, the receive packet descriptors must be linked together via the RXpkt.link fields. Each link field must be written with a 15-bit (A15-A1) pointer to locate the beginning of the next descriptor in the list. The LSB of the RXpkt.link field is the End of List (EOL) bit and is used to indicate the end of the descriptor list. EOL = 1 for the last descriptor and EOL = 0 for the first or middle descriptors. The RXpkt.in\_use field indicates whether the descriptor is owned by the SONIC. The system writes a non-zero value to this field when the descriptor is available, and the SONIC writes all "0's" when it finishes using the descriptor. At startup, the Current Receive Descriptor Address (CRDA) register must be loaded with the address of the first RXpkt.status field in order for

the SONIC to begin receive processing at the first descriptor. An example of two descriptors linked together is shown in Figure 3-9. The fields initialized by the system are displayed in **bold type**. The other fields are written by the SONIC after a packet is accepted. The RXpkt.in\_use field is first written by the system, and then by the SONIC. Note that the descriptors must be aligned properly as discussed in Section 3.3. Also note that the URDA register is concatenated with the CRDA register to generate the full 32-bit address.

FIGURE 3-9. RDA Initialization Example

TL/F/10492-16

#### 3.4.4.4 Initializing the Lower Boundary of the RBA

A "false bottom" is set in the RBA by loading the End Of Buffer Count (EOBC) register with a value equal to the maximum size packet in words (16 bits) that may be received. This creates a lower boundary in the RBA. Whenever the Remaining Buffer Word Count (RBWC0,1) registers decrement below the EOBC register, the SONIC buffers the next packet into another RBA. This also guarantees that a packet is always contiguously buffered into a single Receive Buffer Area (RBA). The SONIC does not buffer a packet into multiple RBAs. Note that in 32-bit mode, the SONIC holds the LSB always low so that it properly compares with the RBWC0,1 registers.

After a hardware reset, the EOBC reset, the EOBC register is automatically initialized to 2F8h (760 words or 1520 bytes). For 32-bit applications this is the suggested value for EOBC. EOBC defaults to 760 words (1520 bytes) instead of 759 words (1518 bytes) because 1518 is not a double word (32-bit) boundary (see Section 3.4.2.1). If the SONIC is used in 16-bit mode, then EOBC should be set to 759 words (1518 bytes) because 1518 is a word (16-bit) boundary.

Sometimes it may be desired to buffer a single packet per RBA. When doing this, it is important to set EOBC and the buffer size correctly. The suggested practice is to set EOBC to a value that is at least 4 bytes, in 32-bit mode, or 2 bytes, in 16-bit mode, less than the buffer size. An example of this for 32-bit mode is to set EOBC to 760 words (1520 bytes)

### 3.0 Buffer Management (Continued)

and the buffer size to 762 words (1524 bytes). A similar example for 16-bit mode would be EOBC = 759 words (1518 bytes) and the buffer size set to 760 words (1520 bytes). The buffer can be any size, but as long as the EOBC is 2 words, for 32-bit mode, or 1 word, for 16-bit mode, less than the buffer size, only one packet will be buffered in that RBA.

**Note 1:** It is possible to filter out most oversized packets by setting the buffer size to 760 words (1520 bytes) in 32-bit mode or 759 words (1518 bytes) in 16-bit mode. EOBC would be set to 758 words (1516 bytes) for both cases. With this configuration, any packet over 1520 bytes, in 32-bit mode, or 1518 bytes, in 16-bit mode, will not be completely buffered because the packet will overflow the buffer. When a packet overflow occurs, a Receive Buffer Area Exceeded interrupt (RBAE) in the Interrupt Status Register, Section 4.3.6) will occur.

**Note 2:** When buffering one packet per buffer, it is suggested that the values in Note 1 above be used. Since the minimum legal sized Ethernet packet is 64 bytes, however, it is possible to set EOBC as much as 64 bytes less than the buffer size and still end up with one packet per buffer. Figure 3-10 shows this "range."

#### 3.4.5 Beginning Of Reception

At the beginning of reception, the SONIC checks its internally stored EOL bit from the previous RXpkt.link field for a "1". If the SONIC finds EOL = 1, it recognizes that after the previous reception, there were no more remaining receive packet descriptors. It re-reads the same RXpkt.link field to check if the system has updated this field since the last reception. If the SONIC still finds EOL = 1, reception ceases. (See Section 3.5 for adding descriptors to the list.) Otherwise, the SONIC begins storing the packet in the RBA starting at the Current Receive Buffer Address (CRBA0,1) registers and continues until the packet has completed. Concurrent with the packet reception, the Remaining Buffer Word Count (RBWC0,1) registers are decremented after each word is written to memory. This register determines the remaining words in the RBA at the end of reception.

#### 3.4.6 End Of Packet Processing

At the end of a reception, the SONIC enters its end of packet processing sequence to determine whether to accept or reject the packet based on receive errors and packet size. At the end of reception the SONIC enters one of the following two sequences:

- Successful reception sequence
- Buffer recovery for runt packets or packets with errors

#### 3.4.6.1 Successful Reception

If the SONIC accepts the packet, it first writes 5 words of descriptor information in the RDA beginning at the address pointed to by the Current Receive Descriptor Address (CRDA) register. It then reads the RXpkt.link field to advance the CRDA register to the next receive descriptor. The SONIC also checks the EOL bit for a "1" in this field. If EOL = 1, no more descriptors are available for the SONIC. The SONIC recovers the address of the current RXpkt.link field (from a temporary register) and generates a "Receive Descriptors Exhausted" indication in the Interrupt Status register. (See Section 3.4.7 on how to add descriptors.) The SONIC maintains ownership of the descriptor by not writing to the RXpkt.in\_\_use field. Otherwise, if EOL = 0, the SONIC advances the CRDA register to the next descriptor and resets the RXpkt.in\_\_use field to all "0's".

The SONIC accesses the complete 7 word RDA descriptor in a single block operation.

The SONIC also checks if there is remaining space in the RBA. The SONIC compares the Remaining Buffer Word Count (RBWC0,1) registers with the static End Of Buffer Count (EOBC). If the RBWC is less than the EOBC, a maximum sized packet will no longer fit in the remaining space in the RBA; hence, the SONIC fetches a resource descriptor from the RRA and loads its registers with the pointer and word count of the next available RBA.

#### 3.4.6.2 Buffer Recovery For Runt Packets Or Packets With Errors

If a runt packet (less than 64 bytes) or packet with errors arrives and the Receive Control register has been configured to not accept these packets, the SONIC recovers its pointers back to the original positions. The CRBA0,1 registers are not advanced and the RBWC0,1 registers are not decremented. The SONIC recovers its pointers by maintaining a copy of the buffer address in the Temporary Receive Buffer Address registers (TRBA0,1). The SONIC recovers the value in the RBWC0,1 registers from the Temporary Buffer Word Count registers (TBWC0,1).

#### 3.4.7 Overflow Conditions

When an overflow condition occurs, the SONIC halts its DMA operations to prevent writing into unauthorized memory. The SONIC uses the Interrupt Status register (ISR) to indicate three possible overflow conditions that can occur

FIGURE 3-10. Setting EOBC for Single Packet RBA

TL/F/10492-17

### 3.0 Buffer Management (Continued)

when its receive resources have been exhausted. The system should respond by replenishing the resources that have been exhausted. These overflow conditions (Descriptor Resources Exhausted, Buffer Resources Exhausted, and RBA Limit Exceeded) are indicated in the Interrupt Status register and are detailed as follows:

**Descriptor Resources Exhausted:** This occurs when the SONIC has reached the last receive descriptor in the list, meaning that the SONIC has detected  $EOL = 1$ . The system must supply additional descriptors for continued reception. The system can do this in one of two ways: 1) appending descriptors to the existing list, or 2) creating a separate list.

1) Appending descriptors to the existing list. This is the easiest and preferred way. To do this, the system, after creating the new list, joins the new list to the existing list by simply writing the beginning address of the new list into the `RXpkt.link` field and setting  $EOL = 0$ . At the next reception, the SONIC re-reads the last `RXpkt.link` field, and updates its CRDA register to point to the next descriptor.

2) Creating a separate list. This requires an additional step because the lists are not joined together and requires that the CRDA register be loaded with the address of the `RXpkt.link` field in the new list.

During this overflow condition, the SONIC maintains ownership of the descriptor (`RXpkt.in_use`  $\neq$  00h) and waits for the system to add additional descriptors to the list. When the system appends more descriptors, the SONIC releases ownership of the descriptor after writing 0000h to the `RXpkt.in_use` field.

**Buffer Resources Exhausted:** This occurs when the SONIC has detected that the Resource Read Pointer (RRP) and Resource Write Pointer (RWP) registers are equal (i.e., all RRA descriptors have been exhausted). The RBE bit in the Interrupt Status register is set when the SONIC finishes using the second to last receive buffer and reads the last RRA descriptor. Actually, the SONIC is not truly out of resources, but gives the system an early warning of an impending out of resources condition. To continue reception after the last RBA is used, the system must supply additional RRA descriptor(s), update the RWP register, and clear the RBE bit in the ISR. The SONIC rereads the RRA after this bit is cleared.

**RBA Limit Exceeded:** This occurs when a packet does not completely fit within the remaining space of the RBA. This can occur if the EOBC register is not programmed to a value greater than the largest packet that can be received. When this situation occurs, the packet is truncated and the SONIC reads the RRA to obtain another RBA. Indication of an RBA limit being exceeded is signified by the Receive Buffer Area Exceeded (RBAE) interrupt being set (see Section 4.3.6). An RDA will not be set up for the truncated packet and the buffer space will not be re-used. To rectify this potential overflow condition, the EOBC register must be loaded with a value equal to or greater than the largest packet that can be accepted. (See Section 3.4.2.)

#### 3.5 TRANSMIT BUFFER MANAGEMENT

To begin transmission, the system software issues the Transmit command ( $TXP = 1$  in the CR). The Transmit Buffer Management uses two areas in memory for transmitting packets (Figure 3-11), the Transmit Descriptor Area (TDA)

and the Transmit Buffer Area (TBA). During transmission, the SONIC fetches control information from the TDA, loads its appropriate registers, and then transmits the data from the TBA. When the transmission is complete, the SONIC writes the status information in the TDA. From a single transmit command, packets can either be transmitted singly or in groups if several descriptors have been linked together.

TL/F/10492-18

**FIGURE 3-11. Overview of Transmit Buffer Management**

#### 3.5.1 Transmit Descriptor Area (TDA)

The TDA contains descriptors that the system has generated to exchange status and control information. Each descriptor corresponds to a single packet and consists of the following 16-bit fields.

**TXpkt.status:** This field is written by the SONIC and provides status of the transmitted packet. (See Section 3.5.1.2 for more details.)

**TXpkt.config:** This field allows programming the SONIC to one of the various transmit modes. The SONIC reads this field and loads the corresponding configuration bits (PINT, POWC, CRCI, and EXDIS) into the Transmit Control register. (See Section 3.5.1.1 for more details.)

**TXpkt.pkt\_size:** This field contains the byte count of the entire packet.

**TXpkt.frag\_count:** This field contains the number of fragments the packet is segmented into.

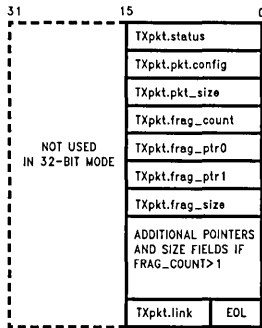

**TXpkt.frag\_ptr0,1:** This field contains a 32-bit pointer which locates the packet fragment to be transmitted in the Transmit Buffer Area (TBA). This pointer is not restricted to any byte alignment.

**TXpkt.frag\_size:** This field contains the byte count of the packet fragment. The minimum fragment size is 1 byte.

**TXpkt.link:** This field contains a 15-bit pointer (A15-A1) to the next TDA descriptor. The LSB, the End Of List (EOL) bit, indicates the last descriptor in the list when set to a "1". When descriptors have been linked together, the SONIC transmits back-to-back packets from a single transmit command.

The data of the packet does not need to be contiguous, but can exist in several locations (fragments) in memory. In this case, the `TXpkt.frag_count` field is greater than one, and additional `TXpkt.frag_ptr0,1` and `TXpkt.frag_size` fields corresponding to each fragment are used. The descriptor format is shown in Figure 3-12. Note that in 32-bit mode the upper word, `D<31:16>`, is not used.

### 3.0 Buffer Management (Continued)

TL/F/10492-19

FIGURE 3-12. Transmit Descriptor Area

#### 3.5.1.1 Transmit Configuration

The TXpkt.config field allows the SONIC to be programmed into one of the transmit modes before each transmission. At the beginning of each transmission, the SONIC reads this field and loads the PINT, POWC, CRCI, and EXDIS bits into the Transmit Control register (TCR). The configuration bits in the TCR correspond directly with the bits in the TXpkt.config field as shown in Figure 3-13. See Section 4.3.4 for the description on the TCR.

15	14	13	12	11	10	9	8
PINT	POWC	CRCI	EXDIS	X	X	X	X
7	6	5	4	3	2	1	0
X	X	X	X	X	X	X	X

Note: x = don't care

FIGURE 3-13. TXpkt.config Field

#### 3.5.1.2 Transmit Status

At the end of each transmission the SONIC writes the status bits (<10:0>) of the Transmit Control Register (TCR) and the number of collisions experienced during the transmission into the TXpkt.status field (Figure 3-14, res = reserved). Bits NC4-NC0 indicate the number of collisions where NC4 is the MSB. See Section 4.3.4 for the description of the TCR.

15	14	13	12	11	10	9	8
NC4	NC3	NC2	NC1	NC0	EXD	DEF	NCRS
7	6	5	4	3	2	1	0
CRSL	EXC	OWC	res	PMB	FU	BCM	PTX

FIGURE 3-14. TXpkt.status Field

#### 3.5.2 Transmit Buffer Area (TBA)

The TBA contains the fragments of packets that are defined by the descriptors in the TDA. A packet can consist of a single fragment or several fragments, depending upon the fragment count in the TDA descriptor. The fragments also can reside anywhere within the full 32-bit address range, and be aligned to any byte boundary. When an odd byte boundary is given, the SONIC automatically begins reading data at the corresponding word boundary in 16-bit mode or a long word boundary in 32-bit mode. The SONIC ignores the extraneous bytes which are written into the FIFO during

odd byte alignment fragments. The minimum allowed fragment size is 1 byte. Figure 3-11 shows the relationship between the TDA and the TBA for single and multi-fragmented packets.

#### 3.5.3 Preparing To Transmit

All fields in the TDA descriptor and the Current Transmit Descriptor Address (CTDA) register of the SONIC must be initialized before the Transmit Command (setting the TXP bit in the Command register) can be issued. If more than one packet is queued, the descriptors must be linked together with the TXpkt.link field. The last descriptor must have EOL = 1 and all other descriptors must have EOL = 0. To begin transmission, the system loads the address of the first TXpkt.status field into the CTDA register. Note that the upper 16-bits of address are loaded in the Upper Transmit Descriptor (UTDA) register. The user performs the following transmit initialization.

- 1) Initialize the TDA
- 2) Load the CTDA register with the address of the first transmit descriptor
- 3) Issue the transmit command

Note that if the Source Address of the packet being transmitted is not in the CAM, the Packet Monitored Bad (PMB) bit in the TXpkt.status field will be set (see Section 6.3.4).

#### 3.5.3.1 Transmit Process

When the Transmit Command (TXP = 1 in the Command register) is issued, the SONIC fetches the control information in the TDA descriptor, loads its appropriate registers (shown below) and begins transmission. (See Section 4.2 for register mnemonics.)

- TCR ← TXpkt.config
- TPS ← TXpkt.pkt\_size
- TFC ← TXpkt.frag\_count
- TSA0 ← TXpkt.frag\_ptr0
- TSA1 ← TXpkt.frag\_ptr1
- TFS ← TXpkt.frag\_size
- CTDA ← TXpkt.link

(CTDA is loaded after all fragments have been read and successfully transmitted. If the halt transmit command is issued (HTX bit in the Command register is set) the CTDA register is not loaded.)

During transmission, the SONIC reads the packet descriptor in the TDA and transmits the data from the TBA. If TXpkt.frag\_count is greater than one, the SONIC, after finishing transmission of the fragment, fetches the next TXpkt.frag\_ptr0,1 and TXpkt.frag\_size fields and transmits the next fragment. This process continues until all fragments of a packet are transmitted. At the end of packet transmission, status is written in to the TXpkt.status field. The SONIC then reads the TXpkt.link field and checks if EOL = 0. If it is "0", the SONIC fetches the next descriptor and transmits the next packet. If EOL = 1 the SONIC generates a "Transmission Done" indication in the Interrupt Status register and resets the TXP bit in the Command register.

In the event of a collision, the SONIC recovers its pointer in the TDA and retransmits the packet up to 15 times. The SONIC maintains a copy of the CTDA register in the Temporary Transmit Descriptor Address (TTDA) register.

The SONIC performs a block operation of 6, 3, or 2 accesses in the TDA, depending on where the SONIC is in the transmit process. For the first fragment, it reads the

### 3.0 Buffer Management (Continued)

TXpkt.config to TXpkt.frag\_size (6 accesses). For the next fragment, if any, it reads the next 3 fields from TXpkt.frag\_ptr0 to TXpkt.frag\_size (3 accesses). At the end of transmission it writes the status information to TXpkt.status and reads the TXpkt.link field (2 accesses).

#### 3.5.3.2 Transmit Completion

The SONIC stops transmitting under two conditions. In the normal case, the SONIC transmits the complete list of descriptors in the TDA and stops after it detects EOL = 1. In the second case, certain transmit errors cause the SONIC to abort transmission. If FIFO Underrun, Byte Count Mismatch, Excessive Collision, or Excessive Deferral (if enabled) errors occur, transmission ceases. The CTDA register points to the last packet transmitted. The system can also halt transmission under software control by setting the HTX bit in the Command register. Transmission halts after the SONIC writes to the TXpkt.status field.

#### 3.5.4 Dynamically Adding TDA Descriptors

Descriptors can be dynamically added during transmission without halting the SONIC. The SONIC can also be guaranteed to transmit the complete list including newly appended descriptors (barring any transmit abort conditions) by observing the following rule: The last TXpkt.link field must point to the next location where a descriptor will be added (see step 3 below and Figure 3-15). The procedure for appending descriptors consists of:

1. Creating a new descriptor with its TXpkt.link pointing to the next vacant descriptor location and its EOL bit set to a "1".
2. Resetting the EOL bit to a "0" of the previously last descriptor.
3. Re-issuing the Transmit command (setting the TXP bit in the Command register).

Step 3 assures that the SONIC will transmit all the packets in the list. If the SONIC is currently transmitting, the Transmit command has no effect and continues transmitting until it detects EOL = 1. If the SONIC had just finished transmitting, it continues transmitting from where it had previously stopped.

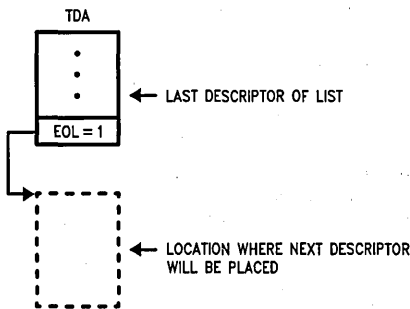

FIGURE 3-15. Initializing Last Link Field

TL/F/10492-20

### 4.0 SONIC Registers

The SONIC contains two sets of registers: The status/control registers and the CAM memory cells. The status/control registers are used to configure, control, and monitor SONIC operation. They are directly addressable registers and occupy 64 consecutive address locations in the system memory space (selected by the RA5-RA0 address pins). There are a total of 64 status/control registers divided into the following categories:

**User Registers:** These registers are accessed by the user to configure, control, and monitor SONIC operation. These are the only SONIC registers the user needs to access. Figure 4-3 shows the programmer's model and Table 4-1 lists the attributes of each register.

**Internal Use Registers:** These registers (Table 4-2) are used by the SONIC during normal operation and are not intended to be accessed by the user.

**National Factory Test Registers:** These registers (Table 4-3) are for National factory use only and should never be accessed by the user. Accessing these registers during normal operation can cause improper functioning of the SONIC.

#### 4.1 THE CAM UNIT

The CAM unit memory cells are indirectly accessed by programming the CAM descriptor area in system memory and issuing the LCAM command (setting the LCAM bit in the Control register). The CAM cells do not occupy address locations in register space and, thus, are not accessible through the RA5-RA0 address pins. The CAM control registers, however, are part of the user register set and must be initialized before issuing the LCAM command (see Section 4.3.10).

The Content Addressable Memory (CAM) consists of sixteen 48-bit entries for complete address filtering (Figure 4-1) of network packets. Each entry corresponds to a 48-bit destination address that is user programmable and can contain any combination of Multicast or Physical addresses. Each entry is partitioned into three 16-bit CAM cells accessible through CAM Address Ports (CAP 2, CAP 1 and CAP 0) with CAP0 corresponding to the least significant 16 bits of the Destination Address and CAP2 corresponding to the most significant bits. The CAM is accessed in a two step process. First, the CAM Entry Pointer is loaded to point to one of the 16 entries. Then, each of the CAM Address Ports is accessed to select the CAM cell. The 16 user programmable CAM entries can be masked out with the CAM Enable register (see Section 4.3.10).

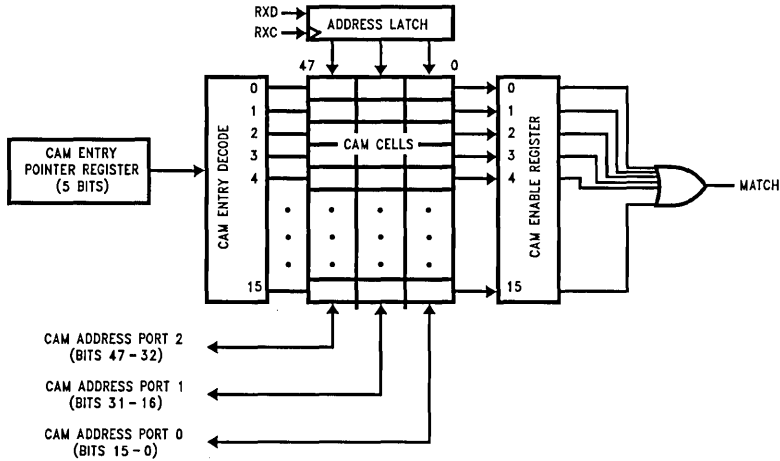

**Note:** It is not necessary to program a broadcast address into the CAM when it is desired to accept broadcast packets. Instead, to accept broadcast packets, set the BRD bit in the Receive Control register. If the BRD bit has been set, the CAM is still active. This means that it is possible to accept broadcast packets at the same time as accepting packets that match physical addresses in the CAM.

##### 4.1.1 The Load CAM Command

Because the SONIC uses the CAM for a relatively long period of time during reception, it can only be written to via the CAM Descriptor Area (CDA) and is only readable when the

## 4.0 SONIC Registers (Continued)

TL/F/10492-21

**FIGURE 4-1. CAM Organization**

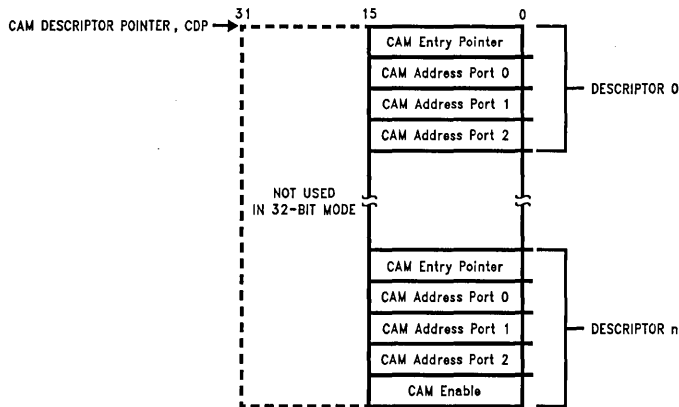

SONIC is in software reset. The CDA resides in the same 64k byte block of memory as the Receive Resource Area (RRA) and contains descriptors for loading the CAM registers. These descriptors are contiguous and each descriptor consists of four 16-bit fields (*Figure 4-2*). In 32-bit mode the upper word,  $D<31:16>$ , is not used. The first field contains the value to be loaded into the CAM Entry Pointer and the remaining fields are for the three CAM Address Ports (see Section 4.3.10). In addition, there is one more field after the last descriptor containing the mask for the CAM Enable register. Each of the CAM descriptors are addressed by the CAM Descriptor Pointer (CDP) register.

After the system has initialized the CDA, it can issue the Load CAM command to program the SONIC to read the CDA and load the CAM. The procedure for issuing the Load CAM command is as follows.

1. Initialize the Upper Receive Resource Address (URRA) register. Note that the CAM Descriptor Area must reside within the same 64k Page as the Receive Resource Area. (See Section 4.3.9).

2. Initialize the CDA as described above.
3. Initialize the CAM Descriptor Count with the number of CAM descriptors. Note, only the lower 5 bits are used in this register. The other bits are don't cares. (See Section 4.3.10).
4. Initialize the CAM Descriptor Pointer to locate the first descriptor in the CDA. This register must be reloaded each time a new Load CAM command is issued.
5. Issue the Load CAM command (LCAM) in the Command register. (See Section 4.3.1).

If a transmission or reception is in progress, the CAM DMA function will not occur until these operations are complete. When the SONIC completes the Load CAM command, the CDP register points to the next location after the CAM enable field and the CDC equals zero. The SONIC resets the LCAM bit in the Command register and sets the Load CAM Done (LCD) bit in the ISR.

### 4.2 STATUS/CONTROL REGISTERS

This set of registers is used to convey status/control information to/from the host system and to control the operation of the SONIC. These registers are used for loading commands generated from the system, indicating transmit and receive status, buffering data to/from memory, and provid-

ing interrupt control. The registers are selected by asserting chip select to the SONIC and providing the necessary address on register address pins RA5-RA0. Tables 4-1, 4-2, and 4-3 show the locations of all SONIC registers and where information on the registers can be found in the data sheet.

TABLE 4-1. User Registers

RA5-RA0	Access	Register	Symbol	Description (section)
<b>COMMAND AND STATUS REGISTERS</b>

## 4.0 SONIC Registers (Continued)

### 4.3 REGISTER DESCRIPTION

#### 4.3.1 Command Register

(RA <5:0> = 0h)

This register (Figure 4-4) is used for issuing commands to the SONIC. These commands are issued by setting the corresponding bits for the function. For all bits, except for the RST bit, the SONIC resets the bit after the command is completed. With the exception of RST, writing a "0" to any bit has no effect. Before any commands can be issued, the RST bit must first be reset to "0". This means that, if the RST bit is set, two writes to the Command Register are required to issue a command to the SONIC; one to clear the RST bit, and one to issue the command.

This register also controls the general purpose 32-bit Watchdog Timer. After the Watchdog Timer register has been loaded, it begins to decrement once the ST bit has been set to "1". An interrupt is issued when the count reaches zero if the Timer Complete interrupt is enabled in the IMR.

During hardware reset, bits 7, 4, and 2 are set to a "1"; all others are cleared. During software reset bits 9, 8, 1, and 0 are cleared and bits 7 and 2 are set to a "1"; all others are unaffected.

0	0	0	0	0	0	LCAM	RRRA	RST	0	ST	STP	RXEN	RXDIS	TXP	HTX
						r/w	r/w	r/w		r/w	r/w	r/w	r/w	r/w	r/w

r/w = read/write

**FIGURE 4-4. Command Register**

Field	Meaning
LCAM	LOAD CAM
RRRA	READ RRA
RST	SOFTWARE RESET
ST	START TIMER
STP	STOP TIMER
RXEN	RECEIVER ENABLE
RXDIS	RECEIVER DISABLE
TXP	TRANSMIT PACKET(S)
HTX	HALT TRANSMISSION

Bit	Description
15–10	Must be 0
9	<p><b>LCAM: LOAD CAM</b></p> <p>Setting this bit causes the SONIC to load the CAM with the descriptor that is pointed to by the CAM Descriptor Pointer register.</p> <p><b>Note:</b> This bit must not be set during transmission (TXP is set). The SONIC will lock up if both bits are set simultaneously.</p>
8	<p><b>RRRA: READ RRA</b></p> <p>Setting this bit causes the SONIC to read the next RRA descriptor pointed to by the Resource Read Pointer (RRP) register. Generally this bit is only set during initialization. Setting this bit during normal operation can cause improper receive operation.</p>
7	<p><b>RST: SOFTWARE RESET</b></p> <p>Setting this bit resets all internal state machines. The CRC generator is disabled and the Tally counters are halted, but not cleared. The SONIC becomes operational when this bit is reset to "0". A hardware reset sets this bit to a "1". It must be reset to "0" before the SONIC becomes operational.</p>
6	Must be 0.
5	<p><b>ST: START TIMER</b></p> <p>Setting this bit enables the general-purpose watchdog timer to begin counting or to resume counting after it has been halted. This bit is reset when the timer is halted (i.e., STP is set). Setting this bit resets STP.</p>
4	<p><b>STP: STOP TIMER</b></p> <p>Setting this bit halts the general-purpose watchdog timer and resets the ST bit. The timer resumes when the ST bit is set. This bit powers up as a "1". <b>Note:</b> Simultaneously setting bits ST and STP stops the timer.</p>

## 4.0 SONIC Registers (Continued)

### 4.3 REGISTER DESCRIPTION (Continued)

#### 4.3.1 Command Register (Continued)

Bit	Description
3	<p><b>RXEN: RECEIVER ENABLE</b></p> <p>Setting this bit enables the receive buffer management engine to begin buffering data to memory. Setting this bit resets the RXDIS bit. Note: If this bit is set while the MAC unit is currently receiving a packet, both RXEN and RXDIS are set until the network goes inactive (i.e., the SONIC will not start buffering in the middle of a packet being received).</p>
2	<p><b>RXDIS: RECEIVER DISABLE</b></p> <p>Setting this bit disables the receiver from buffering data to memory or the Receive FIFO. If this bit is set during the reception of a packet, the receiver is disabled only after the packet is processed. The RXEN bit is reset when the receiver is disabled. Tally counters remain active regardless of the state of this bit.</p> <p><b>Note:</b> If this bit is set while the SONIC is currently receiving a packet, both RXEN and RXDIS are set until the packet is fully received. When both RXEN and RXDIS are set, RXDIS could be cleared by writing zero to it.</p>
1	<p><b>TXP: TRANSMIT PACKET(S)</b></p> <p>Setting this bit causes the SONIC to transmit packets which have been set up in the Transmit Descriptor Area (TDA). The SONIC loads its appropriate registers from the TDA, then begins transmission. The SONIC clears this bit after any of the following conditions have occurred: (1) transmission had completed (i.e., after the SONIC has detected EOL = 1), (2) the Halt Transmission command (HTX) has taken effect, or (3) a transmit abort condition has occurred. This condition occurs when any of the following bits in the TCR have been set: EXC, EXD, FU, or BCM. This bit must not be set if a Load CAM operation is in progress (LCAM is set). The SONIC will lock up if both bits are set simultaneously.</p>
0	<p><b>HTX: HALT TRANSMISSION</b></p> <p>Setting this bit halts the transmit command after the current transmission has completed. TXP is reset after transmission has halted. The Current Transmit Descriptor Address (CTDA) register points to the last descriptor transmitted. The SONIC samples this bit after writing to the TXpkt.status field.</p>

## 4.0 SONIC Registers (Continued)

### 4.3.2 Data Configuration Register

(RA<5:0> = 1h)

This register (Figure 4-5) establishes the bus cycle options for reading/writing data to/from 16- or 32-bit memory systems. During a hardware reset, bits 15 and 13 are cleared; all other bits are unaffected. (Because of this, the first thing the driver software does to the SONIC should be to set up this register.) All bits are unaffected by a software reset. This register must only be accessed when the SONIC is in reset mode (i.e., the RST bit is set in the Command register).

r/w = read/write

FIGURE 4-5. Data Configuration Register

Field	Meaning
EXBUS	EXTENDED BUS MODE
LBR	LATCHED BUS RETRY
PO0,PO1	PROGRAMMABLE OUTPUTS
SBUS	SYNCHRONOUS BUS MODE
USR0, USR1	USER DEFINABLE PINS
WC0, WC1	WAIT STATE CONTROL
DW	DATA WIDTH SELECT
BMS	BLOCK MODE SELECT FOR DMA
RFT0, RFT1	RECEIVE FIFO THRESHOLD
TFT0, TFT1	TRANSMIT FIFO THRESHOLD

Bits	Description
15	<p><b>EXBUS: EXTENDED BUS MODE</b></p> <p>Setting this bit enables the Extended Bus mode which enables the following:</p> <ol style="list-style-type: none"> <li>1)Extended Programmable Outputs, EXUSR &lt;3:0&gt;: This changes the TXD, LBK, RXC and RXD pins from the external ENDEC interface into four programmable user outputs, EXUSR &lt;3:0&gt; respectively, which are similar to USR &lt;1:0&gt;. These outputs are programmed with bits 15-12 in the DCR2 (see Section 4.3.7). On hardware reset, these four pins will be TRI-STATE and will remain that way until the DCR is changed. If EXBUS is enabled, then these pins will remain TRI-STATE until the SONIC becomes a bus master, at which time they will be driven according to the DCR2. If EXBUS is disabled, then these four pins work normally as external ENDEC interface pins.</li> <li>2)Synchronous Termination, STERM: This changes the TXC pin from the External ENDEC interface into a synchronous memory termination input for compatibility with Motorola style processors. This input is only useful when Asynchronous Bus mode is selected (bit 10 below is set to "0") and BMODE = 1 (Motorola mode). On hardware reset, this pin will be TRI-STATE and will remain that way until the DCR is changed. If EXBUS is enabled, this pin will remain TRI-STATE until the SONIC becomes a bus master, at which time it will become the STERM input. If EXBUS is disabled, then this pin works normally as the TXC pin for the external ENDEC interface.</li> <li>3)Asynchronous Bus Retry: Causes <math>\overline{BRT}</math> to be clocked in asynchronously off the falling edge of bus clock. This only applies, however, when the SONIC is operating in asynchronous mode (bit 10 below is set to "0"). If EXBUS is not set, XTO (BRT) is sampled synchronously off the rising edge of bus clock. (See Section 5.4.6.)</li> </ol>
14	Must be 0.
13	<p><b>LBR: LATCHED BUS RETRY</b></p> <p>The LBR bit controls the mode of operation of the <math>\overline{BRT}</math> signal (see pin description). It allows the BUS Retry operation to be latched or unlatched.</p> <p>0:Unlatched mode: The assertion of <math>\overline{BRT}</math> forces the SONIC to finish the current DMA operation and get off the bus. The SONIC will retry the operation when <math>\overline{BRT}</math> is desasserted.</p> <p>1:Latched mode: The assertion of <math>\overline{BRT}</math> forces the SONIC to finish the current DMA operation as above, however, the SONIC will not retry until <math>\overline{BRT}</math> is deasserted, the BR bit in the ISR (see Section 4.3.6) has been reset, and <math>\overline{BRT}</math> is deasserted. Hence, the mode has been latched on until the BR bit is cleared.</p> <p><b>Note:</b> Unless LBR is set to a "1", <math>\overline{BRT}</math> must remain asserted at least until the SONIC has gone idle. See Section 5.4.6 and the timing for Bus Retry in section 7.0.</p>
12, 11	<p><b>PO1, PO0: PROGRAMMABLE OUTPUTS</b></p> <p>The PO1,PO0 bits individually control the USR1,0 pins respectively when SONIC is a bus master (HLDA or <math>\overline{BGACK}</math> is active). When PO1/PO0 are set to a 1 the USR1/USR0 pins are high during bus master operations and when these bits are set to a 0 the USR1/USR0 pins are low during bus master operations.</p>

1

## 4.0 SONIC Registers (Continued)

### 4.3.2 Data Configuration Register (Continued)

Bits	Description															
10	<p><b>SBUS: SYNCHRONOUS BUS MODE</b></p> <p>The SBUS bit is used to select the mode of system bus operation when SONIC is a bus master. This bit selects the internal ready line to be either a synchronous or asynchronous input to SONIC during block transfer DMA operations.</p> <p>0: Asynchronous mode. <math>\overline{RDYi}</math> (BMODE = 0) or <math>\overline{DSACK0,1}</math> (BMODE = 1) are respectively internally synchronized at the falling edge of the bus clock (T2 of the DMA cycle). No setup or hold times need to be met with respect to this edge to guarantee proper bus operation. The minimum memory cycle time is 3 bus clocks.</p> <p>1: Synchronous mode. <math>\overline{RDYi}</math> (BMODE = 0) and <math>\overline{DSACK0,1}</math> (BMODE = 1) must respectively meet the setup and hold times with respect to the rising edge of T1 or T2 to guarantee proper bus operation.</p>															
9, 8	<p><b>USR1,0: USER DEFINABLE PINS</b></p> <p>The USR1,0 bits report the level of the USR1,0 signal pins, respectively, after a chip hardware reset. If the USR1,0 signal pins are at a logical 1 (tied to <math>V_{CC}</math>) during a hardware reset the USR1,0 bits are set to a 1. If the USR1,0 pins are at a logical 0 (tied to ground) during a hardware reset the USR1,0 bits are set to a 0. These bits are latched on the rising edge of RST. Once set they remain set/reset until the next hardware reset.</p>															
7, 6	<p><b>WC1,0: WAIT STATE CONTROL</b></p> <p>These encoded bits determine the number of additional bus cycles (T2 states) that are added during each DMA cycle.</p> <table style="margin-left: 20px;"> <thead> <tr> <th style="text-align: center;">WC1</th> <th style="text-align: center;">WC0</th> <th style="text-align: center;">Bus Cycles Added</th> </tr> </thead> <tbody> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">0</td> <td style="text-align: center;">0</td> </tr> <tr> <td style="text-align: center;">0</td> <td style="text-align: center;">1</td> <td style="text-align: center;">1</td> </tr> <tr> <td style="text-align: center;">1</td> <td style="text-align: center;">0</td> <td style="text-align: center;">2</td> </tr> <tr> <td style="text-align: center;">1</td> <td style="text-align: center;">1</td> <td style="text-align: center;">3</td> </tr> </tbody> </table>	WC1	WC0	Bus Cycles Added	0	0	0	0	1	1	1	0	2	1	1	3

## 4.0 SONIC Registers (Continued)

### 4.3.3 Receive Control Register

(RA <5:0> = 2h)

This register is used to filter incoming packets and provide status information of accepted packets (Figure 4-6). Setting any of bits 15–11 to a “1” enables the corresponding receive filter. If none of these bits are set, only packets which match the CAM Address registers are accepted. Bits 10 and 9 control the loopback operations.

After reception, bits 8–0 indicate status information about the accepted packet and are set to “1” when the corresponding condition is true. If the packet is accepted, all bits in the RCR are written into the RXpkt.status field. Bits 8–6 and 3–0 are cleared at the reception of the next packet.

This register is unaffected by a software reset.

**FIGURE 4-6. Receive Control Register**

Field	Meaning
ERR	ACCEPT PACKET WITH ERRORS
RNT	ACCEPT RUNT PACKETS
BRD	ACCEPT BROADCAST PACKETS
PRO	PHYSICAL PROMISCUOUS PACKETS
AMC	ACCEPT ALL MULTICAST PACKETS
LB0, LB1	LOOPBACK CONTROL
MC	MULTICAST PACKET RECEIVED
BC	BROADCAST PACKET RECEIVED
LPKT	LAST PACKET IN RBA
CRS	CARRIER SENSE ACTIVITY
COL	COLLISION ACTIVITY
CRCR	CRC ERROR
FAER	FRAME ALIGNMENT ERROR
LBK	LOOPBACK PACKET RECEIVED
PRX	PACKET RECEIVED OK

Bit	Description
15	<p><b>ERR: ACCEPT PACKET WITH CRC ERRORS OR COLLISIONS</b>                      0: Reject all packets with CRC errors or when a collision occurs.                      1: Accept packets with CRC errors and ignore collisions.</p>
14	<p><b>RNT: ACCEPT RUNT PACKETS</b>                      0: Normal address match mode.                      1: Accept runt packets (packets less than 64 bytes in length).                      Note: A hardware reset clears this bit.</p>
13	<p><b>BRD: ACCEPT BROADCAST PACKETS</b>                      0: Normal address match mode.                      1: Accept broadcast packets (packets with addresses that match the CAM are also accepted).                      Note: This bit is cleared upon hardware reset.</p>
12	<p><b>PRO: PHYSICAL PROMISCUOUS MODE</b>                      Enable all Physical Address packets to be accepted.                      0: normal address match mode.                      1: promiscuous mode.</p>
11	<p><b>AMC: ACCEPT ALL MULTICAST PACKETS</b>                      0: normal address match mode.                      1: enables all multicast packets to be accepted. Broadcast packets are also accepted regardless of the BRD bit. (Broadcast packets are a subset of multicast packets.)</p>

## 4.0 SONIC Registers (Continued)

### 4.3.3 Receive Control Register (Continued)

Bits	Description															
10, 9	<p><b>LB1, LB0: LOOPBACK CONTROL</b></p> <p>These encoded bits control loopback operations for MAC loopback, ENDEC loopback and Transceiver loopback. For proper loopback operation, the CAM Address registers and Receive Control register must be initialized to accept the Destination address of the loopback packet (see Section 1.7).</p> <p>Note: A hardware reset clears these bits.</p> <table border="1"> <thead> <tr> <th>LB1</th> <th>LB0</th> <th>Function</th> </tr> </thead> <tbody> <tr> <td>0</td> <td>0</td> <td>no loopback, normal operation</td> </tr> <tr> <td>0</td> <td>1</td> <td>MAC loopback</td> </tr> <tr> <td>1</td> <td>0</td> <td>ENDEC loopback</td> </tr> <tr> <td>1</td> <td>1</td> <td>Transceiver loopback</td> </tr> </tbody> </table>	LB1	LB0	Function	0	0	no loopback, normal operation	0	1	MAC loopback	1	0	ENDEC loopback	1	1	Transceiver loopback
LB1	LB0	Function														
0	0	no loopback, normal operation														
0	1	MAC loopback														
1	0	ENDEC loopback														
1	1	Transceiver loopback														
8	<p><b>MC: MULTICAST PACKET RECEIVED</b></p> <p>This bit is set when a packet is received with a Multicast Address.</p>															
7	<p><b>BC: BROADCAST PACKET RECEIVED</b></p> <p>This bit is set when a packet is received with a Broadcast Address.</p>															
6	<p><b>LPKT: LAST PACKET IN RBA</b></p> <p>This bit is set when the last packet is buffered into a Receive Buffer Area (RBA). The SONIC detects this condition when its Remaining Buffer Word Count (RBWC0,1) register is less than or equal to the End Of Buffer Count (EOBC) register. (See Section 3.4.2.)</p>															
5	<p><b>CRS: CARRIER SENSE ACTIVITY</b></p> <p>Set when CRS is active. Indicates the presence of network activity.</p>															
4	<p><b>COL: COLLISION ACTIVITY</b></p> <p>Indicates that the packet received had a collision occur during reception.</p>															
3	<p><b>CRCR: CRC ERROR</b></p> <p>Indicates the packet contains a CRC error. If the packet also contains a Frame Alignment error, FAER will be set instead (see bit 2, below). The rev C SONIC has the potential to report CRC error'd frames as FAE. This bit is also not set during CRC error'd RUNT packets.</p>															
2	<p><b>FAER: FRAME ALIGNMENT ERROR</b></p> <p>Indicates that the incoming packet was not correctly framed on an 8-bit boundary. Note: if no CRC errors have occurred, this bit is not set (i.e., this bit is only set when both a frame alignment and CRC error occurs).</p>															
1	<p><b>LBK: LOOPBACK PACKET RECEIVED</b></p> <p>Indicates that the SONIC has successfully received a loopback packet.</p>															
0	<p><b>PRX: PACKET RECEIVED OK</b></p> <p>Indicates that a packet has been received without CRC, frame alignment, length (runt packet) errors or collisions.</p>															

## 4.0 SONIC Registers (Continued)

### 4.3.4 Transmit Control Register

(RA<5:0> = 3h)

This register is used to program the SONIC's transmit actions and provide status information after a packet has been transmitted (Figure 4-7). At the beginning of transmission, bits 15, 14, 13 and 12 from the TXpkt.config field are loaded into the TCR to configure the various transmit modes (see Section 3.5.1.1). When the transmission ends, bits 10–0 indicate status information and are set to a "1" when the corresponding condition is true. These bits, along with the number of collisions information, are written into the TXpkt.status field at the end of transmission (see Section 3.5.1.2). Bits 9 and 5 are cleared after the TXpkt.status field has been written. Bits 10, 7, 6, and 1 are cleared at the commencement of the next transmission while bit 8 is set at this time.

A hardware reset sets bits 8 and 0 to a "1" and bit 1 to a 0. This register is unaffected by a software reset.

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

r/w	r/w	r/w	r/w	r	r	r	r	r	r	r	r	r	r	r	r

r = read only, r/w = read/write

**FIGURE 4-7. Transmit Control Register**

Field	Meaning
PINT	PROGRAMMABLE INTERRUPT
POWC	PROGRAMMED OUT OF WINDOW COLLISION TIMER
CRCI	CRC INHIBIT
EXDIS	DISABLE EXCESSIVE DEFERRAL TIMER
EXD	EXCESSIVE DEFERRAL
DEF	DEFERRED TRANSMISSION
NCRS	NO CRS
CRSL	CRS LOST
EXC	EXCESSIVE COLLISIONS
OWC	OUT OF WINDOW COLLISION
PMB	PACKET MONITORED BAD
FU	FIFO UNDERRUN
BCM	BYTE COUNT MISMATCH
PTX	PACKET TRANSMITTED OK

Bit	Description
15	<p><b>PINT: PROGRAMMABLE INTERRUPT</b></p> <p>This bit allows transmit interrupts to be generated under software control. The SONIC will issue an interrupt (PINT in the Interrupt Status Register) immediately after reading a TDA and detecting that PINT is set in the TXpkt.config field.</p> <p><b>Note:</b> In order for PINT to operate properly, it must be set and reset in the TXpkt.config field by alternating TDAs. This is necessary because after PINT has been issued in the ISR, PINT in the Transmit Control Register must be cleared before it is set again in order to have the interrupt issued for another packet. The only effective way to do this is to set PINT to a 1 no more often than every other packet.</p>
14	<p><b>POWC: PROGRAM "OUT OF WINDOW COLLISION" TIMER</b></p> <p>This bit programs when the out of window collision timer begins.</p> <p>0: timer begins after the Start of Frame Delimiter (SFD).</p> <p>1: timer begins after the first bit of preamble.</p>
13	<p><b>CRCI: CRC INHIBIT</b></p> <p>0: transmit packet with 4-byte FCS field.</p> <p>1: transmit packet without 4-byte FCS field.</p>
12	<p><b>EXDIS: DISABLE EXCESSIVE DEFERRAL TIMER:</b></p> <p>0: excessive deferral timer enabled.</p> <p>1: excessive deferral timer disabled.</p>
11	Must be 0.
10	<p><b>EXD: EXCESSIVE DEFERRAL</b></p> <p>Indicates that the SONIC has been deferring for 3.2 ms. The transmission is aborted if the excessive deferral timer is enabled (i.e. EXDIS is reset). This bit can only be set if the excessive deferral timer is enabled.</p>

## 4.0 SONIC Registers (Continued)

### 4.3.4 Transmit Control Register (Continued)

Bit	Description
9	<p><b>DEF: DEFERRED TRANSMISSION</b></p> <p>Indicates that the SONIC has deferred its transmission during the first attempt. If subsequent collisions occur, this bit is reset. This bit is cleared after the TXpkt.status field is written in the TDA.</p>
8	<p><b>NCRS: NO CRS</b></p> <p>Indicates that Carrier Sense (CRS) was not present during transmission. CRS is monitored from the beginning of the Start of Frame Delimiter to the last byte transmitted. The transmission will not be aborted. This bit is set at the start of preamble and is reset if CRS is detected. Hence, if CRS is never detected throughout the entire transmission of the packet, this bit will remain set.</p> <p><b>Note:</b> NCRS will remain set in MAC loopback as long as there is no activity on the RX<math>\pm</math>.</p>
7	<p><b>CRSL: CRS LOST</b></p> <p>Indicates that CRS has gone low or has not been present during transmission. CRS is monitored from the beginning of the Start of Frame Delimiter to the last byte transmitted. The transmission will not be aborted.</p> <p><b>Note:</b> If CRS was never present, both NCRS and CRSL will be set simultaneously. Also, CRSL will always be set in MAC loopback.</p>
6	<p><b>EXC: EXCESSIVE COLLISIONS</b></p> <p>Indicates that 16 collisions have occurred. The transmission is aborted.</p>
5	<p><b>OWC: OUT OF WINDOW COLLISION</b></p> <p>Indicates that an illegal collision has occurred after 51.2 <math>\mu</math>s (one slot time) from either the first bit of preamble or from SFD depending upon the POWC bit. The transmission backs off as in a normal transmission. This bit is cleared after the TXpkt.status field is written in the TDA.</p>
4	Must be 0.
3	<p><b>PMB: PACKET MONITORED BAD</b></p> <p>This bit is set, if after the receive unit has monitored the transmitted packet, the CRC has been calculated as invalid as a result of a frame alignment error, or the Source Address does not match any of the CAM address registers.</p> <p><b>Note 1:</b> The SONIC's CRC checker is active during transmission.</p> <p><b>Note 2:</b> If CRC has been inhibited for transmissions (CRCI is set), this bit will always be low. This is true regardless of Frame Alignment or Source Address mismatch errors.</p> <p><b>Note 3:</b> If a Receive FIFO overrun has occurred, the transmitted packet is not monitored completely. Thus, if PMB bit is set along with the RFO bit in the ISR, then PMB has no meaning. The packet must be completely received before PMB has meaning.</p> <p><b>Note 4:</b> This bit is always zero in MAC, ENDEC, and Transceiver loopback modes.</p>
2	<p><b>FU: FIFO UNDERRUN</b></p> <p>Indicates that the SONIC has not been able to access the bus before the FIFO has emptied. This condition occurs from excessive bus latency and/or slow bus clock. The transmission is aborted. (See Section 1.4.2.)</p>
1	<p><b>BCM: BYTE COUNT MISMATCH</b></p> <p>This bit is set when the SONIC detects that the TXpkt.pkt_size field is not equal to the sum of the TXpkt.frag_size field(s). Transmission is aborted. This bit will also be set when Excessive Collisions (bit 6 of the transmit control register) occur during transmission.</p>
0	<p><b>PTX: PACKET TRANSMITTED OK</b></p> <p>Indicates that a packet has been transmitted without the following errors:</p> <ul style="list-style-type: none"> <li>—Excessive Collisions (EXC)</li> <li>—Excessive Deferral (EXD)</li> <li>—FIFO Underrun (FU)</li> <li>—Byte Count Mismatch (BCM)</li> </ul>

## 4.0 SONIC Registers (Continued)

### 4.3.5 Interrupt Mask Register

(RA <5:0> = 4h)

This register masks the interrupts that can be generated from the ISR (Figure 4-8). Writing a "1" to the bit enables the corresponding interrupt. During a hardware reset, all mask bits are cleared.

Bit	Description
15	Must be 0.
14	<b>BREN: BUS RETRY OCCURRED enable:</b> 0: disable 1: enables interrupts when a Bus Retry operation is requested.
13	<b>HBLEN: HEARTBEAT LOST enable:</b> 0: disable 1: enables interrupts when a heartbeat lost condition occurs.
12	<b>LCDEN: LOAD CAM DONE INTERRUPT enable:</b> 0: disable 1: enables interrupts when the Load CAM command has finished.
11	<b>PINTEN: PROGRAMMABLE INTERRUPT enable:</b> 0: disable 1: enables programmable interrupts to occur when the PINT bit the TXpkt.config field is set to a "1".
10	<b>PRXEN: PACKET RECEIVED enable:</b> 0: disable 1: enables interrupts for packets accepted.
9	<b>PTXEN: PACKET TRANSMITTED OK enable:</b> 0: disable 1: enables interrupts for transmit completions.
8	<b>TXEREN: TRANSMIT ERROR enable:</b> 0: disable 1: enables interrupts for packets transmitted with error.

## 4.0 SONIC Registers (Continued)

### 4.3.5 Interrupt Mask Register (Continued)

Bit	Description
7	<b>TCEN: GENERAL PURPOSE TIMER COMPLETE enable:</b> 0: disable 1: enables interrupts when the general purpose timer has rolled over from 0000 0000h to FFFF FFFFh.
6	<b>RDEEN: RECEIVE DESCRIPTORS EXHAUSTED enable:</b> 0: disable 1: enables interrupts when all receive descriptors in the RDA have been exhausted.
5	<b>RBEEN: RECEIVE BUFFERS EXHAUSTED enable:</b> 0: disable 1: enables interrupts when all resource descriptors in the RRA have been exhausted.
4	<b>RBAAEN: RECEIVE BUFFER AREA EXCEEDED enable:</b> 0: disable 1: enables interrupts when the SONIC attempts to buffer data beyond the end of the Receive Buffer Area.
3	<b>CRCEEN: CRC TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the CRC tally counter has rolled over from FFFFh to 0000h.
2	<b>FAEEN: FRAME ALIGNMENT ERROR (FAE) TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the FAE tally counter rolled over from FFFFh to 0000h.
1	<b>MPEN: MISSED PACKET (MP) TALLY COUNTER WARNING enable:</b> 0: disable 1: enables interrupts when the MP tally counter has rolled over from FFFFh to 0000h.
0	<b>RFOEN: RECEIVE FIFO OVERRUN enable:</b> 0: disable 1: enables interrupts when the receive FIFO has overrun.

## 4.0 SONIC Registers (Continued)

### 4.3.6 Interrupt Status Register

(RA<5:0> = 5h)

This register (Figure 4-9) indicates the source of an interrupt when the INT pin goes active. Enabling the corresponding bits in the IMR allows bits in this register to produce an interrupt. When an interrupt is active, one or more bits in this register are set to a "1". A bit is cleared by writing "1" to it. Writing a "0" to any bit has no effect.

This register is cleared by a hardware reset and unaffected by a software reset.

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

r/w = read/write

**FIGURE 4-9. Interrupt Status Register**

Field	Meaning
BR	BUS RETRY OCCURRED
HBL	CD HEARTBEAT LOST
LCD	LOAD CAM DONE
PINT	PROGRAMMABLE INTERRUPT
PKTRX	PACKET RECEIVED
TXDN	TRANSMISSION DONE
TXER	TRANSMIT ERROR
TC	TIMER COMPLETE
RDE	RECEIVE DISCRIPTORS EXHAUSTED
RBE	RECEIVE BUFFERS EXHAUSTED
RBAE	RECEIVE BUFFER AREA EXCEEDED
CRC	CRC TALLY COUNTER ROLLOVER
FAE	FRAME ALIGNMENT ERROR
MP	MISSED PACKET COUNTER ROLLOVER
RFO	RECEIVE FIFO OVERRUN

Bit	Description
15	Must be 0.
14	<b>BR: BUS RETRY OCCURRED</b> Indicates that a Bus Retry (BRT) operation has occurred. In Latched Bus Retry mode (LBR in the DCR), BR will only be set when the SONIC is a bus master. Before the SONIC will continue any DMA operations, BR must be cleared. In Unlatched mode, the BR bit should be cleared also, but the SONIC will not wait for BR to be cleared before requesting the bus again and continuing its DMA operations. (See Sections 4.3.2 and 5.4.6 for more information on Bus Retry.)
13	<b>HBL: CD HEARTBEAT LOST</b> If the transceiver fails to provide a collision pulse (heart beat) during the first 6.4 μs of the Interframe Gap after transmission, this bit is set.
12	<b>LCD: LOAD CAM DONE</b> Indicates that the Load CAM command has finished writing to all programmed locations in the CAM. (See Section 4.1.1.)
11	<b>PINT: PROGRAMMED INTERRUPT</b> Indicates that upon reading the TXpkt.config field, the SONIC has detected the PINT bit to be set. (See Section 4.3.4.)
10	<b>PKTRX: PACKET RECEIVED</b> Indicates that a packet has been received and been buffered to memory. This bit is set after the RXpkt.seq_no field is written to memory.
9	<b>TXDN: TRANSMISSION DONE</b> Indicates that either (1) there are no remaining packets to be transmitted in the Transmit Descriptor Area (i.e., the EOL bit has been detected as a "1"), (2) the Halt Transmit command has been given (HTX bit in CR is set to a "1"), or (3) a transmit abort condition has occurred. This condition occurs when any of following bits in the TCR are set: BCM, EXC, FU, or EXD. This bit is set after the TXpkt.status field has been written to.

## 4.0 SONIC Registers (Continued)

### 4.3.6 Interrupt Status Register (Continued)

Bit	Description
8	<p><b>TXER: TRANSMIT ERROR</b></p> <p>Indicates that a packet has been transmitted with at least one of the following errors.</p> <ul style="list-style-type: none"> <li>—Byte count mismatch (BCM)</li> <li>—Excessive collisions (EXC)</li> <li>—FIFO underrun (FU)</li> <li>—Excessive deferral (EXD)</li> </ul> <p>The TXpkt.status field reveals the cause of the error(s).</p>
7	<p><b>TC: GENERAL PURPOSE (Watchdog) TIMER COMPLETE</b></p> <p>Indicates that the timer has rolled over from 0000 0000h to FFFF FFFFh. (See Section 4.3.12.)</p>
6	<p><b>RDE: RECEIVE DESCRIPTORS EXHAUSTED</b></p> <p>Indicates that all receive packet descriptors in the RDA have been exhausted. This bit is set when the SONIC detects EOL = 1. (See Section 3.4.7.)</p>
5	<p><b>RBE: RECEIVE BUFFER EXHAUSTED</b></p> <p>Indicates that the SONIC has detected the Resource Read Pointer (RRP) is equal to the Resource Write Pointer (RWP). This bit is set after the last field is read from the resource area. (See Section 3.4.7.)</p> <p><b>Note 1:</b> This bit will be set as the SONIC finishes using the second to last receive buffer and reads the last RRA descriptor. This gives the system an early warning of impending no resources.</p> <p><b>Note 2:</b> The SONIC will stop reception of packets when the last RBA has been used and will not continue reception until additional receive buffers have been added (i.e., RWP is incremented beyond RRP) and this bit has been reset.</p> <p><b>Note 3:</b> If additional buffers have been added, resetting this bit causes the SONIC to read the next resource descriptor pointed to by the RRP in the Receive Resource Area. Note that resetting this bit under this condition is similar to issuing the Read RRA command (setting the RRRA bit in the Command Register). This bit should never be reset until after the additional resources have been added to the RRA.</p>
4	<p><b>RBAE: RECEIVE BUFFER AREA EXCEEDED</b></p> <p>Indicates that during reception, the SONIC has reached the end of the Receive Buffer Area. Reception is aborted and the SONIC fetches the next available resource descriptors in the RRA. The buffer space is not re-used and an RDA is not setup for the truncated packet (see Section 3.4.7).</p>
3	<p><b>CRC: CRC TALLY COUNTER ROLLOVER</b></p> <p>Indicates that the tally counter has rolled over from FFFFh to 0000h. (See Section 4.3.11.)</p>
2	<p><b>FAE: FRAME ALIGNMENT ERROR (FAE) TALLY COUNTER ROLLOVER</b></p> <p>Indicates that the FAE tally counter has rolled over from FFFFh to 0000h. (See Section 4.3.11.)</p>
1	<p><b>MP: MISSED PACKET (MP) COUNTER ROLLOVER</b></p> <p>Indicates that the MP tally counter has rolled over from FFFFh to 0000h. (See Section 4.3.11.)</p>
0	<p><b>RFO: RECEIVE FIFO OVERRUN</b></p> <p>Indicates that the SONIC has been unable to access the bus before the receive FIFO has filled from the network. This condition is due to excessively long bus latency and/or slow bus clock. Note that FIFO underruns are indicated in the TCR. (See Section 1.4.1.)</p>

## 4.0 SONIC Registers (Continued)

### 4.3.7 Data Configuration Register 2

(RA<5:0> = 3Fh)

This register (Figure 4-10) is for enabling the extended bus interface options.

A hardware reset will set all bits in this register to "0" except for the Extended Programmable Outputs which are unknown until written to and bits 5 to 11 which must always be written with 0s but are "don't cares" when read. A software reset will not affect any bits in this register. This register should only be written to when the SONIC is in software reset (the RST bit in the Command Register is set).

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
EXPO3	EXPO2	EXPO1	EXPO0	0	0	0	0	0	0	0	PH	0	PCM	PCNM	RJCM
r/w	r/w	r/w	r/w								r/w		r/w	r/w	r/w

r/w = read/write

**FIGURE 4-10. Data Configuration Register**

Field	Meaning
EXPO3-0	EXTENDED PROGRAMMABLE OUTPUTS
PH	PROGRAM HOLD
PCM	PACKET COMPRESS WHEN MATCHED
PCNM	PACKET COMPRESS WHEN NOT MATCHED
RJCM	REJECT ON CAM MATCH

Bit	Description
15-12	<p><b>EXPO&lt;3:0&gt; EXTENDED PROGRAMMABLE OUTPUTS</b></p> <p>These bits program the level of the Extended User outputs (EXUSR&lt;3:0&gt;) when the SONIC is a bus master. Writing a "1" to any of these bits programs a high level to the corresponding output. Writing a "0" to any of these bits programs a low level to the corresponding output. EXUSR&lt;3:0&gt; are similar to USR&lt;1:0&gt; except that EXUSR&lt;3:0&gt; are only available when the Extended Bus mode is selected (bit 15 in the DCR is set to "1", see Section 4.3.2).</p>
11-5	Must be written with zeroes.
4	<p><b>PH: PROGRAM HOLD</b></p> <p>When this bit is set to "0", the HOLD request output is asserted/deasserted from the falling edge of bus clock. If this bit is set to "1", HOLD will be asserted/deasserted 1/2 clock later on the rising edge of bus clock.</p>
3	Must be zero.
2	<p><b>PCM: PACKET COMPRESS WHEN MATCHED</b></p> <p>When this bit is set to a "1" (and the PCNM bit is reset to a "0"), the <math>\overline{PCOMP}</math> output will be asserted if the destination address of the packet being received matches one of the entries in the CAM (Content Addressable Memory). This bit, along with PCNM, is used with the Management Bus of the DP83950, Repeater Interface Controller (RIC). See the DP83950 datasheet for more details on the RIC Management Bus. This mode is also called the Managed Bridge Mode.</p> <p><b>Note 1:</b> Setting PCNM and PCM to "1" at the same time is not allowed.</p> <p><b>Note 2:</b> If PCNM and PCM are both "0", the <math>\overline{PCOMP}</math> output will remain TRI-STATE until PCNM or PCM are changed.</p>
1	<p><b>PCNM: COMPRESS WHEN NOT MATCHED</b></p> <p>When this bit is set to a "1" (and the PCM bit is set to "0"), the <math>\overline{PCOMP}</math> output will be asserted if the destination address of the packet does not match one of the entries in the CAM. See the PCM bit above. This mode is also called the Managed Hub Mode.</p> <p><b>Note:</b> <math>\overline{PCOMP}</math> will not be asserted if the destination address is a broadcast address. This is true regardless of the state of the BRD bit in the Receive Control Register.</p>
0	<p><b>RJCM: REJECT ON CAM MATCH</b></p> <p>When this bit is set to "1", the SONIC will reject a packet on a CAM match. Setting RJCM to "0" causes the SONIC to operate normally by accepting packets on a CAM match. Setting this mode is useful for a small bridge with a limited number of nodes attached to it. RJCM only affects the CAM, though. Setting RJCM will not invert the function of the BRD, PRO or AMC bits (to accept broadcast, all physical or multicast packets respectively) in the Receive Control Register (see Section 4.3.3). This means, for example, that it is not possible to set RJCM and BRD to reject all broadcast packets. If RJCM and BRD are set at the same time, however, all broadcast packets will be accepted, but any packets that have a destination address that matches an address in the CAM will be rejected.</p>

## 4.0 SONIC Registers (Continued)

### 4.3.8 Transmit Registers

The transmit registers described in this section are part of the User Register set. The UTDA and CTDA must be initialized prior to issuing the transmit command (setting the TXP bit) in the Command register.

#### Upper Transmit Descriptor Address Register (UTDA):

This register contains the upper address bits ( $A<31:16>$ ) for accessing the transmit descriptor area (TDA) and is concatenated with the contents of the CTDA when the SONIC accesses the TDA in system memory. The TDA can be as large as 32k words or 16k long words and can be located anywhere in system memory. This register is unaffected by a hardware or software reset.

#### Current Transmit Descriptor Address Register (CTDA):

The 16-bit CTDA register contains the lower address bits ( $A<15:1>$ ) of the 32-bit transmit descriptor address. During initialization this register must be programmed with the lower address bits of the transmit descriptor. The SONIC concatenates the contents of this register with the contents of the UTDA to point to the transmit descriptor. For 32-bit memory systems bit 1, corresponding to address signal A1, must be set to "0" for alignment to long-word boundaries. Bit 0 of this register is the End of List (EOL) bit and is used to denote the end of the list. This register is unaffected by a hardware or software reset.

### 4.3.9 Receive Registers

The receive registers described in this section are part of the User Register set. A software reset has no effect on these registers and a hardware reset only affects the EOBC and RSC registers. The receive registers must be initialized prior to issuing the receive command (setting the RXEN bit) in the Command register.

#### Upper Receive Descriptor Address Register (URDA):

This register contains the upper address bits ( $A<31:16>$ ) for accessing the receive descriptor area (RDA) and is concatenated with the contents of the CRDA when the SONIC accesses the RDA in system memory. The RDA can be as large as 32k words or 16k long words and can be located anywhere in system memory. This register is unaffected by a hardware or software reset.

#### Current Receive Descriptor Address Register (CRDA):

The CRDA is a 16-bit read/write register used to locate the received packet descriptor block within the RDA. It contains the lower address bits ( $A<15:1>$ ). The SONIC concatenates the contents of the CRDA with the contents of the URDA to form the complete 32-bit address. The resulting 32-bit address points to the first field of the descriptor block. For 32-bit memory systems, bit 1, corresponding to address signal A1, must be set to "0" for alignment to long-word boundaries. Bit 0 of this register is the End of List (EOL) bit and is used to denote the end of the list. This register is unaffected by a hardware or software reset.

**End of Buffer Word Count Register (EOBC):** The SONIC uses the contents of this register to determine where to place the next packet. At the end of packet reception, the SONIC compares the contents of the EOBC register with the contents of the Remaining Buffer Word Count registers (RBWC0,1) to determine whether: (1) to place the next packet in the same RBA or (2) to place the next packet in another RBA. If the EOBC is less than or equal to the remaining number of words in the RBA after a packet is received (i.e.,  $EOB \leq RBWC0,1$ ), the SONIC buffers the next packet in the same RBA. If the EOBC is greater than

the remaining number of words in the RBA after a packet is received (i.e.,  $EOBC > RBWC0,1$ ), the Last Packet in RBA bit, LPKT in the Receive Control Register, Section 4.3.3, is set and the SONIC fetches the next resource descriptor. Hence, the next packet received will be buffered in a new RBA. A hardware reset sets this register to 02F8H (760 words or 1520 bytes). See Sections 3.4.2 and 3.4.4.4 for more information about using EOBC.

#### Upper Receive Resource Address Register (URRA):

The URRA is a 16-bit read/write register. It is programmed with the base address of the receive resource area (RRA). This 16-bit upper address value ( $A<31:16>$ ) locates the receive resource area in system memory. SONIC uses the URRA register when accessing the receive descriptors within the RRA by concatenating the lower address value from one of four receive resource registers (RSA, REA, RWP, or RRP).

#### Resource Start Address Register (RSA):

The RSA is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RSA is programmed with the lower 15-bits ( $A<15:1>$ ) of the starting address of the receive resource area. SONIC concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

#### Resource End Address Register (REA):

The REA is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The REA is programmed with the lower 15-bits ( $A<15:1>$ ) of the ending address of the receive resource area. SONIC concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

#### Resource Read Pointer Register (RRP):

The RRP is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RRP is programmed with the lower 15-bit address ( $A<15:1>$ ) of the first field of the next descriptor the SONIC will read. SONIC concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address.

#### Resource Write Pointer Register (RWP):

The RWP is a 15-bit read/write register. The LSB is not used and always reads back as a 0. The RWP is programmed with the lower 15-bit address ( $A<15:1>$ ) of the next available location the system can add a descriptor. SONIC concatenates the contents of this register with the contents of the URRA to form the complete 32-bit address. In 32-bit mode, bit 1, corresponding to address signal A1, must be zero to insure the proper equality comparison between this register and the RRP register.

#### Receive Sequence Counter Register (RSC):

This is a 16-bit read/write register containing two fields. The SONIC uses this register to provide status information on the number of packets within a RBA and the number of RBAs. The RSC register contains two 8-bit (modulo 256) counters. After each packet is received the packet sequence number is incremented. The SONIC maintains a single sequence number for each RBA. When the SONIC uses the next RBA, the packet sequence number is reset to zero and the RBA sequence number is incremented. This register is reset to 0 by a hardware reset or by writing zero to it. A software reset has no affect.

15	8	7	0
RBA Sequence Number (Modulo 256)		Packet Sequence Number (Modulo 256)	

## 4.0 SONIC Registers (Continued)

### 4.3.10 CAM Registers

The CAM registers described in this section are part of the User Register set. They are used to program the Content Addressable Memory (CAM) entries that provide address filtering of packets. These registers, except for the CAM Enable register, are unaffected by a hardware or software reset.

**CAM Entry Pointer Register (CEP):** The CEP is a 4-bit register used by SONIC to select one of the sixteen CAM entries. SONIC uses the least significant 4-bits of this register. The value of 0h points to the first CAM entry and the value of Fh points to the last entry.

**CAM Address Port 2, 1, 0 Registers (CAP2, CAP1, CAP0):** Each CAP is a 16-bit read-only register used to access the CAM cells. Each CAM cell is 16-bits wide and contains one third of the 48-bit CAM entry which is used by the SONIC for address filtering. The CAP2 register is used to access the upper bits (<47:32>), CAP1 the middle bits (<31:16>) and CAP0 the lower bits (<15:0>) of the CAM entry. Given the physical address 60:50:40:30:20:10, which is made up of 6 octets or bytes, where 10h is the least significant byte and 60h is the most significant byte (60h would be the first byte received from the network and 10h would be the last), CAP0 would be loaded with 2010h, CAP1 with 4030h and CAP2 with 6050h.

To read a CAM entry, the user first places the SONIC in software reset (set the RST bit in the Command register), programs the CEP register to select one of sixteen CAM entries, then reads CAP2, CAP1, and CAP0 to obtain the complete 48-bit entry. The user can not write to the CAM entries directly. Instead, the user programs the CAM descriptor area in system memory (see Section 4.1.1), then issues the Load CAM command (setting LCAM bit in the Command register). This causes the SONIC to read the descriptors from memory and loads the corresponding CAM entry through CAP2-0.

**CAM Enable Register (CE):** The CE is a 16-bit read/write register used to mask out or enable individual CAM entries. Each register bit position corresponds to a CAM entry. When a register bit is set to a "1" the corresponding CAM entry is enabled. When "0" the entry is disabled. This register is unaffected by a software reset and cleared to zero (disabling all entries) during a hardware reset. Under normal operations the user does not access this register. Instead the user sets up this register through the last entry in the CAM descriptor area. The SONIC loads the CE register during execution of the LCAM Command.

**CAM Descriptor Pointer Register (CDP):** The CDP is a 15-bit read/write register. The LSB is unused and always reads back as 0. The CDP is programmed with the lower

address (A<15:1>) of the first field of the CAM descriptor block in the CAM descriptor area (CDA) of system memory. SONIC uses the contents of the CDP register when accessing the CAM descriptors. This register must be programmed by the user before issuing the LCAM command. During execution of the LCAM Command SONIC concatenates the contents of this register with the contents of the URRR register to form the complete 32-bit address. During the Load CAM operation this register is incremented to address the fields in the CDA. After the Load Command completes, this register points to the next location after the CAM Descriptor Area.

**CAM Descriptor Count Register (CDC):** The CDC is a 5-bit read/write register. It is programmed with the number of CAM descriptor blocks in the CAM descriptor area. This register must be programmed by the user before issuing the LCAM command. SONIC uses the value in this register to determine how many entries to place in the CAM during execution of the LCAM command. During LCAM execution SONIC decrements this register each time it reads a descriptor block. When the CDC decrements to zero SONIC terminates the LCAM execution. Since the CDC register is programmed with the number of CAM descriptor blocks in the CAM Descriptor Area, the value programmed into the CDC register ranges 1 to 16 (1h to 10h).

### 4.3.11 Tally Counters

The SONIC provides three 16-bit counters used for monitoring network statistics on the number of CRC errors, Frame Alignment errors, and missed packets. These registers roll-over after the count of FFFFh is reached and produce an interrupt if enabled in the Interrupt Mask Register (IMR). These counters are unaffected by the RXEN bit in the CR, but are halted when the RST bit in the CR is set. The data written to these registers is inverted before being latched. This means that if a value of FFFFh is written to these registers by the system, they will contain and read back the value 0000h. Data is not inverted during a read operation. The Tally registers, therefore, are cleared by writing all "1's" to them. A software or hardware reset does not clear the tally counters.

**CRC Tally Counter Register (CRCT):** The CRCT is a 16-bit read/write register. This register is used to keep track of the number of packets received with CRC errors. After a packet is accepted by the address recognition logic, this register is incremented if a CRC error is detected. If the packet also contains a Frame Alignment error, this counter is not incremented.

**FAE Tally Counter Register (FAET):** The FAET is a 16-bit read/write register. This register is used to keep track of the number of packets received with frame alignment errors. After a packet is accepted by the address recognition logic, this register is incremented if a FAE error is detected.

**Missed Packet Tally Counter Register (MPT):** The MPT is a 16-bit read/write register. After a packet is received, this counter is incremented if there is: (1) lack of memory resources to buffer the packet, (2) a FIFO overrun, or (3) a valid packet has been received, but the receiver is disabled (RXDIS is set in the command register).

## 4.0 SONIC Registers (Continued)

### 4.3.12 General Purpose Timer

The SONIC contains a 32-bit general-purpose Watchdog Timer for timing user-definable events. This timer is accessed by the user through two 16-bit read/write registers (WT1 and WT0). The lower count value is programmed through the WT0 register and the upper count value is programmed through the WT1 register.

These two registers are concatenated together to form the complete 32-bit timer. This timer, clocked at  $\frac{1}{2}$  the Transmit Clock (TXC) frequency, counts down from its programmed value and generates an interrupt, if enabled (Interrupt Mask register), when it rolls over from 0000 0000h to FFFF FFFFh. When the counter rolls over it continues decrementing unless explicitly stopped (setting the STP bit). The timer is controlled by the ST (Start Timer) and STP (Stop Timer) bits in the Command register. A hardware or software reset halts, but does not clear, the General Purpose timer.

31	16	15	0
WT1 (Upper Count Value)		WT0 (Lower Count Value)	

### 4.3.13 Silicon Revision Register

This is a 16-bit read only register. It contains information on the current revision of the SONIC. The value of the DP83932CVF revision register is 6h.

## 5.0 Bus Interface

SONIC features a high speed non-multiplexed address and data bus designed for a wide range of system environments. The data bus can be programmed (via the Data Configuration Register) to a width of either 32- or 16-bits. SONIC con-

tains an on-chip DMA and supplies all the necessary signals for DMA operation. With 31 address lines SONIC can access a full 2 G-word address space. To accommodate different memory speeds wait states can be added to the bus cycle by two methods. The memory subsystem can add wait states by simply withholding the appropriate handshake signals. In addition, the SONIC can be programmed (via the Data Configuration Register) to add wait states.

The SONIC is designed to interface to both the National/Intel and Motorola style buses. To facilitate minimum chip count designs and complete bus compatibility the user can program the SONIC for the following bus modes:

- National/Intel bus operating in synchronous mode
- National/Intel bus operating in asynchronous mode
- Motorola bus operating in synchronous mode
- Motorola bus operating in asynchronous mode

The mode pin (BMODE) along with the SBUS bit in the Data Configuration Register are used to select the bus mode.

This section describes the SONIC's pin signals, provides system interface examples, and describes the various SONIC bus operations.

### 5.1 PIN CONFIGURATIONS

There are two user selectable pin configurations for SONIC to provide the proper interface signals for either the National/Intel or Motorola style buses. The state of the BMODE pin is used to define the pin configuration. *Figure 5-1* shows the pin configuration when BMODE = 1 (tied to  $V_{CC}$ ) for the Motorola style bus. *Figure 5-2* shows the pin configuration when BMODE = 0 (tied to ground) for the National/Intel style bus.

### 5.2 PIN DESCRIPTION

I = input

O = output

Z = TRI-STATE inputs are TTL compatible

ECL = ECL-like drivers for interfacing to the Attachment Unit Interface.

TP = Totem pole like drivers. These drivers are driven either high or low and are always driven. Drive levels are CMOS compatible.

TRI = TRI-STATE drivers. These pins are driven high, low or TRI-STATE. Drive levels are CMOS compatible. These pins may also be inputs (depending on the pin).

OC = Open Collector type drivers. These drivers are TRI-STATE when inactive and are driven low when active. These pins may also be inputs (depending on the pin). Pin names which contain a "/" indicate dual function pins.

TABLE 5-1. Pin Description

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS</b>			
EXT		I	<b>External ENDEC Select:</b> Tying this pin to $V_{CC}$ (EXT = 1) disables the internal ENDEC and allows an external ENDEC to be used. Tying this pin to ground (EXT = 0) enables the internal ENDEC. This pin must be tied either to $V_{CC}$ or ground. Note the alternate pin definitions for CRS <sub>o</sub> /CRS <sub>i</sub> , COL <sub>o</sub> /COL <sub>i</sub> , RXD <sub>o</sub> /RXD <sub>i</sub> , RXC <sub>o</sub> /RXC <sub>i</sub> , and TXC <sub>o</sub> /TXC <sub>i</sub> . When EXT = 0 the first pin definition is used and when EXT = 1 the second pin definition is used.
CD+		I	<b>Collision +:</b> The positive differential collision input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
CD-		I	<b>Collision -:</b> The negative differential collision input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
RX+		I	<b>Receive +:</b> The positive differential receive data input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
RX-		I	<b>Receive -:</b> The negative differential receive data input from the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
TX+	ECL	O	<b>Transmit +:</b> The positive differential transmit output to the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
TX-	ECL	O	<b>Transmit -:</b> The negative differential transmit output to the transceiver. This pin should be unconnected when an external ENDEC is selected (EXT = 1).
CRS <sub>o</sub> / CRS <sub>i</sub>	TP	O I	<b>Carrier Sense Output (CRS<sub>o</sub>)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the CRS <sub>o</sub> signal is internally connected between the ENDEC and MAC units. It is asserted on the first valid high-to-low transition in the receive data (RX + / -). This signal remains active 1.5 bit times after the last bit of data. Although this signal is used internally by the SONIC it is also provided as an output to the user. <b>Carrier Sense Input (CRS<sub>i</sub>)</b> from an external ENDEC (EXT = 1): The CRS <sub>i</sub> signal is activated high when the external ENDEC detects valid data at its receive inputs.
COL <sub>o</sub> / COL <sub>i</sub>	TP	O I	<b>Collision Output (COL<sub>o</sub>)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the COL <sub>o</sub> signal is internally connected between the ENDEC and MAC units. This signal generates an active high signal when the 10 MHz collision signal from the transceiver is detected. Although this signal is used internally by the SONIC it is also provided as an output to the user. <b>Collision Detect Input (COL<sub>i</sub>)</b> from an external ENDEC (EXT = 1): The COL <sub>i</sub> signal is activated from an external ENDEC when a collision is detected. This pin is monitored during transmissions from the beginning of the Start Of Frame Delimiter (SFD) to the end of the packet. At the end of transmission, this signal is monitored by the SONIC for CD heartbeat.

## 5.0 Bus Interface (Continued)

TABLE 5-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS (Continued)</b>			
RXDo/ RXDi/ EXUSR0	TP TRI	O I O, Z	<p>This pin will be TRI-STATE until the DCR has been written to. (See Section 4.3.2, EXBUS, for more information.)</p> <p><b>Receive Data Output (RXDo)</b> from the internal ENDEC (EXT = 0): NRZ data output. When EXT = 0 the RXDOUT signal is internally connected between the ENDEC and MAC units. This signal must be sampled on the rising edge of the receive clock output (RXCo). Although this signal is used internally by the SONIC it is also provided as an output to the user.</p> <p><b>Receive Data Input (RXDi)</b> from an external ENDEC (EXT = 1): The NRZ data decoded from the external ENDEC. This data is clocked in on the rising edge of RXCi.</p> <p><b>Extended User Output (EXUSR0):</b> When EXBUS has been set (see Section 4.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (Section 4.3.7).</p>
RXCo/ RXCi/ EXUSR1	TP TRI	O I O, Z	<p>This pin will be TRI-STATE until the DCR has been written to. (See Section 4.3.2, EXBUS, for more information.)</p> <p><b>Receive Clock Output (RXCo)</b> from the internal ENDEC (EXT = 0): When EXT = 0 the RXCo signal is internally connected between the ENDEC and MAC units. This signal is the separated receive clock from the Manchester data stream. It remains active 5-bit times after the deassertion of CRS0. Although this signal is used internally by the SONIC it is also provided as an output to the user.</p> <p><b>Receive Clock Input (RXCi)</b> from an external ENDEC (EXT = 1): The separated received clock from the Manchester data stream. This signal is generated from an external ENDEC.</p> <p><b>Extended User Output (EXUSR1):</b> When EXBUS has been set (see Section 4.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (Section 4.3.7).</p>
TXD/ EXUSR3	TP TRI	O O, Z	<p>This pin will be TRI-STATE until the DCR has been written to. (See Section 4.3.2, EXBUS, for more information.)</p> <p><b>Transmit Data (TXD):</b> The serial NRZ data from the MAC unit which is to be decoded by an external ENDEC. Data is valid on the rising edge of TXC. Although this signal is used internally by the SONIC it is also provided as an output to the user.</p> <p><b>Extended User Output (EXUSR3):</b> When EXBUS has been set (see Section 4.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (Section 4.3.7).</p>
TXE	TP	O	<p><b>Transmit Enable:</b> This pin is driven high when the SONIC begins transmission and remains active until the last byte is transmitted. Although this signal is used internally by the SONIC it is also provided as an output to the user.</p>
TXCo/ TXCi/ STERM	TRI	O, Z I I	<p>This pin will be TRI-STATE until the DCR has been written to. (See Section 4.3.2, EXBUS, for more information.)</p> <p><b>Transmit Clock Output (TXCo)</b> from the internal ENDEC (EXT = 0): This 10 MHz clock transmit clock output is derived from the 20 MHz oscillator. When EXT = 0 the TXCOUT signal is internally connected between the ENDEC and MAC units. Although this signal is used internally by the SONIC it is also provided as an output to the user.</p> <p><b>Transmit Clock Input (TXCi)</b> (EXT = 1): This input clock from an external ENDEC is used for shifting data out of the MAC unit serializer. This clock is nominally 10 MHz.</p> <p><b>Synchronous Termination (STERM):</b> When the SONIC is a bus master, it samples this pin before terminating its memory cycle. This pin is sampled synchronously and may only be used in asynchronous bus mode when BMODE = 1. See Section 5.4.5 for more details.</p>

## 5.0 Bus Interface (Continued)

TABLE 5-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>NETWORK INTERFACE PINS</b> (Continued)			
LBK/ EXUSR2	TP TRI	O O, Z	This pin will be TRI-STATE until the DCR has been written to. (See Section 4.3.2, EXBUS, for more information.) <b>Loopback (LBK):</b> When ENDEC loopback is programmed, LBK is asserted high. Although this signal is used internally by the SONIC it is also provided as an output to the user. <b>Extended User Output (EXUSR2):</b> When EXBUS has been set (see Section 4.3.2), this pin becomes a programmable output. It will remain TRI-STATE until the SONIC becomes a bus master, at which time it will be driven according to the value programmed in the DCR2 (Section 4.3.7).
PCOMP	TRI	O, Z	<b>Packet Compression:</b> This pin is used with the Management Bus of the DP83950, Repeater Interface Controller (RIC). The SONIC can be programmed to assert PCOMP whenever there is a CAM match, or when there is not a match. The RIC uses this signal to compress (shorten) a received packet for management purposes and to reduce memory usage. (See the DP83950 datasheet for more details on the RIC Management Bus.) The operation of this pin is controlled by bits 1 and 2 in the DCR2 register. PCOMP will remain TRI-STATE until these bits are written to. This signal is asserted right after the 4th bit of the 7th byte of the incoming packet and is deasserted one transmit clock (TXC) after CRS is driven low.
SEL		I	<b>Mode Select (EXT = 0):</b> This pin is used to determine the voltage relationship between TX+ and TX- during idle at the primary of the isolation transformer on the network interface. When tied to V <sub>CC</sub> , TX+ and TX- are at equal voltages during idle. When tied to ground, the voltage at TX+ is positive with respect to TX- during idle on the primary side of the isolation transformer ( <i>Figure 6-2</i> ).
PREJ		I	<b>Packet Reject:</b> This signal is used to reject received packets. When asserted low for at least two receive clocks (RXC), the SONIC will reject the incoming packet. This pin can be asserted up to the 2nd to the last bit of reception to reject a packet.
OSCOU	TP	O	<b>Crystal Feedback Output:</b> This signal is used to provide clocking signals for the internal ENDEC. A crystal can be connected to this pin along with OSCIN. See Section 6.1.3 for more information about using oscillators or crystals.
OSCIN		I	<b>Crystal Feedback Input or External Oscillator Input:</b> This signal is used to provide clocking signals for the internal ENDEC. A crystal may be connected to this pin along with OSCOUT, or an oscillator module may be used. Typically the output of an oscillator module is connected to this pin. See Section 6.1.3 for more information about using oscillator modules or crystals.
<b>BUS INTERFACE PINS</b>			
BMODE		I	<b>Bus Mode:</b> This input enables the SONIC to be compatible with standard microprocessor buses. The level of this pin affects byte ordering (little or big endian) and controls the operation of the bus interface control signals. A high level (tied to V <sub>CC</sub> ) selects Motorola mode (big endian) and a low level (tied to ground) selects National/Intel mode (little endian). Note the alternate pin definitions for AS/ADS, MRW/MWR, INT/INT, BR/HOLD, BG/HLDA, SRW/SWR, DSACK0/RDY0, and DSACK1/RDY1.

## 5.0 Bus Interface (Continued)

TABLE 5-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>BUS INTERFACE PINS (Continued)</b>			
D31–D0	TRI	I, O, Z	<b>Data Bus:</b> These bidirectional lines are used to transfer data on the system bus. When the SONIC is a bus master, 16-bit data is transferred on D15–D0 and 32-bit data is transferred on D31–D0. When the SONIC is accessed as a slave, register data is driven onto lines D15–D0. D31–D16 are held TRI-STATE if SONIC is in 16-bit mode. If SONIC is in 32-bit mode, they are driven, but invalid.
A31–A1	TRI	O, Z	<b>Address Bus:</b> These signals are used by the SONIC to drive the DMA address after the SONIC has acquired the bus. Since the SONIC aligns data to word boundaries, only 31 address lines are needed.
RA5–RA0		I	<b>Register Address Bus:</b> These signals are used to access SONIC's internal registers. When the SONIC is accessed, the CPU drives these lines to select the desired SONIC register.
$\overline{AS}$ / $\overline{ADS}$	TRI TRI	O, Z O, Z	<b>Address Strobe (<math>\overline{AS}</math>):</b> When BMODE = 1, the falling edge indicates valid status and address. The rising edge indicates the termination of the memory cycle. <b>Address Strobe (<math>\overline{ADS}</math>):</b> When BMODE = 0, the rising edge indicates valid status and address.
$\overline{MRW}$ / $\overline{MWR}$	TRI TRI	O, Z O, Z	When the SONIC has acquired the bus, this signal indicates the direction of data. <b>Memory Read/Write Strobe (<math>\overline{MRW}</math>):</b> When BMODE = 1, this signal is high during a read cycle and low during a write cycle. <b>Memory Read/Write Strobe (<math>\overline{MWR}</math>):</b> When BMODE = 0, the signal is low during a read cycle and high during a write cycle.
$\overline{INT}$ / INT	OC TP	O, Z O	Indicates that an interrupt (if enabled) is pending from one of the sources indicated by the Interrupt Status register. Interrupts that are disabled in the Interrupt Mask register will not activate this signal. <b>Interrupt (<math>\overline{INT}</math>):</b> This signal is active low when BMODE = 1. <b>Interrupt (INT):</b> This signal is active high when BMODE = 0.
$\overline{RESET}$		I	<b>Reset:</b> This signal is used to hardware reset the SONIC. When asserted low, the SONIC transitions into the reset state after 10 transmit clocks or 10 bus clocks if the bus clock period is greater than the transmit clock period.
S2–S0	TP	O	<b>Bus Status:</b> These three signals provide a continuous status of the current SONIC bus operations. See Section 5.4.3 for status definitions.
BCLK		I	<b>Bus Clock:</b> This clock provides the timing for the SONIC DMA engine.
$\overline{BR}$ / HOLD	OC TP	O, Z O	<b>Bus Request (<math>\overline{BR}</math>):</b> When BMODE = 1, the SONIC asserts this pin low when it attempts to gain access to the bus. When inactive this signal is tri-stated. <b>Hold Request (HOLD):</b> When BMODE = 0, the SONIC drives this pin high when it intends to use the bus and is driven low when inactive.
$\overline{BG}$ / HLDA		I I	<b>Bus Grant (<math>\overline{BG}</math>):</b> When BMODE = 1 this signal is a bus grant. The system asserts this pin low to indicate potential mastership of the bus. <b>Hold Acknowledge (HLDA):</b> When BMODE = 0 this signal is used to inform the SONIC that it has attained the bus. When the system asserts this pin high, the SONIC has gained ownership of the bus. This signal is sampled synchronously and the setup time must be met to ensure proper operation.
$\overline{BGACK}$	TRI	I, O, Z	<b>Bus Grant Acknowledge:</b> When BMODE = 1, the SONIC asserts this pin low when it has determined that it can gain ownership of the bus. The SONIC checks the following signal before driving $\overline{BGACK}$ . 1) $\overline{BG}$ has been received through the bus arbitration process. 2) $\overline{AS}$ is deasserted, indicating that the CPU has finished using the bus. 3) $\overline{DSACK0}$ and $\overline{DSACK1}$ are deasserted, indicating that the previous slave device is off the bus. 4) $\overline{BGACK}$ is deasserted, indicating that the previous master is off the bus. This pin is only used when BMODE = 1.

## 5.0 Bus Interface (Continued)

TABLE 5-1. Pin Description (Continued)

Symbol	Driver Type	Direction	Description
<b>BUS INTERFACE PINS (Continued)</b>			
$\overline{CS}$		I	<p><b>Chip Select:</b> The system asserts this pin low to access the SONIC's registers. The registers are selected by placing an address on lines RA5–RA0.</p> <p><b>Note:</b> Both <math>\overline{CS}</math> and <math>\overline{MREQ}</math> must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting edge of the first signal and the asserting edge of the second signal.</p>
$\overline{SAS}$		I	<p><b>Slave Address Strobe:</b> The system asserts this pin to latch the register address on lines RA0–RA5. When BMODE = 1, the address is latched on the falling edge of <math>\overline{SAS}</math>. When BMODE = 0 the address is latched on the rising edge of <math>\overline{SAS}</math>.</p>
SRW/ SWR		I I	<p>The system asserts this pin to indicate whether it will read from or write to the SONIC's registers.</p> <p><b>Slave Read/Write (SRW):</b> When BMODE = 1, this signal is asserted high during a read and low during a write.</p> <p><b>Slave Write/Read (SWR):</b> when BMODE = 0, this signal is asserted low during a read and high during a write.</p>
$\overline{DS}$	TRI	O, Z	<p><b>Data Strobe:</b> When the SONIC is bus master, it drives this pin low during a read cycle to indicate that the slave device may drive data onto the bus; in a write cycle, this pin indicates that the SONIC has placed valid data onto the bus.</p>
$\overline{DSACK0}/$ $\overline{RDYi}/$ $\overline{DSACK1}/$ $\overline{RDY0}$	TRI TRI TP	I, O, Z I I, O, Z O	<p><b>Data and Size Acknowledge 0 and 1 (<math>\overline{DSACK0,1}</math> BMODE = 1):</b> These pins are the output slave acknowledge to the system when the SONIC registers have been accessed and the input slave acknowledgement when the SONIC is busmaster. When a register has been accessed, the SONIC drives both <math>\overline{DSACK0}</math> and <math>\overline{DSACK1}</math> pins low to terminate the slave cycle. (Note that the SONIC responds as a 32-bit peripheral by driving both <math>\overline{DSACK0}</math> and <math>\overline{DSACK1}</math> low, but drives data only on lines D0–D15. Lines D16–D31 are driven, but invalid.) When the SONIC is bus master, it samples these pins before terminating its memory cycle. When SONIC is in 32-bit bus master mode, both <math>\overline{DSACK0}</math> and <math>\overline{DSACK1}</math> must be asserted to terminate the cycle. However, if the SONIC is in 16-bit bus master mode, only the assertion of <math>\overline{DSACK1}</math> is required to terminate the cycle. These pins are sampled synchronously or asynchronously depending on the state of the SBUS bit in the Data Configuration register. See Section 5.4.5 for details. Note that the SONIC does not allow dynamic bus sizing. Bus size is statically defined in the Data Configuration register (see Section 4.3.2).</p> <p><b>Ready Input (RDYi, BMODE = 0):</b> When the SONIC is a bus master, the system asserts this signal high to insert wait-states and low to terminate the memory cycle. This signal is sampled synchronously or asynchronously depending on the state of the SBUS bit. See Section 5.4.5 and 4.3.2 for details.</p> <p><b>Ready Output (<math>\overline{RDY0}</math>, BMODE = 0):</b> When a register is accessed, the SONIC asserts this signal to terminate the slave cycle.</p>
BRT		I	<p><b>Bus Retry:</b> When the SONIC is bus master, the system asserts this signal to rectify a potentially correctable bus error. This pin has 2 modes. Mode 1 (the LBR in the Data Configuration register is set to 0): Assertion of this pin forces the SONIC to terminate the current bus cycle and will repeat the same cycle after BRT has been deasserted. Mode 2 (the LBR bit in the Data Configuration register is set to 1): Assertion of this signal forces the SONIC to retry the bus operation as in Mode 1. However, the SONIC will not continue DMA operations until the BR bit in the ISR is reset.</p>
ECS	TRI	O, Z	<p><b>Early Cycle Start:</b> This output gives the system earliest indication that a memory operation is occurring. This signal is driven low at the rising edge of T1 and high at the falling edge of T1.</p>

## 5.0 Bus Interface (Continued)

**TABLE 5-1. Pin Description (Continued)**

Symbol	Driver Type	Direction	Description
<b>SHARED-MEMORY ACCESS PINS</b>			
$\overline{\text{MREQ}}$		I	<p><b>Memory Request:</b> The system asserts this signal low when it attempts to access the shared-buffer RAM. The on-chip arbiter resolves accesses between the system and the SONIC.</p> <p><b>Note:</b> Both <math>\overline{\text{CS}}</math> and <math>\overline{\text{MREQ}}</math> must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting edge of the first signal and the asserting edge of the second signal.</p> <p>In Motorola mode, if a bus master uses the <math>\overline{\text{MREQ}}</math> to request the bus from the SONIC, care should be taken to isolate the <math>\overline{\text{DSACK0,1}}</math> from the bus (e.g., use tri-state buffers) because the <math>\overline{\text{DSACK0,1}}</math> will be driven by the SONIC even after the SONIC has given up the bus.</p>
$\overline{\text{SMACK}}$	TP	O	<p><b>Slave and Memory Acknowledge:</b> SONIC asserts this dual function pin low in response to either a Chip Select (<math>\overline{\text{CS}}</math>) or a Memory Request (<math>\overline{\text{MREQ}}</math>) when the SONIC's registers or its buffer memory is available for accessing. This pin can be used for enabling bus drivers for dual-bus systems.</p>
<b>USER DEFINABLE PINS</b>			
USR0,1	TRI	I, O, Z	<p><b>User Define 0,1:</b> These signals are inputs when SONIC is hardware reset and are outputs when SONIC is a bus master (HLDA or <math>\overline{\text{BGACK}}</math> asserted). When hard reset (<math>\overline{\text{RST}}</math>) is low, these signals input directly into bits 8 and 9 of the Data Configuration register (DCR) respectively. The levels on these pins are latched on the rising edge of <math>\overline{\text{RST}}</math>. During busmaster operations (HLDA or <math>\overline{\text{BGACK}}</math> is active), these pins are outputs whose levels are programmable through bits 11 and 12 of the DCR respectively. The USR0,1 pins should be pulled up to <math>V_{\text{CC}}</math> or pulled down to ground. A 4.7 k<math>\Omega</math> pull-up resistor is recommended.</p>
<b>POWER AND GROUND PINS</b>

TXVCC RXVCC PLLVCC			<p><b>Power:</b> These pins are the +5V power supply for the SONIC ENDEC unit. These pins must be tied to <math>V_{\text{CC}}</math> even if the internal ENDEC is not used.</p>
GND1-6 GNDL			<p><b>Ground:</b> The ground reference for the digital portions of the SONIC.</p>
TXGND ANGND			<p><b>Ground:</b> These pins are the ground references for the SONIC ENDEC unit. These pins must be tied to ground even if the internal ENDEC is not used.</p>

### 5.3 SYSTEM CONFIGURATION

Any device that meets the SONIC interface protocol and electrical requirements (timing, threshold, and loading) can be interfaced to SONIC. Since two bus protocols are provided, via the BMODE pin, the SONIC can interface directly to most microprocessors. *Figure 5-3* shows a typical interface to the National/Intel style bus (BMODE=0) and *Figure 5-4* shows a typical interface to the Motorola style bus (BMODE=1).

The BMODE pin also controls byte ordering. When BMODE=1 big endian byte ordering is selected and when BMODE=0 little endian byte ordering is selected.

### 5.4 BUS OPERATIONS

There are two types of system bus operations: 1) SONIC as a slave, and 2) SONIC as a bus master. When SONIC is a slave (e.g., a CPU accessing SONIC registers) all transfers are non-DMA. When SONIC is a bus master (e.g., SONIC accessing receive or transmit buffer/descriptor areas) all transfers are block transfers using SONIC's on-chip DMA. This section describes the SONIC bus operations. Pay special attention to all sections labeled as "**Note**". These conditions must be met for proper bus operation.

## 5.0 Bus Interface (Continued)

### 5.4.1 Acquiring The Bus

The SONIC requests the bus when 1) its FIFO threshold has been reached or 2) when the descriptor areas in memory (i.e., RRA, RDA, CDA, and TDA) are accessed. Note that when the SONIC moves from one area in memory to another (e.g., RBA to RDA), it always deasserts its bus request and then requests the bus again when accessing the next area in memory.

The SONIC provides two methods to acquire the bus for compatibility with National/Intel or Motorola type microprocessors. These two methods are selected by setting the proper level on the BMODE pin.

Figures 5-5 and 5-6 show the National/Intel (BMODE = 0) and Motorola (BMODE = 1) bus request timing. Descriptions of each mode follows. For both modes, when the SONIC relinquishes the bus, there is an extra holding state (Th) for one bus cycle after the last DMA cycle (T2). This assures that the SONIC does not contend with another bus master after it has released the bus.

#### BMODE = 0

The National/Intel processors require a 2-way handshake using a HOLD REQUEST/HOLD ACKNOWLEDGE protocol (Figure 5-5). When the SONIC needs to access the bus, it issues a HOLD REQUEST (HOLD) to the microprocessor. The microprocessor, responds with a HOLD ACKNOWLEDGE (HLDA) to the SONIC. The SONIC then begins its memory transfers on the bus. As long as the CPU maintains HLDA active, the SONIC continues until it has finished its memory block transfer. The CPU, however, can preempt the SONIC from finishing the block transfer by deasserting HLDA before the SONIC deasserts HOLD. This allows a higher priority device to preempt the SONIC from continuing to use the bus. The SONIC will request the bus again later to complete any operation that it was doing at the time of preemption. The HLDA signal is sampled synchronously by the SONIC at the rising edge of the BSCCK, setup time must be met to ensure proper operation.

As shown in Figure 5-5, the SONIC will assert HOLD to either the falling or rising edge of the bus clock (BSCCK). The default is for HOLD to be asserted on the falling edge. Setting the PH bit in the DCR2 (see Section 4.3.7) causes HOLD to be asserted  $\frac{1}{2}$  bus clock later on the rising edge (shown by the dotted line). Before HOLD is asserted, the SONIC checks the HLDA line. If HLDA is asserted, HOLD will not be asserted until after HLDA has been deasserted first.

**Note:** If HLDA is driven low to preempt the SONIC from the bus while the SONIC is accessing the CAM (LCAM command), the SONIC will get off the bus but will not deassert HOLD even though the status bit will indicate idle state. If HLDA is driven low while the SONIC is accessing descriptor areas (RRA, RDA, TDA), the SONIC will be preempted normally (i.e., get off the bus and deassert HOLD) and the HOLD signal will be reasserted again after one bus clock. If HLDA is driven low while the SONIC is accessing data areas (RBA, TBA), the SONIC will be preempted normally but may not reassert HOLD unless required to do so depending on the threshold condition of the FIFO.

#### BMODE = 1

The Motorola protocol requires a 3-way handshake using a BUS REQUEST, BUS GRANT, and BUS GRANT ACKNOWLEDGE handshake (Figure 5-6). When using this protocol, the SONIC requests the bus by lowering BUS REQUEST ( $\overline{BR}$ ). The CPU responds by issuing BUS GRANT ( $\overline{BG}$ ). Upon receiving  $\overline{BG}$ , the SONIC assures that all devices have relinquished control of the bus before using the bus. The following signals must be deasserted before the SONIC acquires the bus:

- $\overline{BGACK}$
- $\overline{AS}$
- $\overline{DSACK0,1}$
- STERM (Asynchronous Mode Only)

Deasserting  $\overline{BGACK}$  indicates that the previous master has released the bus. Deasserting  $\overline{AS}$  indicates that the previous master has completed its cycle and deasserting  $\overline{DSACK0,1}$  and STERM indicates that the previous slave has terminated its connection to the previous master. The SONIC maintains its mastership of the bus until it deasserts  $\overline{BGACK}$ . It cannot be preempted from the bus.

TL/F/10492-27

## 5.0 Bus Interface (Continued)

FIGURE 5-6. Bus Request Timing BMODE = 1

TL/F/10492-28

### 5.4.2 Block Transfers

The SONIC performs block operations during all bus actions, thereby providing efficient transfers to memory. The block cycle consists of three parts. The first part is the bus acquisition phase, as discussed above, in which the SONIC gains access to the bus. Once it has access of the bus, the SONIC enters the second phase by transferring data to/from its internal FIFOs or registers from/to memory. The SONIC transfers data from its FIFOs in either EXACT BLOCK mode or EMPTY/FILL mode.

**EXACT BLOCK mode:** In this mode the number of words (or long words) transferred during a block transfer is determined by either the Transmit or Receive FIFO thresholds programmed in the Data Configuration Register.

**EMPTY/FILL mode:** In this mode the DMA completely fills the Transmit FIFO during transmission, or completely empties the Receive FIFO during reception. This allows for greater bus latency.

When the SONIC accesses the Descriptor Areas (i.e., RRA, RDA, CDA, and TDA), it transfers data between its registers and memory. All fields which need to be used are accessed in one block operation. Thus, the SONIC performs 4 accesses in the RRA (see Section 3.4.4.2), 7 accesses in the RDA (see Section 3.4.6.1), 2, 3, or 6 accesses in the TDA (see Section 3.5.4) and 4 accesses in the CDA.

### 5.4.3 Bus Status

The SONIC presents three bits of status information on pins S2-S0 which indicate the type of bus operation the SONIC is currently performing (Table 5-2). Bus status is valid at the falling edge of AS or the rising edge of ADS.

TABLE 5-2. Bus Status

S2	S1	S0	Status
1	1	1	The bus is idle. The SONIC is not performing any transfers on the bus.
1	0	1	The Transmit Descriptor Area (TDA) is currently being accessed.
0	0	1	The Transmit Buffer Area (TBA) is currently being read.
0	1	1	The Receive Buffer Area (RBA) is currently being written to. Only data is being written, though, not a Source or Destination address.
0	1	0	The Receive Buffer Area (RBA) is currently being written to. Only the Source or Destination address is being written though.
1	1	0	The Receive Resource Area (RRA) is currently being read.
1	0	0	The Receive Descriptor Area (RDA) is currently being accessed.
0	0	0	The CAM Descriptor Area (CDA) is currently being accessed.

## 5.0 Bus Interface (Continued)

### 5.4.3.1 Bus Status Transitions

When the SONIC acquires the bus, it only transfers data to/from a single area in memory (i.e., TDA, TBA, RDA, RBA, RRA, or CDA). Thus, the bus status pins remain stable for the duration of the block transfer cycle with the following three exceptions: 1) If the SONIC is accessed during a block transfer, S2-S0 indicates bus idle during the register access, then returns to the previous status. 2) If the SONIC finishes writing the Source Address during a block transfer S2-S0 changes from [0,1,0] to [0,1,1]. 3) During an RDA access between the RXpkt.seq\_no and RXpkt.link access, and between the RXpkt.link and RXpkt.in\_use access, S2-S0 will respectively indicate idle [1,1,1] for 2 or 1 bus clocks. Status will be valid on the falling edge of  $\overline{AS}$  or rising edge of  $\overline{ADS}$ .

Figure 5-7 illustrates the SONIC's transitions through memory during the process of transmission and reception. During transmission, the SONIC reads the descriptor information from the TDA and then transmits data of the packet from the TBA. The SONIC moves back and forth between the TDA and TBA until all fragments and packets are transmitted. During reception, the SONIC takes one of two paths. In the first case (path A), when the SONIC detects EOL=0 from the previous reception, it buffers the accepted packet into the RBA, and then writes the descriptor information to the RDA. If the RBA becomes depleted (i.e., RBWC0,1 < EOBC), it moves to the RRA to read a resource descriptor. In the second case (path B), when the SONIC detects EOL=1 from the previous reception, it rereads the

RXpkt.link field to determine if the system has reset the EOL bit since the last reception. If it has, the SONIC buffers the packet as in the first case. Otherwise, it rejects the packet and returns to idle.

### 5.4.4 Bus Mode Compatibility

For compatibility with different microprocessor and bus architectures, the SONIC operates in one of two modes (set by the BMODE pin) called the National/Intel or little endian mode (BMODE tied low) and the Motorola or big endian mode (BMODE tied high). The definitions for several pins change depending on the mode the SONIC is in. Table 5-3 shows these changes. These modes affect both master and slave bus operations with the SONIC.

TABLE 5-3. Bus Mode Compatibility

Pin Name	BMODE = 0 (National/Intel)	BMODE = 1 (Motorola)
$\overline{BR}/\text{HOLD}$	HOLD	$\overline{BR}$
$\overline{BG}/\text{HLDA}$	HLDA	$\overline{BG}$
$\overline{MRW}/\overline{MWR}$	$\overline{MWR}$	$\overline{MRW}$
$\overline{SRW}/\overline{SWR}$	$\overline{SWR}$	$\overline{SRW}$
$\overline{DSACK0}/\overline{RDYi}$	$\overline{RDYi}$	$\overline{DSACK0}$
$\overline{DSACK1}/\overline{RDYo}$	$\overline{RDYo}$	$\overline{DSACK1}$
$\overline{AS}/\overline{ADS}$	$\overline{ADS}$	$\overline{AS}$
$\overline{INT}/\text{INT}$	INT	$\overline{INT}$

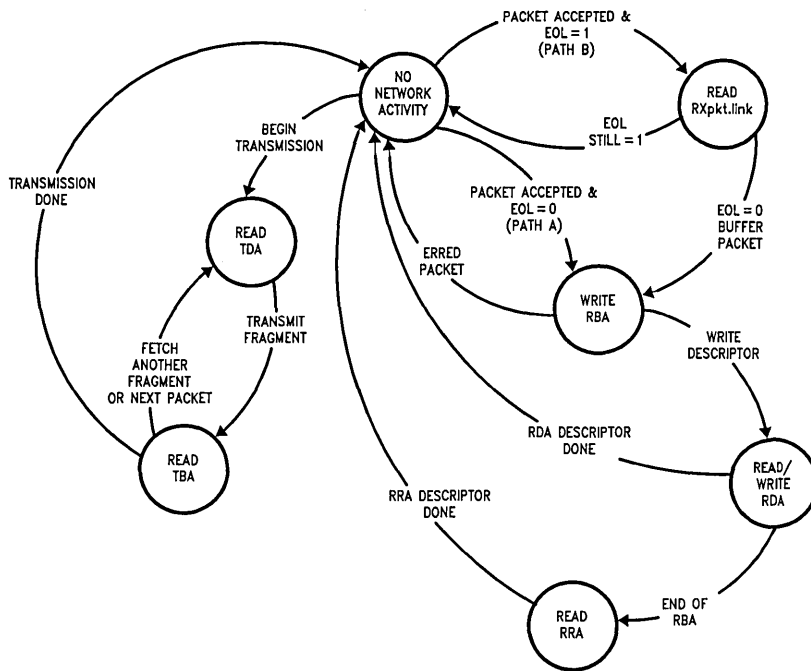

FIGURE 5-7. Bus Status Transitions

TL/F/10492-29

## 5.0 Bus Interface (Continued)

### 5.4.5 Master Mode Bus Cycles

In order to add additional compatibility with different bus architectures, there are two other modes that affect the operation of the bus. These modes are called the synchronous and asynchronous modes and are programmed by setting or resetting the SBUS bit in the Data Configuration Register (DCR). The synchronous and asynchronous modes do not have an effect on slave accesses to the SONIC but they do affect the master mode operation. Within the particular bus/processor mode, synchronous and asynchronous modes are very similar. This section discusses all four modes of operation of the SONIC (National/Intel vs. Motorola, synchronous vs. asynchronous) when it is a bus master.

In this section, the rising edge of T1 and T2 means the beginning of these states, and the falling edge of T1 and T2 means the middle of these states.

#### 5.4.5.1 Adding Wait States

To accommodate different memory speeds, the SONIC provides two methods for adding wait states for its bus operations. Both of these methods can be used individually or in conjunction with each other. A memory cycle is extended by adding additional T2 states. The first method inserts wait-states by withholding the assertion of  $\overline{DSACK0,1}$ / $\overline{STERM}$  or  $\overline{RDYi}$ . The other method allows software to program wait-states. Programming the WC0, WC1 bits in the Data Configuration Register allows 1 to 3 wait-states to be added on each memory cycle. These wait states are inserted between the T1 and T2 bus states and are called T2(wait) bus states. The SONIC will not look at the  $\overline{DSACK0,1}$ ,  $\overline{STERM}$  or  $\overline{RDYi}$  lines until the programmed wait states have passed. Hence,

in order to complete a bus operation that includes programmed wait states, the  $\overline{DSACK0,1}$ ,  $\overline{STERM}$  or  $\overline{RDYi}$  lines must be asserted at their proper times at the end of the cycle during the last T2, not during a programmed wait state. The only exception to this is asynchronous mode where  $\overline{DSACK0,1}$  or  $\overline{RDYi}$  would be asserted during the last programmed wait state, T2 (wait). See the timing for these signals in the timing diagrams for more specific information. Programmed wait states do not affect Slave Mode bus cycles.

#### 5.4.5.2 Memory Cycle for BMODE = 1, Synchronous Mode

On the rising edge of T1, the SONIC asserts  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe (MRW) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC deasserts  $\overline{ECS}$  and asserts  $\overline{AS}$ .

In synchronous mode,  $\overline{DSACK0,1}$  are sampled on the rising edge of T2. T2 states will be repeated until  $\overline{DSACK0,1}$  are sampled properly in a low state.  $\overline{DSACK0,1}$  must meet the setup and hold times with respect to the rising edge of bus clock for proper operation.

During read cycles (*Figure 5-8*) data (D31-D0) is latched at the falling edge of T2 and  $\overline{DS}$  is asserted at the falling edge of T1. For write cycles (*Figure 5-9*) data is driven on the rising edge of T1. If there are wait states inserted,  $\overline{DS}$  is asserted on the falling edge of T2.  $\overline{DS}$  is not asserted for zero wait state write cycles. The SONIC terminates the memory cycle by deasserting  $\overline{AS}$  and  $\overline{DS}$  at the falling edge of T2.

## 5.0 Bus Interface (Continued)

FIGURE 5-8. Memory Read, BMODE = 1, Synchronous (1 Wait-State)

TL/F/10492-31

FIGURE 5-9. Memory Write, BMODE = 1, Synchronous (1 Wait-State)

TL/F/10492-33

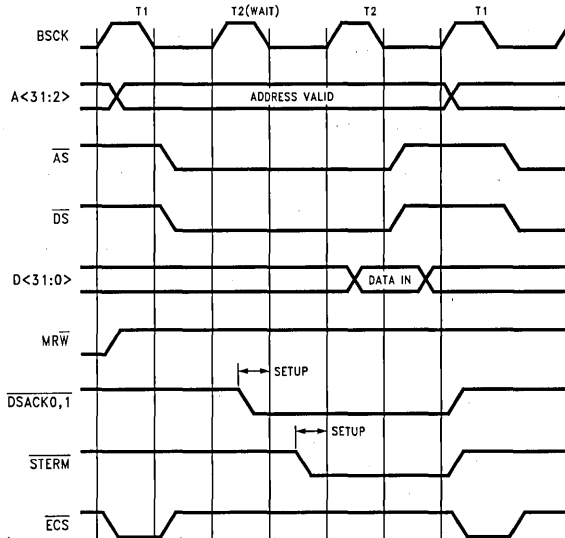

## 5.0 Bus Interface (Continued)

### 5.4.5.3 Memory Cycle for BMODE = 1, Asynchronous Mode

On the rising edge of T1, the SONIC asserts  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe (MRW) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC deasserts  $\overline{ECS}$  and asserts  $\overline{AS}$ .

In asynchronous mode,  $\overline{DSACK0,1}$  are asynchronously sampled on the falling edge of both T1 and T2.  $\overline{DSACK0,1}$

do not need to be synchronized to the bus clock because the chip always resolves these signals to either a high or low state. If a synchronous termination of the bus cycle is required, however,  $\overline{STERM}$  may be used.  $\overline{STERM}$  is sampled on the rising edge of T2 and must meet the setup and hold times with respect to that edge for proper operation. Meeting the setup time for  $\overline{DSACK0,1}$  or  $\overline{STERM}$  guarantees that the SONIC will terminate the memory cycle 1.5

TL/F/10492-36

FIGURE 5-10. Memory Read, BMODE = 1, Asynchronous (1 Wait-State)

TL/F/10492-37

FIGURE 5-11. Memory Read, BMODE = 1, Asynchronous (2 Wait-State)

## 5.0 Bus Interface (Continued)

bus clocks after  $\overline{DSACK0,1}$  were sampled, or 1 cycle after  $\overline{STERM}$  was sampled. T2 states will be repeated until  $\overline{DSACK0,1}$  or  $\overline{STERM}$  are sampled properly in a low state (see note below).

During read cycles (Figures 5-10 and 5-11), data (D31:0) is latched at the falling edge of T2 and  $\overline{DS}$  is asserted at the falling edge of T1. For write cycles (Figures 5-12 and 5-13) data is driven on the rising edge of T1. If there are wait

states inserted,  $\overline{DS}$  is asserted on the falling edge of the first T2 (wait).  $\overline{DS}$  is not asserted for zero wait state write cycles. The  $\overline{SONIC}$  terminates the memory cycle by deasserting  $\overline{AS}$  and  $\overline{DS}$  at the falling edge of T2.

**Note:** If the setup time for  $\overline{DSACK0,1}$  is met during T1, or the setup time for  $\overline{STERM}$  is met during the first T2, the full asynchronous bus cycle will take only 2 bus clocks. This may be an unwanted situation. If so,  $\overline{DSACK0,1}$  and  $\overline{STERM}$  should normally be deasserted during T1 and the start of T2 respectively.

FIGURE 5-12. Memory Write, BMODE = 1, Asynchronous (1 Wait-State)

TL/F/10492-34

FIGURE 5-13. Memory Write, BMODE = 1, Asynchronous (2 Wait-State)

TL/F/10492-35

## 5.0 Bus Interface (Continued)

### 5.4.5.4 Memory Cycle for BMODE = 0, Synchronous Mode

On the rising edge of T1, the SONIC asserts  $\overline{ADS}$  and  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe ( $\overline{MWR}$ ) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC deasserts  $\overline{ECS}$ .  $\overline{ADS}$  is deasserted on the rising edge of T2.

In Synchronous mode,  $\overline{RDYi}$  is sampled on the rising edge at the end of T2 (the rising edge of the next T1). T2 states will be repeated until  $\overline{RDYi}$  is sampled properly in a low state.  $\overline{RDYi}$  must meet the setup and hold times with respect to the rising edge of bus clock for proper operation. During read cycles (Figure 5-14), data (D31-D0) is latched at the rising edge at the end of T2. For write cycles (Figure 5-15) data is driven on the rising edge of T1 and stays driven until the end of the cycle.

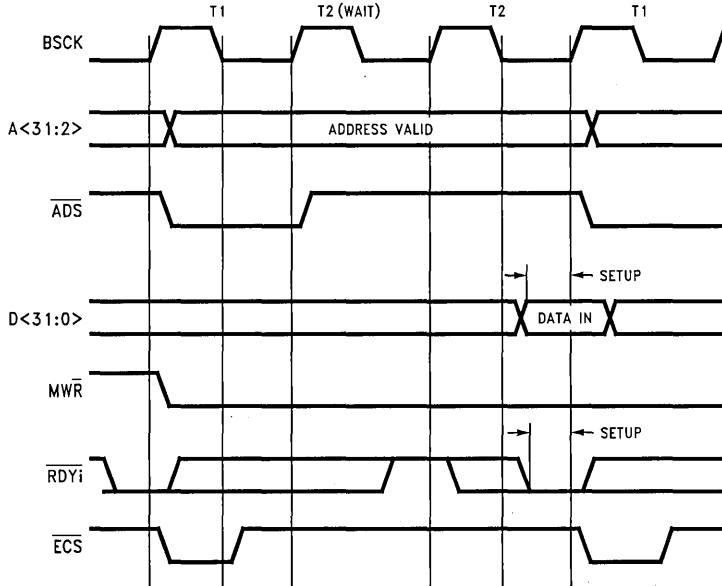

FIGURE 5-14. Memory Read, BMODE=0, Synchronous (1 Wait-State)

TL/F/10492-38

FIGURE 5-15. Memory Write, BMODE=0, Synchronous (1 Wait-State)

TL/F/10492-40

## 5.0 Bus Interface (Continued)

### 5.4.5.5 Memory Cycle for BMODE = 0, Asynchronous Mode

On the rising edge of T1, the SONIC asserts  $\overline{ADS}$  and  $\overline{ECS}$  to indicate that the memory cycle is starting. The address (A31-A1), bus status (S2-S0) and the direction strobe ( $\overline{MWR}$ ) are driven and do not change for the remainder of the memory cycle. On the falling edge of T1, the SONIC deasserts  $\overline{ECS}$ .  $\overline{ADS}$  is deasserted on the rising edge of T2.

In Asynchronous mode,  $\overline{RDYi}$  is asynchronously sampled on the falling edge of both T1 and T2.  $\overline{RDYi}$  does not need to be synchronized to the bus clock because the chip always resolves these signals to either a high or low state. Meeting the setup time for  $\overline{RDYi}$  guarantees that the SONIC will terminate the memory cycle 1.5 bus clocks after  $\overline{RDYi}$  was sampled. T2 states will be repeated until  $\overline{RDYi}$  is sampled properly in a low state (see note on following page).

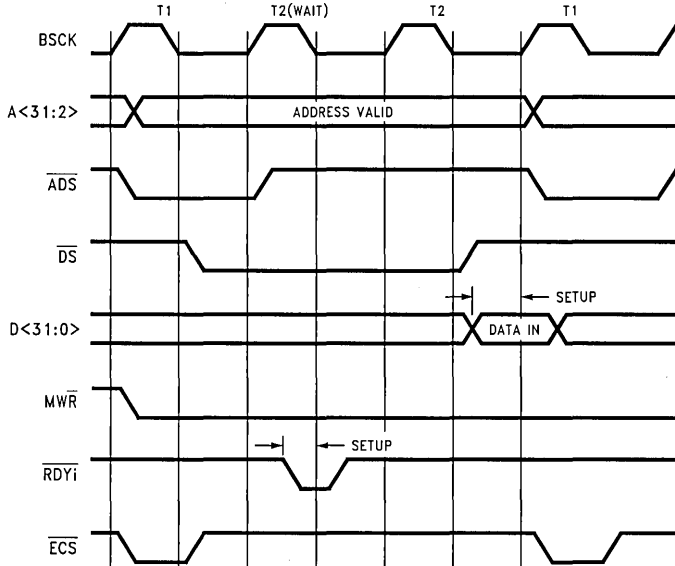

FIGURE 5-16. Memory Read, BMODE = 0, Asynchronous (1 Wait-State)

TL/F/10492-44

FIGURE 5-17. Memory Read, BMODE = 0, Asynchronous (2 Wait-State)

TL/F/10492-45

## 5.0 Bus Interface (Continued)

During read cycles (*Figures 5-16 and 5-17*), data (D31-D0) is latched on the rising edge at the end of T2 and  $\overline{DS}$  is asserted at the falling edge of T1. For write cycles (*Figures 5-18 and 5-19*) data is driven on the rising edge of T1. If there are wait states inserted,  $\overline{DS}$  is asserted on the falling edge of the first T2(wait).  $\overline{DS}$  is not asserted for zero wait state write cycles. The SONIC terminates the memory cycle by deasserting  $\overline{DS}$  at the falling edge of T2.

**Note:** If the setup time for  $\overline{RDYi}$  is met during T1, the full asynchronous bus cycle will take only 2 bus clocks. This may be an unwanted situation. If so,  $\overline{RDYi}$  should be deasserted during T1.

### 5.4.6 Bus Exceptions (Bus Retry)

The SONIC provides the capability of handling errors during the execution of the bus cycle (*Figure 5-20*).

The system asserts  $\overline{BRT}$  (bus retry) to force the SONIC to repeat the current memory cycle. When the SONIC detects the assertion of  $\overline{BRT}$ , it completes the memory cycle at the end of T2 and gets off the bus by deasserting  $\overline{BGACK}$  or HOLD. Then, if Latched Bus Retry mode is not set (LBR in the Data Configuration Register, Section 4.3.2), the SONIC requests the bus again to retry the same memory cycle. If

FIGURE 5-18. Memory Write, BMODE=0, Asynchronous (1 Wait-State)

TL/F/10492-42

FIGURE 5-19. Memory Write, BMODE=0, Asynchronous (2 Wait-State)

TL/F/10492-43

## 5.0 Bus Interface (Continued)

FIGURE 5-20. Bus Exception (Bus Retry)

TL/F/10492-46

Latched Bus Retry is set though, the SONIC will not retry until the BR bit in the ISR (see Section 4.3.6) has been reset and  $\overline{\text{BRT}}$  is deasserted.  $\overline{\text{BRT}}$  has precedence of terminating a memory cycle over  $\overline{\text{DSACK0,1}}$ ,  $\overline{\text{STERM}}$  or  $\overline{\text{RDYi}}$ .

$\overline{\text{BRT}}$  may be sampled synchronously or asynchronously by setting the EXBUS bit in the DCR (see Section 4.3.2). If synchronous Bus Retry is set,  $\overline{\text{BRT}}$  is sampled on the rising edge of T2. If asynchronous Bus Retry is set,  $\overline{\text{BRT}}$  is double synchronized from the falling edge of T1. The asynchronous setup time does not need to be met, but doing so will guarantee that the bus exception will occur in the current bus cycle instead of the next bus cycle. Asynchronous Bus Retry may only be used when the SONIC is set to asynchronous mode.

**Note 1:** The deassertion edge of HOLD is dependent on the PH bit in the DCR2 (see Section 4.3.7). Also,  $\overline{\text{BGACK}}$  is driven high for about 1/2 bus clock before going TRI-STATE.

**Note 2:** If Latched Bus Retry is set,  $\overline{\text{BRT}}$  need only satisfy its setup time (the hold time is not important). Otherwise,  $\overline{\text{BRT}}$  must remain asserted until after the Th state.

**Note 3:** If  $\overline{\text{DSACK0,1}}$ ,  $\overline{\text{STERM}}$  or  $\overline{\text{RDYi}}$  remain asserted after  $\overline{\text{BRT}}$ , the next memory cycle may be adversely affected.

### 5.4.7 Slave Mode Bus Cycle

The SONIC's internal registers can be accessed by one of two methods (BMODE = 1 or BMODE = 0). In both methods, the SONIC is a slave on the bus. This section describes the SONIC's slave mode bus operations.

#### 5.4.7.1 Slave Cycle for BMODE = 1

The system accesses the SONIC by driving  $\overline{\text{SAS}}$ ,  $\overline{\text{CS}}$ ,  $\overline{\text{SRW}}$  and RA<5:0>. SONIC will start a slave cycle once  $\overline{\text{CS}}$  and  $\overline{\text{SAS}}$  are asserted properly. SONIC samples  $\overline{\text{CS}}$  asynchronously at the falling edge of each BSCCK.  $\overline{\text{SAS}}$  signal can be asserted anytime as long as it is before the next falling edge of the clock that the  $\overline{\text{CS}}$  is sampled on.

The register address RA<5:0> and the read/write signal  $\overline{\text{SRW}}$  will be latched by the SONIC on the falling edge of the  $\overline{\text{SAS}}$  signal. Once  $\overline{\text{SAS}}$  and  $\overline{\text{CS}}$  are asserted,  $\overline{\text{SMACK}}$  will be asserted by the SONIC to signify that the SONIC has started the slave cycle. Although  $\overline{\text{CS}}$  and  $\overline{\text{SAS}}$  are asynchronous inputs, meeting their setup times (as shown in Figures 5-21 and 5-22) will guarantee that  $\overline{\text{SMACK}}$ , which is asserted off

of a falling edge, will be asserted 1 bus clock after the falling edge that  $\overline{\text{CS}}$  was clocked in on. This is assuming that the SONIC is not a bus master when  $\overline{\text{CS}}$  was asserted. If the SONIC is a bus master, then, when  $\overline{\text{CS}}$  is asserted, the SONIC will complete its current master bus cycle and get off the bus temporarily (see Section 5.4.8). In this case,  $\overline{\text{SMACK}}$  will be asserted maximum 5 bus clocks after the falling edge that  $\overline{\text{CS}}$  was clocked in on. This is assuming that there were no wait states in the current master mode access. Wait states will increase the time for  $\overline{\text{SMACK}}$  to go low by the number of wait states in the cycle.

If the slave access is a read cycle (Figure 5-21), then the data will be driven off the same edge as  $\overline{\text{SMACK}}$ . If it is a write cycle (Figure 5-22), then the data will be latched in exactly 2 bus clocks after the assertion of  $\overline{\text{SMACK}}$ . In either case,  $\overline{\text{DSACK0,1}}$  are driven low 2 bus clocks after  $\overline{\text{SMACK}}$  to terminate the slave cycle. For a read cycle, the assertion of  $\overline{\text{DSACK0,1}}$  indicates valid register data and for a write cycle, the assertion indicates that the SONIC has latched the data. The SONIC deasserts  $\overline{\text{DSACK0,1}}$  at the rising edge of  $\overline{\text{SAS}}$  or  $\overline{\text{CS}}$  depending on which is deasserted first. The data bus is deasserted on the rising edge of  $\overline{\text{SAS}}$ . The SONIC deasserts  $\overline{\text{SMACK}}$  and causes  $\overline{\text{DSACK0,1}}$  to become TRI-STATE on the falling edge of the BSCCK that  $\overline{\text{SAS}}$  was sampled high on.

**Note 1:** Although the SONIC responds as a 32-bit peripheral when it drives both  $\overline{\text{DSACK0}}$  and  $\overline{\text{DSACK1}}$  low, it transfers data only on lines D<15:0>.

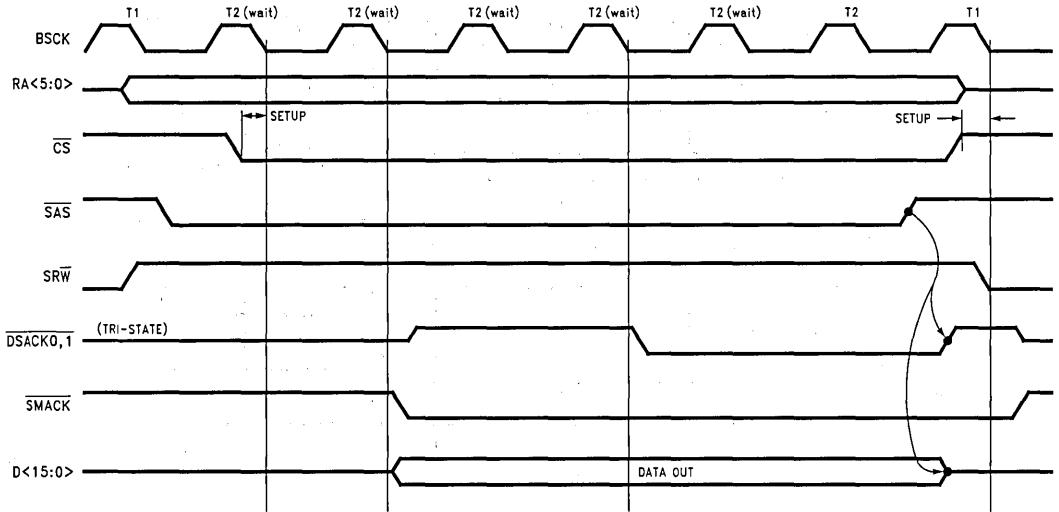

**Note 2:** For multiple register accesses,  $\overline{\text{CS}}$  can be held low and  $\overline{\text{SAS}}$  can be used to delimit the slave cycle. In this case,  $\overline{\text{SMACK}}$  will be driven low due to  $\overline{\text{SAS}}$  going low since  $\overline{\text{CS}}$  has already been asserted. Notice that this means  $\overline{\text{SMACK}}$  will not stay asserted low during the entire time  $\overline{\text{CS}}$  is low (as is the case for  $\overline{\text{MREQ}}$ , Section 5.4.8).

**Note 3:** If memory request ( $\overline{\text{MREQ}}$ ) follows a chip select ( $\overline{\text{CS}}$ ), it must be asserted at least 2 bus clocks after  $\overline{\text{CS}}$  is deasserted. Both  $\overline{\text{CS}}$  and  $\overline{\text{MREQ}}$  must not be asserted concurrently.

**Note 4:** When  $\overline{\text{CS}}$  is deasserted, it must remain deasserted for at least one bus clock.

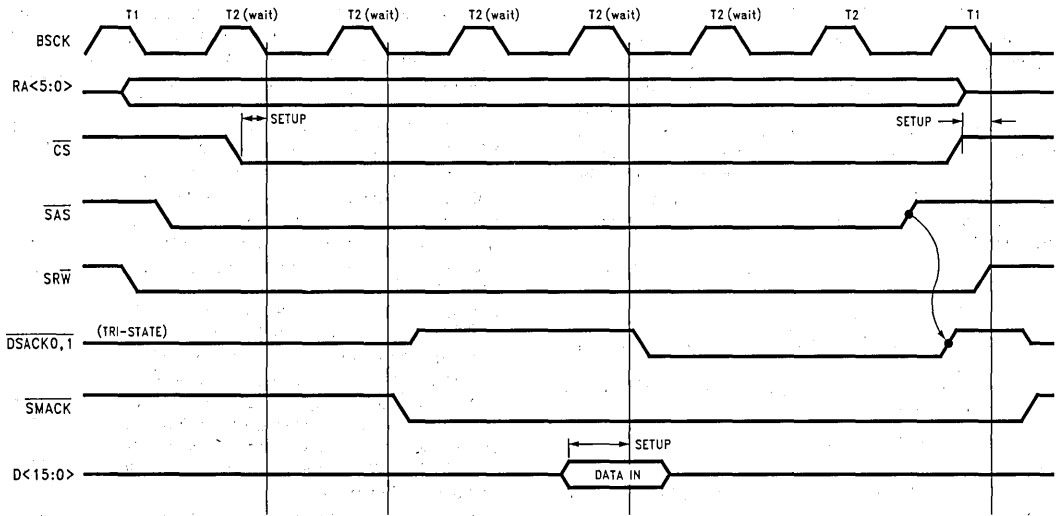

**Note 5:** The way in which  $\overline{\text{SMACK}}$  is asserted due to  $\overline{\text{CS}}$  is not the same as the way in which  $\overline{\text{SMACK}}$  is asserted due to  $\overline{\text{MREQ}}$ . The assertion of  $\overline{\text{SMACK}}$  is dependent upon both  $\overline{\text{CS}}$  and  $\overline{\text{SAS}}$  being low, not just  $\overline{\text{CS}}$ . This is not the same as the case for  $\overline{\text{MREQ}}$  (see Section 5.4.8). The assertion of  $\overline{\text{SMACK}}$  in these two cases should not be confused.

FIGURE 5-22. Register Write, BMODE = 1

## 5.0 Bus Interface (Continued)

### 5.4.7.2 Slave Cycle for BMODE = 0

The system accesses the SONIC by driving  $\overline{SAS}$ ,  $\overline{CS}$ ,  $\overline{SWR}$  and  $RA <5:0>$ . SONIC will start a slave cycle once  $\overline{CS}$  and  $\overline{SAS}$  are asserted properly. SONIC samples  $\overline{CS}$  asynchronously at the falling edge of each BCLK.  $\overline{SAS}$  signal may be asserted low anytime before or simultaneously to the falling edge of the  $\overline{CS}$  and the deassertion of  $\overline{SAS}$  will start the slave cycle.  $\overline{CS}$  should not be asserted low before the falling edge of  $\overline{SAS}$  as this will cause improper slave operation. The register address  $RA <5:0>$  and the read/write signal  $\overline{SWR}$  will be latched by the SONIC on the rising edge of the  $\overline{SAS}$  signal. Once  $\overline{CS}$  is asserted and  $\overline{SAS}$  is deasserted,  $\overline{SMACK}$  will be asserted by the SONIC to signify that the SONIC has started the slave cycle. Although  $\overline{CS}$  and  $\overline{SAS}$  are asynchronous inputs, meeting their setup times (as shown in Figures 5-23 and 5-24) will guarantee that  $\overline{SMACK}$ , which is asserted off a falling edge, will be asserted on the falling edge of the BCLK and  $\overline{SAS}$  was sampled high on. This is assuming that the SONIC is not a bus master when  $\overline{CS}$  is asserted. If the SONIC is a bus master, then, when  $\overline{CS}$  is asserted, the SONIC will complete its current master bus cycle and get off the bus temporarily (see Section 5.4.8). In this case,  $\overline{SMACK}$  will be asserted maximum 4 bus clocks after the falling edge of BCLK that  $\overline{SAS}$  was sampled high on. This is assuming that there were no wait states in the current master mode access. Wait states will increase the time for  $\overline{SMACK}$  to go low by the number of wait states in the cycle.

If the slave access is a read cycle (Figure 5-23), then the data will be driven off the same edge as  $\overline{SMACK}$ . If it is a write cycle (Figure 5-24), then the data will be latched in exactly 2 bus clocks after the assertion of  $\overline{SMACK}$ . In either case,  $\overline{RDY}_0$  is driven low 2.5 bus clocks after  $\overline{SMACK}$  to terminate the slave cycle. For a read cycle, the assertion of  $\overline{RDY}_0$  indicates valid register data and for a write cycle, the assertion indicates that the SONIC has latched the data. The SONIC deasserts  $\overline{RDY}_0$ ,  $\overline{SMACK}$  and the data if the cycle is a read cycle at the falling edge of  $\overline{SAS}$  or the rising edge of  $\overline{CS}$  depending on which is first.

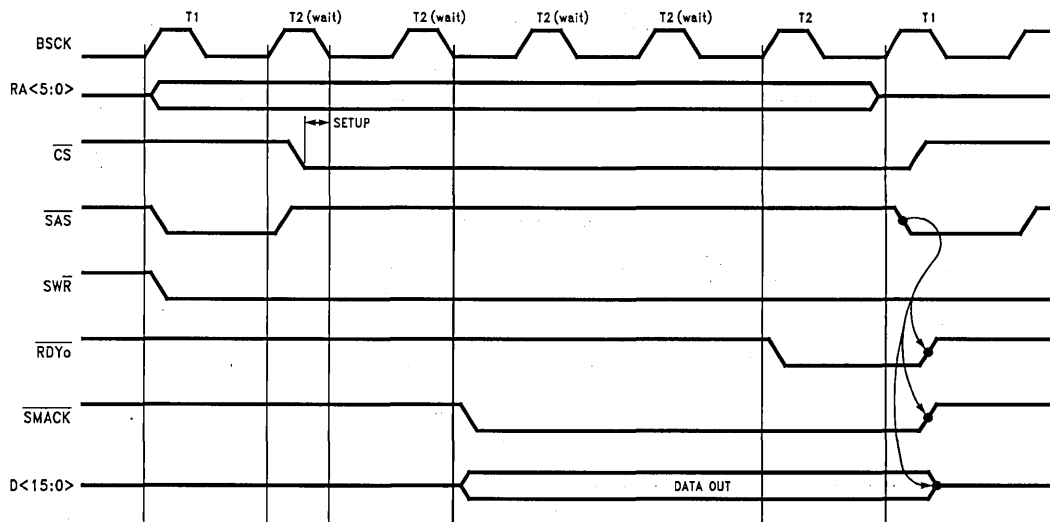

**Note 1:** The SONIC transfers data only on lines  $D <15:0>$  during slave mode accesses.

**Note 2:** For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle (this is the only case where  $\overline{CS}$  may be asserted before  $\overline{SAS}$ ). In this case,  $\overline{SMACK}$  will be driven low due to  $\overline{SAS}$  going high since  $\overline{CS}$  has already been asserted. Notice that this means  $\overline{SMACK}$  will not stay asserted low during the entire time  $\overline{CS}$  is low (as is the case for  $\overline{MREQ}$ , see Section 5.4.8).

**Note 3:** If memory request ( $\overline{MREQ}$ ) follows a chip select  $\overline{CS}$ , it must be asserted at least 2 bus clocks after  $\overline{CS}$  is deasserted. Both  $\overline{CS}$  and  $\overline{MREQ}$  must not be asserted concurrently.

**Note 4:** When  $\overline{CS}$  is deasserted, it must remain deasserted for at least one bus clock.

**Note 5:** The way in which  $\overline{SMACK}$  is asserted due to  $\overline{CS}$  is not the same as the way in which  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ . The assertion of  $\overline{SMACK}$  is dependent upon both  $\overline{CS}$  and  $\overline{SAS}$  being low, not just  $\overline{CS}$ . This is not the same as the case for  $\overline{MREQ}$  (see Section 5.4.8). The assertion of  $\overline{SMACK}$  in these two cases should not be confused.

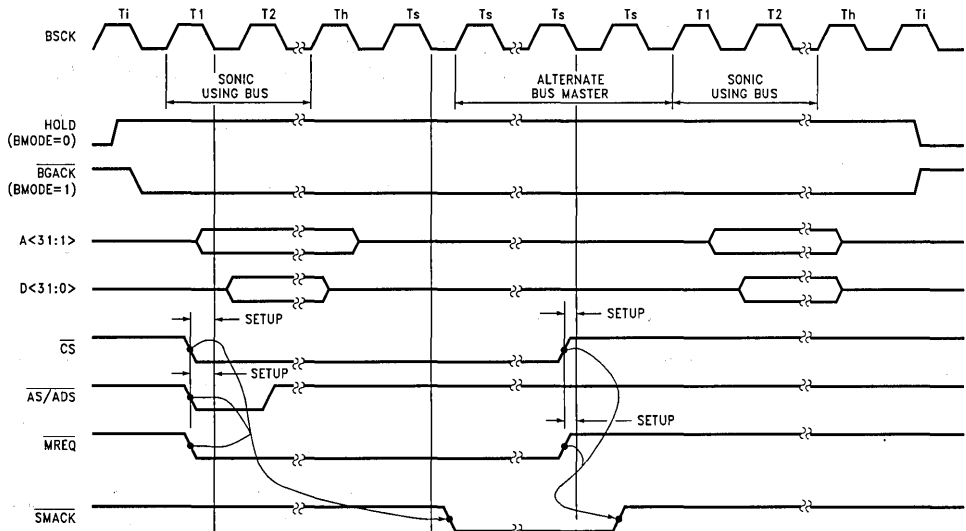

FIGURE 5-25. On-Chip Memory Arbitration

TL/F/10492-51

## 5.0 Bus Interface (Continued)

### 5.4.8 On-Chip Memory Arbiter

For applications which share the buffer memory area with the host system (shared-memory applications), the SONIC provides a fast on-chip memory arbiter for efficiently resolving accesses between the SONIC and the host system (Figure 5-25). The host system indicates its intentions to use the shared-memory by asserting Memory Request (MREQ). The SONIC will allow the host system to use the shared memory by acknowledging the host system's request with Slave and Memory Acknowledge (SMACK). Once SMACK is asserted, the host system may use the shared memory freely. The host system gives up the shared memory by deasserting MREQ.

MREQ is clocked in on the falling edge of bus clock and is double synchronized internally to the rising edge. SMACK is asserted on the falling edge of a Ts bus cycle. If the SONIC is not currently accessing the memory, SMACK is asserted immediately after MREQ was clocked in. If, however, the SONIC is accessing the shared memory, it finishes its current memory transfer and then issues SMACK. SMACK will be asserted one bus clock minimum to five bus clocks maximum after MREQ is clocked in. Since MREQ is double synchronized, it is not necessary to meet its setup time. Meeting the setup time for MREQ will, however, guarantee that SMACK is asserted one to five bus clocks after the current bus clock. SMACK will deassert within one bus clock after MREQ is deasserted. The SONIC will then finish its master operation if it was using the bus previously.

If the host system needs to access the SONIC's registers instead of shared memory, CS would be asserted instead of MREQ. Accessing the SONIC's registers works almost exactly the same as accessing the shared memory except that the SONIC goes into a slave cycle instead of going idle. See Section 5.4.7 for more information about how register accesses work.

**Note 1:** The successive assertion of CS and MREQ must be separated by at least two bus clocks. Both CS and MREQ must not be asserted concurrently.

**Note 2:** The number of bus clocks between MREQ being asserted and the assertion of SMACK when the SONIC is in Master Mode is 5 bus clocks assuming there were no wait states in the Master Mode access. Wait states will increase the time for SMACK to go low by the number of wait states in the cycle (the time will be 5 + the number of wait states).

**Note 3:** The way in which SMACK is asserted due to CS is not the same as the way in which SMACK is asserted due to MREQ. SMACK goes low as a direct result of the assertion of MREQ, whereas, for CS, SAS must also be driven low (BMODE = 1) or high (BMODE = 0) before SMACK will be asserted. This means that when SMACK is asserted due to MREQ, SMACK will remain asserted until MREQ is deasserted. Multiple memory accesses can be made to the shared memory without SMACK ever going high. When SMACK is asserted due to CS, however, SMACK will only remain low as long as SAS is also low (BMODE = 1). SMACK will not remain low throughout multiple register accesses to the SONIC because SAS must toggle for each register access. This is an important difference to consider when designing shared memory designs.

**Note 4:** In Motorola mode, if a bus master uses the MREQ to request the bus from the SONIC, care should be taken to isolate the DSACK0,1 from the bus (e.g., use TRI-STATE buffers) because the DSACK0,1 will be driven by the SONIC even after the SONIC has given up the bus.

### 5.4.9 Chip Reset

The SONIC has two reset modes; a hardware reset and a software reset. The SONIC can be hardware reset by asserting the RESET pin or software reset by setting the RST bit in the Command Register (Section 4.3.1). The two reset modes are not interchangeable since each mode performs a different function.

**TABLE 5-4. Internal Register Content after RESET**

Register	Contents after Reset	
	Hardware Reset	Software Reset
Command	0094h	0094h/00A4h
Data Configuration (DCR and DCR2)	*	unchanged
Interrupt Mask	0000h	unchanged
Interrupt Status	0000h	unchanged
Transmit Control	0101h	unchanged
Receive Control	**	unchanged
End Of Buffer Count	02F8h	unchanged
Sequence Counters	0000h	unchanged
CAM Enable	0000h	unchanged

\*Bits 15 and 13 of the DCR and bits 4 through 0 of the DCR2 are reset to a 0 during a hardware reset. Bits 15-12 of the DCR2 are unknown until written to. All other bits in these two registers are unchanged.

\*\*Bits LB1, LB0 and BRD are reset to a 0 during hardware reset. All other bits are unchanged.

After power-on, the SONIC must be hardware reset before it will become operational. This is done by asserting RESET for a minimum of 10 transmit clocks (10 ethernet transmit clock periods, TXC). If the bus clock (BSCK) period is greater than the transmit clock period, RESET should be asserted for 10 bus clocks instead of 10 transmit clocks. A hardware reset places the SONIC in the following state. (The registers affected are listed in parenthesis. See Table 5-4 and Section 4.3 for more specific information about the registers and how they are affected by a hardware reset. Only those registers listed below and in Table 5-4 are affected by a hardware reset.)

1. Receiver and Transmitter are disabled (CR).
2. The General Purpose timer is halted (CR).
3. All interrupts are masked out (IMR).
4. The NCRS and PTX status bits in the Transmit Control Register (TCR) are set.
5. The End Of Byte Count (EOBC) register is set to 02F8h (760 words).
6. Packet and buffer sequence number counters are set to zero.
7. All CAM entries are disabled. The broadcast address is also disabled (CAM Enable Register and the RCR).
8. Loopback operation is disabled (RCR).
9. The latched bus retry is set to the unlatched mode (DCR).
10. All interrupt status bits are reset (ISR).
11. The Extended Bus Mode is disabled (DCR).
12. HOLD will be asserted/deasserted from the falling clock edge (DCR2).

### 5.0 Bus Interface (Continued)

- 13. Latched Ready Mode is disabled (DCR2).
- 14. PCOMP will not be asserted (DCR2).
- 15. Packets will be accepted (not rejected) on CAM match (DCR2).

A software reset immediately terminates DMA operations and future interrupts. The chip is put into an idle state where registers can be accessed, but the SONIC will not be active in any other way. The registers are affected by a software reset as shown in Table 5-4 (only the Command Register is changed).

### 6.0 Network Interfacing

The SONIC contains an on-chip ENDEC that performs the network interfacing between the AUI (Attachment Unit Interface) and the SONIC's MAC unit. A pin selectable option allows the internal ENDEC to be disabled and the MAC/

ENDEC signals to be supplied to the user for connection to an external ENDEC. If the EXT pin is tied to ground (EXT=0) the internal ENDEC is selected and if EXT is tied to V<sub>CC</sub> (EXT=1) the external ENDEC option is selected.

**Internal ENDEC:** When the internal ENDEC is used (EXT=0) the interface signals between the ENDEC and MAC unit are internally connected. While these signals are used internally by the SONIC they are also provided as an output to the user (Figure 6-1).

The internal ENDEC allows for a 2-chip solution for the complete Ethernet interface. Figure 6-2 shows a typical diagram of the network interface.

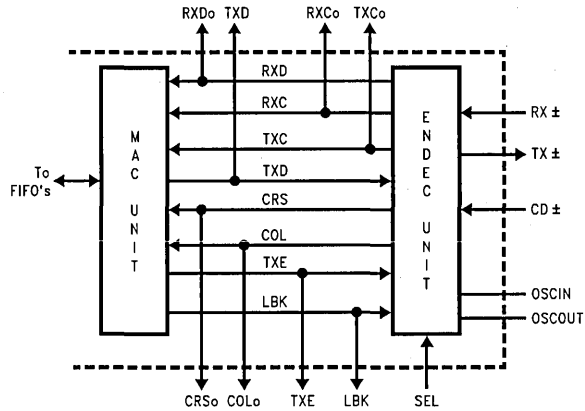

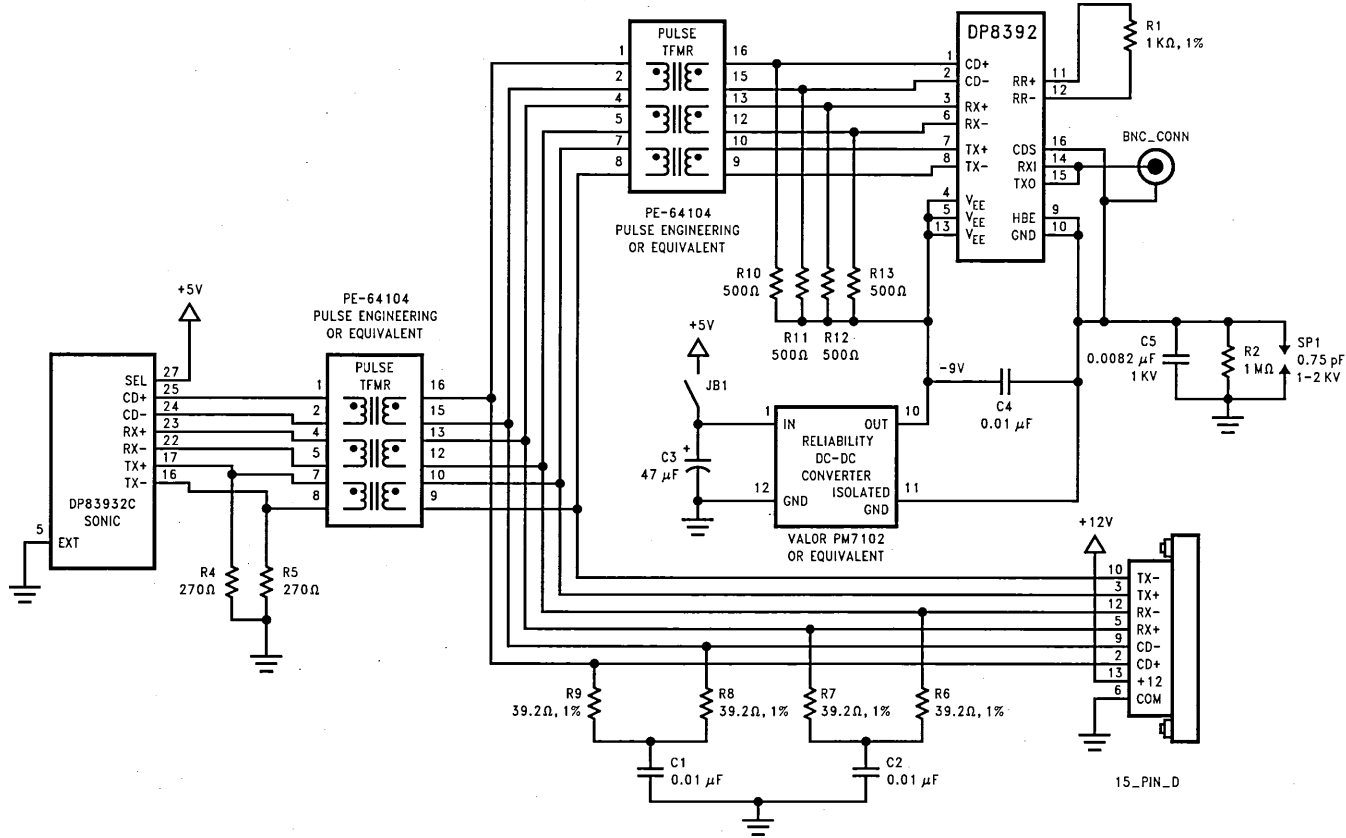

FIGURE 6-1. MAC and Internal ENDEC Interface Signals

TL/F/10492-52

Note: When using BNC-CONN only, R10 to R13 should be 1.5 kΩ each

FIGURE 6-2. Network Interface Example (EXT = 0), using a single jumper, JB1, for network interface selection

TL/F/10492-53

## 6.0 Network Interfacing (Continued)

**External ENDEC:** When EXT = 1 the internal ENDEC is bypassed and the signals are provided directly to the user. Since SONIC's on-chip ENDEC is the same as National's DP83910 Serial Network Interface (SNI) the interface considerations discussed in this section would also apply to using this device in the external ENDEC mode.

### 6.1 MANCHESTER ENCODER AND DIFFERENTIAL DRIVER

The ENDEC unit's encoder begins operation when the MAC section begins sending the serial data stream. It converts NRZ data from the MAC section to Manchester data for the differential drivers (TX+ / -). In Manchester encoding, the first half of the bit cell contains the complementary data and the second half contains the true data (Figure 6-3). A transition always occurs at the middle of the bit cell. As long as the MAC continues sending data, the ENDEC section remains in operation. At the end of transmission, the last transition is always positive, occurring at the center of the bit cell if the last bit is a one, or at the end of the bit cell if the last bit is a zero.

The differential transmit pair drives up to 50 meters of twisted pair AUI cable. These outputs are source followers which require two 270 $\Omega$  pull-down resistors to ground. In addition, a pulse transformer is required between the transmit pair output and the AUI interface.

The driver allows both half-step and full-step modes for compatibility with Ethernet and IEEE 802.3. When the SEL pin is tied to ground (for Ethernet), TX+ is positive with respect to TX- during idle on the primary side of the isolation transformer (Figure 6-2). When SEL is tied to V<sub>CC</sub> (for IEEE 802.3), TX+ and TX- are equal in the idle state.

FIGURE 6.3. Manchester Encoded Data Stream

#### 6.1.1 Manchester Decoder

The decoder consists of a differential receiver and a phase lock loop (PLL) to separate the Manchester encoded data stream into clock signals and NRZ data. The differential input must be externally terminated with two 39 $\Omega$  resistors connected in series. In addition, a pulse transformer is required between the receive input pair and the AUI interface. To prevent noise from falsely triggering the decoder, a squelch circuit at the input rejects signals with a magnitude less than -175 mV. Signals more negative than -300 mV are decoded.

Once the input exceeds the squelch requirements, the decoder begins operation. The decoder detects the end of a frame within one and a half bit times after the last bit of data.

#### 6.1.2 Collision Translator

When the Ethernet transceiver (DP8392 CTI) detects a collision, it generates a 10 MHz signal to the differential collision inputs (CD+ and CD-) of the SONIC. When SONIC detects these inputs active, its Collision translator converts the 10 MHz signal to an active collision signal to the MAC section. This signal causes SONIC to abort its current transmission and reschedule another transmission attempt.

The collision differential inputs are terminated the same way as the differential receive inputs and a pulse transformer is required between the collision input pair and the AUI interface. The squelch circuitry is also similar, rejecting pulses with magnitudes less than -175 mV.

#### 6.1.3 Oscillator Inputs

The oscillator inputs to the SONIC (OSCIN and OSCOUT) can be driven with a parallel resonant crystal or an external clock. In either case the oscillator inputs must be driven with a 20 MHz signal. The signal is divided by 2 to generate the 10 MHz transmit clock (TXC) for the MAC unit. The oscillator also provides internal clock signals for the encoding and decoding circuits.

##### 6.1.3.1 External Crystal

According to the IEEE 802.3 standard, the transmit clock (TXC) must be accurate to 0.01%. This means that the oscillator circuit, which includes the crystal and other parts involved must be accurate to 0.01% after the clock has been divided in half. Hence, when using a crystal, it is necessary to consider all aspects of the crystal circuit. An example of a recommended crystal circuit is shown in Figure 6-4 and suggested crystal specifications are shown in Table 6-1.

The load capacitors in Figure 6-4, C1 and C2, should be no greater than 36 pF each, including all stray capacitance (see note 2 below). The resistor, R1, may be required in order to minimize frequency drift due to changes in V<sub>CC</sub>. If R1 is required, its value must be carefully selected since R1 decreases the loop gain. If R1 is made too large, the loop gain will be greatly reduced and the crystal will not oscillate. If R1 is made too small, normal variations in V<sub>CC</sub> may cause the oscillation frequency to drift out of specification. As a first rule of thumb, the value of R1 should be made equal to five times the motional resistance of the crystal. The motional resistance of 20 MHz crystals is usually in the range of 10 $\Omega$  to 30 $\Omega$ . This implies that reasonable values for R1 should be in the range of 50 $\Omega$  to 150 $\Omega$ . The decision of whether or not to include R1 should be based upon measured variations of crystal frequency as each of the circuit parameters are varied.

## 6.0 Network Interfacing (Continued)

TL/F/10492-81

**FIGURE 6.4. Crystal Connection to the SONIC** (see text)

**Note 1:** The OSCOUT pin is not guaranteed to provide a TTL compatible logic output, and should not be used to drive any external logic. If additional logic needs to be driven, then an external oscillator should be used as described in the following section.

**Note 2:** The frequency marked on the crystal is usually measured with a fixed load capacitance specified in the crystal's data sheet. The actual load capacitance used should be the specified value minus the stray capacitance.

**TABLE 6-1. Crystal Specifications**

Resonant frequency	20 MHz
Tolerance (see text)	0.01% at 25°C
Accuracy	0.005% (50 ppm) at 0 to 70°C
Fundamental Mode Series Resistance	≤25Ω
Specified Load Capacitance	≤18 pF
Type	AT cut
Circuit	Parallel Resonance

### 6.1.3.2 Clock Oscillator Module

The SONIC also allows for an external clock oscillator to be used. The connection configuration is shown in *Figure 6.5*. This connection requires an oscillator with the following specifications:

1. TTL or CMOS output with a 0.01% frequency tolerance
2. 40%–60% duty cycle (50% duty cycle preferred)
3. One CMOS loads output drive

The above assumes no other circuitry is driven. In this configuration, the OSCOUT pin must be left open.

TL/F/10492-83

**FIGURE 6.5. Oscillator Module Connection to the SONIC**

### 6.1.3.3 PCB Layout Considerations

Care should be taken when connecting a crystal. Stray capacitance (e.g., from PC board traces and plated through holes around the OSCIN and OSCOUT pins) can shift the crystal's frequency out of range, causing the transmitted frequency to exceed the 0.01% tolerance specified by IEEE. The layout considerations for using an external crystal are rather straightforward. The oscillator layout should locate all components close to the OSCIN and OSCOUT pins and should use short traces that avoid excess capacitance and inductance. A solid ground should be used to connect the ground legs of the two capacitors.

When connecting an external oscillator, the only considerations are to keep the oscillator module as close to the SONIC as possible to reduce stray capacitance and inductance and to give the module a clean V<sub>CC</sub> and a solid ground.

### 6.1.4 Power Supply Considerations

In general, power supply routing and design for the SONIC need only follow standard practices. In some situations, however, additional care may be necessary in the layout of the analog supply. Specifically, special care may be needed for the TXVCC, RXVCC and PLLVCC power supplies and the TXGND and ANGND. In most cases the analog and digital power supplies can be interconnected. However, to ensure optimum performance of the SONIC's analog functions, power supply noise should be minimized. To reduce analog supply noise, any of several techniques can be used.

1. Route analog supplies as a separate set of traces or planes from the digital supplies with their own decoupling capacitors.
2. Provide noise filtering on the analog supply pins by inserting a low pass filter. Alternatively, a ferrite bead could be used to reduce high frequency power supply noise.
3. Utilize a separate regulator to generate the analog supply.

The PLLV<sub>CC</sub> pin is the +5V power supply for the phase lock loop (PLL) of the SONIC ENDEC unit. Since this is an analog circuit, excessive noise on the PLLV<sub>CC</sub> pin can affect the performance of the PLL. This noise, if in the 10 kHz to 400 kHz range, can reduce the jitter performance of the ENDEC, resulting in missing packets or CRC errors. If the power supply noise is causing significant packet reception error, a low pass filter could be added to reduce the power supply noise and hence improve the jitter performance. Standard analog design techniques should be utilized when laying out the power supply traces on the board. If the digital power supply is used, it may be desirable to add a one pole RC filter (designed to have a cut-off frequency of 1 kHz) as shown in *Figure 6.6* to improve the jitter performance. The PLLV<sub>CC</sub> only draws 3 mA–4 mA so the voltage across the resistor is less than 90 mV, which will not affect the PLL's operation.

TL/F/10492-87

## 7.0 AC and DC Specifications

### Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage ( $V_{CC}$ )	-0.5V to 7.0V
DC Input Voltage ( $V_{IN}$ )	-0.5V to $V_{CC} + 0.5V$
DC Output Voltage ( $V_{OUT}$ )	-0.5V to $V_{CC} + 0.5V$
Storage Temperature Range ( $T_{STG}$ )	-65°C to 150°C
Power Dissipation (PD)	500 mW
Lead Temp. (TL) (Soldering, 10 sec.)	260°C
ESD Rating	
( $R_{ZAP} = 1.5k, C_{ZAP} = 120 pF$ )	1.5 kV

### DC Specifications $T_A = 0^\circ C$ to $70^\circ C$ , $V_{CC} = 5V \pm 5\%$ , unless otherwise specified

Symbol	Parameter	Conditions	Min	Max	Units
$V_{OH}$	Minimum High Level Output Voltage	$I_{OH} = -8 mA$	3.0		V
$V_{OL}$	Maximum Low Level Output Voltage	$I_{OL} = 8 mA$		0.4	V
$V_{IH}$	Minimum High Level Input Voltage		2.0		V
$V_{IL}$	Maximum Low Level Input Voltage			0.8	V
$I_{IN}$	Input Current	$V_{IN} = V_{CC}$ or GND	-1.0	1.0	$\mu A$
$I_{OZ}$	TRI-STATE Output Leakage Current	$V_{OUT} = V_{CC}$ or GND	-10	10	$\mu A$
$I_{CC}$	Average Operating Supply Current	$I_{OUT} = 0 mA$ , Freq = 20 MHz		90	mA
$I_{CC}$	Average Operating Supply Current	$I_{OUT} = 0 mA$ , Freq = 25 MHz		100	mA
$I_{CC}$	Average Operating Supply Current	$I_{OUT} = 0 mA$ , Freq = 33 MHz		115	mA

#### AUI INTERFACE PINS (TX $\pm$ , RX $\pm$ , and CD $\pm$ )

$V_{OD}$	Diff. Output Voltage (TX $\pm$ )	78 $\Omega$ Termination and 270 $\Omega$ from Each to GND	$\pm 550$	$\pm 1200$	mV
$V_{OB}$	Diff. Output Voltage Imbalance (TX $\pm$ )	78 $\Omega$ Termination and 270 $\Omega$ from Each to GND	Typical: 40 mV		
$V_U$	Undershoot Voltage (TX $\pm$ )	78 $\Omega$ Termination and 270 $\Omega$ from Each to GND	Typical: 80 mV		
$V_{DS}$	Diff. Squelch Threshold (RX $\pm$ and CD $\pm$ )		-175	-300	mV

#### OSCILLATOR PINS (OSCIN AND OSCOUT)

$V_{IH}$	OSCIN Input High Voltage	OSCIN is Connected to an Oscillator and OSCOUT is Open	2.0		V
$V_{IL}$	OSCIN Input Low Voltage	OSCIN is Connected to an Oscillator and OSCOUT is Open		0.8	V
$I_{OSC2}$	X2 Input Leakage Current	OSCIN is Connected to an Oscillator and OSCOUT is Open $V_{IN} = V_{CC}$ or GND	-10	10	$\mu A$

## 7.0 AC and DC Specifications (Continued)

### AC Characteristics

#### BUS CLOCK TIMING

TL/F/10492-56

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T1	Bus Clock Low Time	20		16		13.5		ns
T2	Bus Clock High Time	20		16		13.5		ns
T3	Bus Clock Cycle Time	50		40		30		ns

#### POWER-ON RESET

TL/F/10492-57

#### NON POWER-ON RESET

TL/F/10492-58

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T4	USR<1:0> Setup to $\overline{\text{RST}}$	7		6		5		ns
T5	USR<1:0> Hold from $\overline{\text{RST}}$	9		8		7		ns
T6	Power-On Reset Low (Notes 1, 2)			10		10		TXC
T8	Reset Pulse Width (Notes 1, 2)			10		10		TXC

**Note 1:** The reset time is determined by the slower of BSCK or TXC. If BSCK > TXC, T6 and T8 equal 10 TXCs. If BSCK < TXC, T6 and T8 equal 10 BSCKs (T3).

**Note 2:** These specifications are not tested.

## 7.0 AC and DC Specifications (Continued)

MEMORY WRITE, BMODE = 0, SYNCHRONOUS MODE (one wait-state shown)

TL/F/10492-59

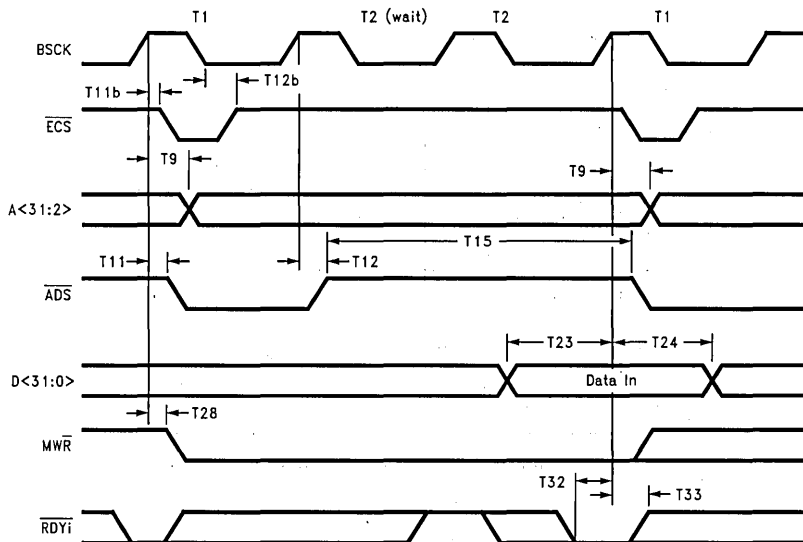

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T9	BSCk to Address Valid/Hold Time	3	26	3	24	3	22	ns
T11	BSCk to $\overline{ADS}$ Low		26		24		22	ns
T11b	BSCk to $\overline{ECS}$ Low		19		17		15	ns
T12	BSCk to $\overline{ADS}$ High		24		22		20	ns
T12b	BSCk to $\overline{ECS}$ High		29		27		25	ns
T15	$\overline{ADS}$ High Width	45		35		25		ns
T32	$\overline{RDYi}$ Setup to BSCk	19		17		15		ns
T33	$\overline{RDYi}$ Hold from BSCk	5		3		3		ns
T36	BSCk to Memory Write Data Valid/Hold Time (Note 2)	3	50	3	48	3	46	ns
T37	BSCk to $\overline{MWR}$ (Write) Valid (Note 1)		24		22		20	ns

**Note 1:** For successive write operations,  $\overline{MWR}$  remains high.

**Note 2:** One idle clock cycle (T1) will be inserted between the last write cycle and the following read cycle in RDA and TDA operation. Note that the data bus will become TRI-STATE from the rising edge of the clock after the idle cycle (see T52 for BSCk to data TRI-STATE timing).

## 7.0 AC and DC Specifications (Continued)

MEMORY READ, BMODE = 0, SYNCHRONOUS MODE (one wait-state shown)

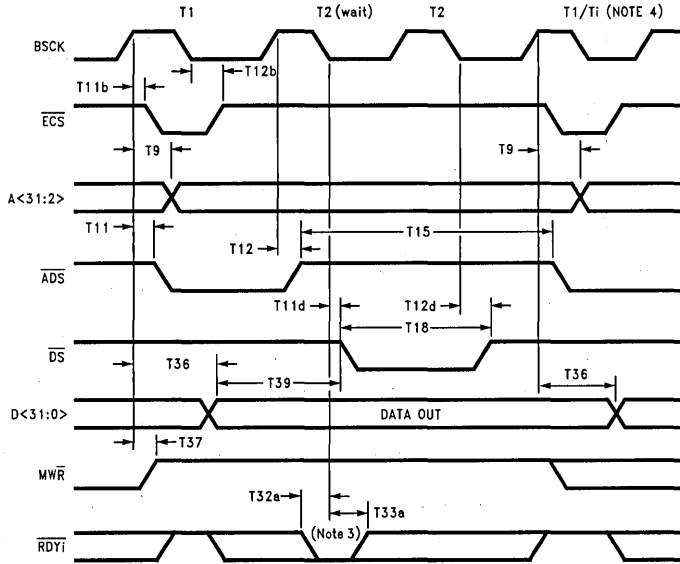

TL/F/10492-60

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T9	BSCCK to Address Valid/Hold Time	3	26	3	24	3	22	ns
T11	BSCCK to $\overline{ADS}$ Low		26		24		22	ns
T11b	BSCCK to $\overline{ECS}$ Low		19		17		15	ns
T12	BSCCK to $\overline{ADS}$ High		24		22		20	ns
T12b	BSCCK to $\overline{ECS}$ High		29		27		25	ns
T15	$\overline{ADS}$ High Width	45		35		25		ns
T23	Read Data Setup Time to BSCCK	5		4		3		ns
T24	Read Data Hold Time to BSCCK	5		5		5		ns
T28	BSCCK to $\overline{MWR}$ (Read) Valid (Note 1)		26		24		22	ns
T32	$\overline{RDYi}$ Setup Time to BSCCK	19		17		15		ns
T33	$\overline{RDYi}$ Hold Time to BSCCK	5		3		3		ns

**Note 1:** For successive read operations,  $\overline{MWR}$  remains low.

## 7.0 AC and DC Specifications (Continued)

### MEMORY WRITE, BMODE = 0, ASYNCHRONOUS MODE

TL/F/10492-61

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T9	BSCCK to Address Valid/Hold Time	3	26	3	24	3	22	ns
T11	BSCCK to $\overline{ADS}$ Low		26		24		22	ns
T11b	BSCCK to $\overline{ECS}$ Low		19		17		15	ns
T11d	BSCCK to $\overline{DS}$ Low		17		15		13	ns
T12	BSCCK to $\overline{ADS}$ High		24		22		20	ns
T12b	BSCCK to $\overline{ECS}$ High		29		27		25	ns
T12d	BSCCK to $\overline{DS}$ High		17		15		13	ns
T15	$\overline{ADS}$ High Width	45		35		25		ns
T18	Write Data Strobe Low Width (Note 2)	40		30		20		ns
T32a	$\overline{RDYi}$ Asynch. Setup to BSCCK (Note 3)	5		4		3		ns
T33a	$\overline{RDYi}$ Asynch. Hold from BSCCK	5		5		5		ns
T36	BSCCK to Memory Write Data Valid/Hold Time (Note 4)	3	50	3	48	3	46	ns
T37	BSCCK to $\overline{MWR}$ (Write) Valid (Note 1)		24		22		20	ns
T39	Write Data Valid to $\overline{DS}$ Low	34		21		7		ns

**Note 1:** For successive write operations,  $\overline{MWR}$  remains high.

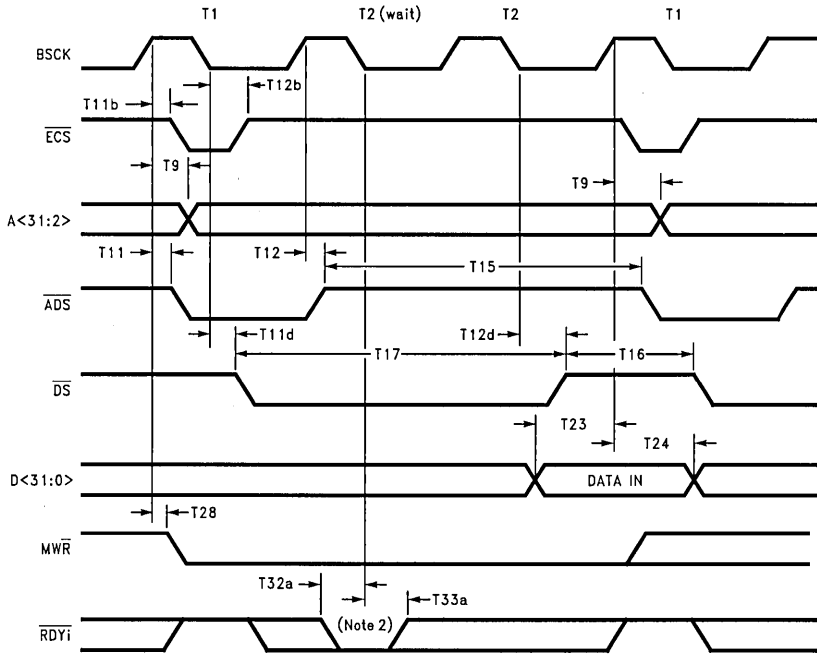

**Note 2:**  $\overline{DS}$  will only be asserted if the bus cycle has at least one wait state inserted.

**Note 3:** This setup time assures that the SONIC terminates the memory cycle on the next bus clock (BSCCK).  $\overline{RDYi}$  does not need to be synchronized to the bus clock, though, since it is an asynchronous input in this case.  $\overline{RDYi}$  is sampled during the falling edge of BSCCK. If the SONIC samples  $\overline{RDYi}$  low during the T1 cycle, the SONIC will finish the current access in a total of two bus clocks instead of three, which would be the case if  $\overline{RDYi}$  had been sampled low during T2(wait). (This is assuming that programmable wait states are set to 0).

**Note 4:** One idle clock cycle (T1) will be inserted between the last write cycle and the following read cycle in RDA and TDA operation. Note that the data bus will become TRI-STATE from the rising edge of the clock after the idle cycle (see T52 for BSCCK to data TRI-STATE timing).

## 7.0 AC and DC Specifications (Continued)

MEMORY READ, BMODE = 0, ASYNCHRONOUS MODE

TL/F/10492-62

## 7.0 AC and DC Specifications (Continued)

### BUS REQUEST TIMING, BMODE = 0

TL/F/10492-67

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T43	BSCK to HOLD High (Note 2)		18		16		14	ns
T44	BSCK to HOLD Low (Note 2)		19		17		15	ns
T45	HLDA Synchronous Setup Time to BSCK (Note 5)	7		6		5		ns
T46	HLDA Synchronous Deassert Setup Time (Note 1)	7		6		5		ns
T51	BSCK to Address, $\overline{ADS}$ , $\overline{MWR}$ , $\overline{DS}$ , $\overline{ECS}$ , $USR<1:0>$ and $EXUSR<3:0>$ TRI-STATE (Note 4)		34		32		30	ns
T52	BSCK to Data TRI-STATE		34		32		30	ns
T53	BSCK to $USR<1:0>$ or $EXUSR<3:0>$ Valid		34		32		30	ns
T55	BSCK to Bus Status Valid		29		27		25	ns
T55b	$S<2:0>$ Hold from BSCK	3		3		3		ns

**Note 1:** A block transfer by the SONIC can be pre-empted from the bus by deasserting HLDA provided HLDA is deasserted T46 before the rising edge of the last T2 in the current access.

**Note 2:** The assertion edge for HOLD is dependent upon the PH bit in the DCR2. The default situation is shown with a solid line in the timing diagram. T43 and T44 apply for both modes. Also, if HLDA is asserted when the SONIC wants to acquire the bus, HOLD will not be asserted until HLDA has been deasserted first.

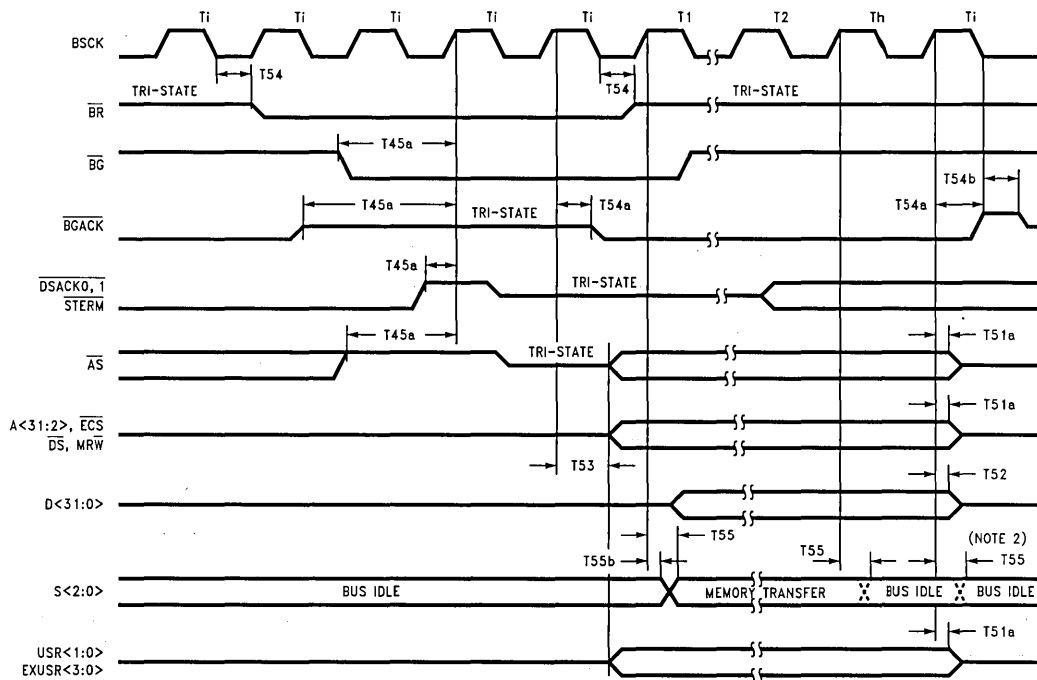

**Note 3:**  $S<2:0>$  will indicate IDLE at the end of T2 if the last operation is a read operation, or at the end of Th if the last operation is a write operation.

**Note 4:** This timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

**Note 5:** The HLDA signal is sampled by the SONIC on each rising edge of BSCK. The maximum setup time is  $((BSCK\_period - T45\_min\_spec) - 5ns)$ . The HLDA max setup time is for information only, and is not tested.

T54	BSCK Low to $\overline{BR}$ Low/TRI-STATE		23		21		19	ns
T54a	BSCK High to $\overline{BGACK}$ Low/High		24		22		20	ns
T54b	BSCK High to $\overline{BGACK}$ TRI-STATE		19		17		15	ns
T55	BSCK to Bus Status Valid		29		27		25	ns
T55b	$S<2:0>$ Hold from BSCK	3		3		3		ns

**Note 1:**  $\overline{BGACK}$  is asserted one bus clock after all the signals ( $\overline{AS}$ ,  $\overline{DSACK0,1}$ ,  $\overline{BGACK}$ ,  $\overline{STERM}$  (Extended bus mode), and  $\overline{BG}$ ) meet the T45a setup time (see Section 5.4.1 for more information). The address bus,  $\overline{AS}$ ,  $\overline{DS}$ ,  $\overline{ECS}$ ,  $\overline{MRW}$ ,  $\overline{USR}<1:0>$ , and  $\overline{EXUSR}<3:0>$  will also be driven active on the same clock.

**Note 2:**  $S<2:0>$  will indicate IDLE at the end of T2 if the last operation is a read operation, or at the end of Th if the last operation is a write operation.

## 7.0 AC and DC Specifications (Continued)

### BUS RETRY

TL/F/10492-69

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T41	Bus Retry Synchronous Setup Time to BSCCK (Note 3)	5		4		3		ns
T41a	Bus Retry Asynchronous Setup Time to BSCCK (Note 3)	6		5		4		ns
T42	Bus Retry Hold Time from BSCCK (Note 2)	7		6		5		ns

**Note 1:** Depending upon the mode, the SONIC will assert and deassert HOLD from the rising or falling edge of BSCCK.

**Note 2:** Unless Latched Bus Retry mode is set (LBR in the Data Configuration Register, Section 4.3.2), BRT must remain asserted until after the Th state. If Latched Bus Retry mode is used, BRT does not need to satisfy T42.

**Note 3:** T41 is for synchronous bus retry and T41a is for asynchronous bus retry (see Section 4.3.2, bit 15, Extended Bus Mode). Since T41a is an asynchronous setup time, it is not necessary to meet it, but doing so will guarantee that the bus exception occurs in the current memory transfer, not the next.

## 7.0 AC and DC Specifications (Continued)

### MEMORY ARBITRATION/S�AVE ACCESS

TL/F/10492-70

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T56	$\overline{CS}$ Low Asynch. Setup to BSCk (Note 2)	8		7		6		ns
T58	$\overline{MREQ}$ Low Asynch. Setup to BSCk (Note 2)	8		7		6		ns
T60	$\overline{MREQ}$ or $\overline{CS}$ Valid to $\overline{SMACK}$ Low (Notes 3, 4)	1	5	1	5	1	5	bcyc
T80	$\overline{MREQ}$ to $\overline{SMACK}$ High		18		16		14	ns
T81	BSCk to $\overline{SMACK}$ Low		22		20		18	ns

**Note 1:** Both  $\overline{CS}$  and  $\overline{MREQ}$  must not be asserted concurrently. If these signals are successively asserted, there must be at least two bus clocks between the deasserting and asserting edges of these signals.

**Note 2:** It is not necessary to meet the setup times for  $\overline{MREQ}$  or  $\overline{CS}$  since these signals are asynchronously sampled. Meeting the setup time for these signals, however, makes it possible to use T60 to determine when  $\overline{SMACK}$  will be asserted.

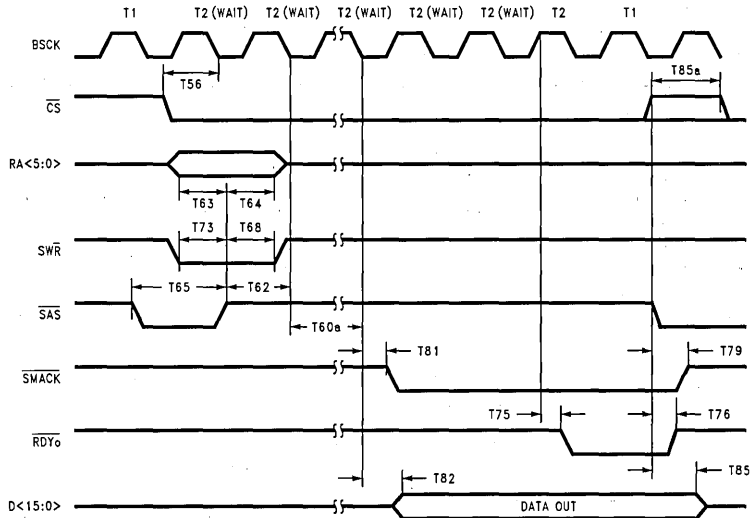

**Note 3:** T60 could range from 1 bus clock minimum to 5 bus clock maximum depending on what state machine the SONIC is in when the  $\overline{CS}$  or  $\overline{MREQ}$  signal is asserted. This timing is not tested, but is guaranteed by design. This specification assumes that  $\overline{CS}$  or  $\overline{MREQ}$  is asserted before the falling edge that these signals are asynchronously clocked in on (see T56 and T58).  $\overline{SAS}$  must have been asserted for this timing to be correct. See  $\overline{SAS}$  and  $\overline{CS}$  timing in the Register Read, and Register Write timing specifications.

**Note 4:** bcyc = bus clock cycle time (T3).

**Note 5:** The way in which  $\overline{SMACK}$  is asserted due to  $\overline{CS}$  is not the same as the way in which  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ .  $\overline{SMACK}$  goes low as a direct result of the assertion of  $\overline{MREQ}$ , whereas, for  $\overline{CS}$ ,  $\overline{SAS}$  must also be driven low (BMODE = 1) or high (BMODE = 0) before  $\overline{SMACK}$  will be asserted. This means that when  $\overline{SMACK}$  is asserted due to  $\overline{MREQ}$ ,  $\overline{SMACK}$  will remain asserted until  $\overline{MREQ}$  is deasserted. Multiple memory accesses can be made to the shared memory without  $\overline{SMACK}$  ever going high. When  $\overline{SMACK}$  is asserted due to  $\overline{CS}$ , however,  $\overline{SMACK}$  will only remain low as long as  $\overline{SAS}$  is also low (BMODE = 1) or high (BMODE = 0).  $\overline{SMACK}$  will not remain low throughout multiple register accesses to the SONIC because  $\overline{SAS}$  must toggle for each register access. This is an important difference to consider when designing shared memory designs.

## 7.0 AC and DC Specifications (Continued)

### REGISTER READ, BMODE = 0 (Note 1)

TL/F/10492-88

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T56	$\overline{CS}$ Asynch. Setup to BSCCK (Notes 4, 6)	8		7		6		ns
T60a	$\overline{CS}$ and $\overline{SAS}$ to $\overline{SMACK}$ Low (Notes 3, 5, 6)	0	4	0	4	0	4	bcyk
T62	$\overline{SAS}$ Asynch. Setup to BSCCK (Notes 4, 6)	7		6		5		ns
T63	Register Address Setup Time to $\overline{SAS}$	7		6		5		ns
T64	Register Address Hold Time from $\overline{SAS}$	8		7		6		ns
T65	Minimum $\overline{SAS}$ Low Width (Notes 4, 6)	20		17		15		ns
T68	$\overline{SWR}$ (Read) Hold from $\overline{SAS}$	8		7		6		ns
T73	$\overline{SWR}$ (Read) Setup to $\overline{SAS}$	7		6		5		ns
T75	BSCCK to $\overline{RDY0}$ Low		20		18		16	ns
T76	$\overline{SAS}$ or $\overline{CS}$ to $\overline{RDY0}$ High (Note 2)		34		32		30	ns
T79	$\overline{SAS}$ or $\overline{CS}$ to $\overline{SMACK}$ High (Note 2)		18		16		14	ns
T81	BSCCK to $\overline{SMACK}$ Low		22		20		18	ns
T82	BSCCK to Register Data Valid		44		42		40	ns
T85	$\overline{SAS}$ or $\overline{CS}$ to Data TRI-STATE (Notes 2, 7)		34		32		30	ns
T85a	Min. $\overline{CS}$ Deassert Time (Note 3)	1		1		1		bcyk

**Note 1:** This figure shows a slave access to the SONIC. The BSCCK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** If  $\overline{CS}$  is deasserted before the falling edge of  $\overline{SAS}$ , T76, T79 and T85 are referenced from the rising edge of  $\overline{CS}$ .

**Note 3:** bcyk = bus clock cycle time (T3).

**Note 4:** It is not necessary to meet the setup time for  $\overline{CS}$  (T56) and the setup time for  $\overline{SAS}$  (T62) since these signals are asynchronously sampled. Meeting these setup times for these signals, however, makes it possible to use T60a to determine exactly when  $\overline{SMACK}$  will be asserted. For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle. In this case,  $\overline{SMACK}$  will be driven low by the SONIC after T60a when T62 is met. T85a must be met to ensure proper slave operation once  $\overline{CS}$  is deasserted.

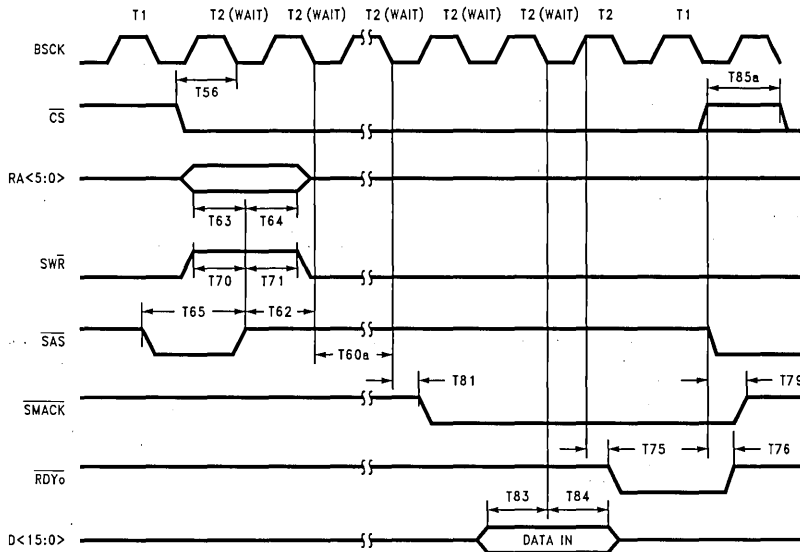

**Note 5:** The smaller value for T60a refers to when the SONIC is accessed during an Idle condition and the other value refers to when the SONIC is accessed during non-idle conditions. These values are not tested, but are guaranteed by design.

**Note 6:**  $\overline{SAS}$  may be asserted low anytime before or simultaneous to the falling edge of  $\overline{CS}$ . Register address and slave read/write signals are latched on the rising edge of the  $\overline{SAS}$ , and if T62 is met,  $\overline{SMACK}$  will be asserted by the SONIC after T60a. If T62 is not met, SONIC will sample  $\overline{SAS}$  again on the next falling edge of the clock, and  $\overline{SMACK}$  will not be asserted until  $\overline{SAS}$  is deasserted.

**Note 7:** This timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

## 7.0 AC and DC Specifications (Continued)

REGISTER WRITE, BMODE = 0 (Note 1)

TLF/10492-89

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T56	$\overline{CS}$ Asynch. Setup to BCLK (Notes 4, 6)	8		7		6		ns
T60a	$\overline{CS}$ and $\overline{SAS}$ to $\overline{SMACK}$ Low (Notes 3, 5, 6)	0	4	0	4	0	4	bcyc
T62	$\overline{SAS}$ Asynch. Setup to BCLK (Notes 4, 6)	7		6		5		ns
T63	Register Address Setup Time to $\overline{SAS}$	7		6		5		ns
T64	Register Address Hold Time from $\overline{SAS}$	8		7		6		ns
T65	Minimum $\overline{SAS}$ Low Width (Notes 4, 6)	20		17		15		ns

T71	$\overline{SWR}$ (Write) Hold from $\overline{SAS}$	8		7		6		ns
T75	BCLK to $\overline{RDY0}$ Low		20		18		16	ns
T76	$\overline{SAS}$ or $\overline{CS}$ to $\overline{RDY0}$ High (Note 2)		34		32		30	ns
T79	$\overline{SAS}$ or $\overline{CS}$ to $\overline{SMACK}$ High (Note 2)		18		16		14	ns
T81	BCLK to $\overline{SMACK}$ Low		22		20		18	ns
T83	Register Write Data Setup to BCLK	7		6		5		ns
T84	Register Write Data Hold from BCLK	14		12		10		ns
T85a	Min. $\overline{CS}$ Deassert Time (Note 3)	1		1		1		bcyc

**Note 1:** This figure shows a slave access to the SONIC. The BCLK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** If  $\overline{CS}$  is deasserted before the falling edge of  $\overline{SAS}$ , T76, T79 and T85 are referenced from the rising edge of  $\overline{CS}$ .

**Note 3:** bcyc = bus clock cycle time (T3).

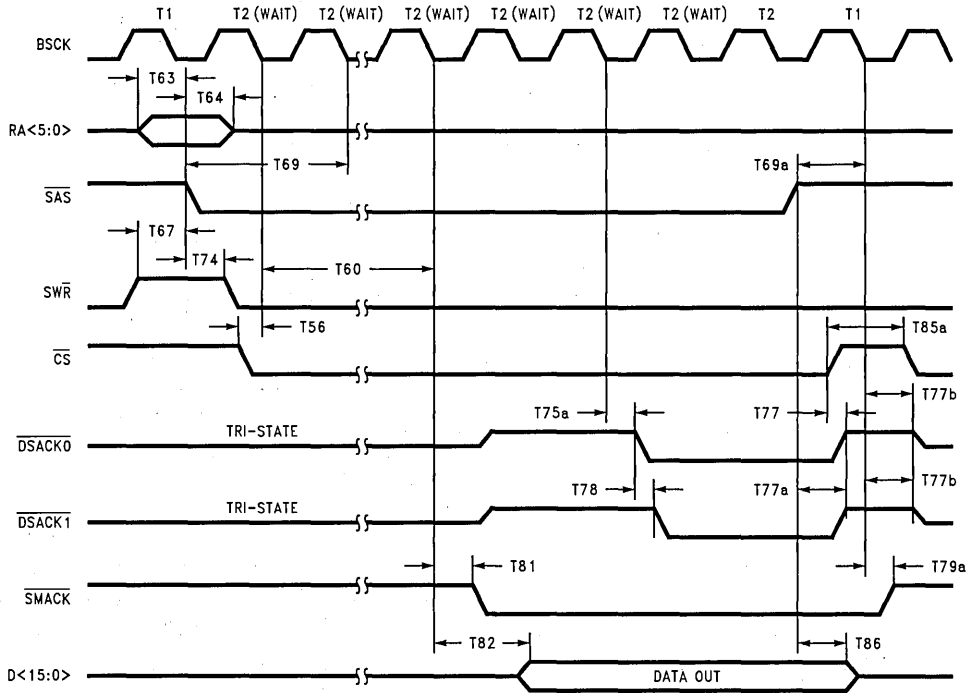

**Note 4:** It is not necessary to meet the setup time for  $\overline{CS}$  (T56) and the setup time for  $\overline{SAS}$  (T62) since these signals are asynchronously sampled. Meeting these setup times for these signals, however, makes it possible to use T60a to determine exactly when  $\overline{SMACK}$  will be asserted. For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle. In this case,  $\overline{SMACK}$  will be driven low by the SONIC after T60a when T62 is met. T85a must be met to ensure proper slave operation once  $\overline{CS}$  is deasserted.

**Note 5:** The smaller value for T60a refers to when the SONIC is accessed during an Idle condition and the other value refers to when the SONIC is accessed during non-idle conditions. These values are not tested, but are guaranteed by design.

**Note 6:**  $\overline{SAS}$  may be asserted low anytime before or simultaneous to the falling edge of  $\overline{CS}$ . Register address and slave read/write signals are latched on the rising edge of the  $\overline{SAS}$ , and if T62 is met,  $\overline{SMACK}$  will be asserted by the SONIC after T60a. If T62 is not met, SONIC will sample  $\overline{SAS}$  again on the next falling edge of the clock, and  $\overline{SMACK}$  will not be asserted until  $\overline{SAS}$  is deasserted.

### 7.0 AC and DC Specifications (Continued)

REGISTER READ, BMODE = 1 (Note 1)

TL/F/10492-90

## 7.0 AC and DC Specifications (Continued)

Number	Parameter	20 MHz		25 MHz		33 MHz		Units
		Min	Max	Min	Max	Min	Max	
T56	$\overline{CS}$ Asynch. Setup to BSCK (Notes 3, 4)	8		7		6		ns

T63	Register Address Setup to $\overline{SAS}$	6		5		4		ns
T64	Register Address Hold from $\overline{SAS}$	8		7		6		ns
T67	$SR\overline{W}$ (Read) Setup to $\overline{SAS}$	4		3		2		ns
T69	$\overline{SAS}$ Asynch. Setup to BSCK (Notes 3, 4)	7		6		5		ns
T69a	$\overline{SAS}$ Asynch. Setup to BSCK (Notes 3, 5)	5		4		3		ns
T74	$SR\overline{W}$ (Read) Hold from $\overline{SAS}$	8		7		6		ns
T75a	BSCK to $\overline{DSACK0,1}$ Low		14		12		10	ns
T77	$\overline{CS}$ to $\overline{DSACK0,1}$ High (Note 5)		20		18		16	ns
T77a	$\overline{SAS}$ to $\overline{DSACK0,1}$ High (Note 5)		24		22		20	ns
T77b	BSCK to $\overline{DSACK0,1}$ TRI-STATE (Note 5)		19		17		15	ns
T78	Skew between $\overline{DSACK0,1}$		3		3		2	ns
T79a	BSCK to $\overline{SMACK}$ High (Note 5)		19		17		15	ns
T81	BSCK to $\overline{SMACK}$ Low		22		20		18	ns
T82	BSCK to Register Data Valid		44		42		40	ns
T85a	Min. $\overline{CS}$ Deassert Time (Notes 2, 3)	1		1		1		bcyc
T86	$\overline{SAS}$ to Register Data TRI-STATE (Note 6)		42		40		38	ns

**Note 1:** This figure shows a slave access to the SONIC when the SONIC is idle, or rather not in master mode. If the SONIC is a bus master, there will be some differences as noted in the Memory Arbitration/Slave Access diagram. The BSCK states (T1, T2, etc.) are the equivalent processor states during a slave access.

**Note 2:** bcyc = bus clock cycle time (T3).

**Note 3:** It is not necessary to meet the setup time for  $\overline{CS}$  and  $\overline{SAS}$  (T56 and T69) since these signals are asynchronously sampled. Meeting the setup time for these signals, however, makes it possible to use T60 to determine when  $\overline{SMACK}$  will be asserted.  $\overline{SAS}$  may be asserted anytime before the next falling edge of the clock that the  $\overline{CS}$  is sampled on (as shown by specification T69). For multiple register accesses,  $\overline{CS}$  can be held low and  $\overline{SAS}$  can be used to delimit the slave cycle (T69a must be met in order to terminate and start another cycle). In this case,  $\overline{SMACK}$  will be asserted as soon as T69 timing is met.

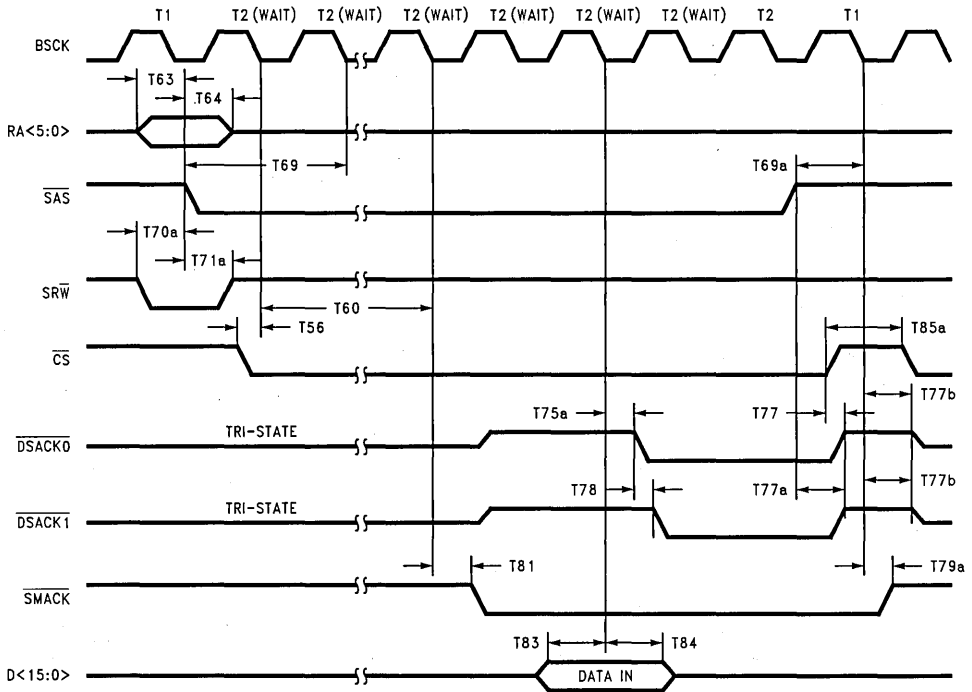

**Note 4:** T60 could range from 1 bus clock minimum to 5 bus clock maximum depending on what state machine the SONIC is in when the  $\overline{CS}$  signal is asserted. This timing is not tested, but is guaranteed by design. This specification assumes that both T56 is met for  $\overline{CS}$  and T69 is met for  $\overline{SAS}$ . T60 specification also assumes that there were no wait states in the current master mode access (if  $\overline{CS}$  is asserted when SONIC is in Master Mode). If there were wait states, then it would increase the T60 further.

**Note 5:** It is not necessary to meet the setup times for  $\overline{SAS}$  (T69a) since this signal is asynchronously sampled. Meeting the setup time for this signal, however, will ensure  $\overline{DSACK0,1}$  becomes TRI-STATE (T77b) and  $\overline{SMACK}$  goes high (T79) at the falling edge of T1. Both  $\overline{CS}$  and  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to deassert but only  $\overline{SAS}$  could cause  $\overline{DSACK0,1}$  to become TRI-STATE.

**Note 6:** This timing value includes an RC delay inherent in the test measurement. These signals typically TRI-STATE 7 ns earlier, enabling other devices to drive these lines without contention.

### ENDEC TRANSMIT TIMING

TL/F/10492-75

Number	Parameter	Min	Max	Units
T87	Transmit Clock High Time (Note 1)	40		ns
T88	Transmit Clock Low Time (Note 1)	40		ns
T89	Transmit Clock Cycle Time (Note 1)	99.99	100.01	ns
T95	Transmit Output Delay (Note 1)		55	ns
T96	Transmit Output Fall Time (80% to 20%, Note 1)		7	ns
T97	Transmit Output Rise Time (20% to 80%, Note 1)		7	ns
T98	Transmit Output Jitter (Not Shown)	0.5 Typical		ns
T100	Transmit Output High before Idle (Half Step)	200		ns
T101	Transmit Output Idle Time (Half Step)		8000	ns

Note 1: This specification is provided for information only and is not tested.

## 7.0 AC and DC Specifications (Continued)

### ENDEC RECEIVE TIMING (INTERNAL ENDEC MODE)

TL/F/10492-76

### ENDEC COLLISION TIMING

TL/F/10492-77

Number	Parameter	Min	Max	Units
T102	Receive Clock Duty Cycle Time (Note 1)	40	60	ns
T105	Carrier Sense On Time		70	ns
T106	Data Acquisition Time		700	ns
T107	Receive Data Output Delay		150	ns
T108	Receive Data Valid from RXC		15	ns
T109	Receive Data Stable Valid Time	85		ns
T112	Carrier Sense Off Delay (Note 2)		250	ns
T113	Minimum Number of RXCs after CRS Low (Note 3)	5		rcyc
T114	Collision Turn On Time		55	ns
T115	Collision Turn Off Time		250	ns

**Note 1:** This parameter is measured at the 50% point of each clock edge.

**Note 2:** When CRSi goes low, it remains low for a minimum of 2 receive clocks (RXC).

**Note 3:** rcyc = receive clocks.

## 7.0 AC and DC Specifications (Continued)

### ENDEC-MAC SERIAL TIMING FOR RECEPTION (EXTERNAL ENDEC MODE)

TL/F/10492-78

Number	Parameter	Min	Max	Units
T118	Receive Clock High Time	40		ns
T119	Receive Clock Low Time	40		ns
T120	Receive Clock Cycle Time	90	110	ns
T121	RXD Setup to RXC	20		ns
T122	RXD Hold from RXC	15		ns
T124	Maximum Allowed Dribble Bits		6	Bits
T125	Receive Recovery Time (Note 2)			
T126	RXC to Carrier Sense Low (Notes 1, 3)		1	rcyc

**Note 1:**  $t_{cyc}$  = transmit clocks,  $r_{cyc}$  = receive clocks,  $b_{cyc}$  = T3.

**Note 2:** This parameter refers to longest time (not including wait-states) the SONIC requires to perform its end of receive processing and be ready for the next start of frame delimiter. This time is  $4 + 36 t_{cyc} b_{cyc}$ . This is guaranteed by design and is not tested.

**Note 3:** To ensure proper receive operation, a minimum of 5 RXCs after CRS low are required.

### ENDEC-MAC SERIAL TIMING FOR TRANSMIT (NO COLLISION)

TL/F/10492-79

Number	Parameter	Min	Max	Units
T127	Transmit Clock High Time	40		ns
T128	Transmit Clock Low Time	40		ns
T129	Transmit Clock Cycle Time	90	110	ns
T130	TXC to TXE High		40	ns
T131	TXC to TXD Valid		15	ns
T132	TXD Hold Time from TXC	5		ns
T133	TXC to TXE Low		40	ns
T134	TXE Low to Start of CD Heartbeat (Note 1)		64	$t_{cyc}$
T135	Collision Detect Width (Note 1)	2		$t_{cyc}$

**Note 1:**  $t_{cyc}$  = transmit clock.

## 7.0 AC and DC Specifications (Continued)

### ENDEC-MAC SERIAL TIMING FOR TRANSMISSION (COLLISION)

Number	Parameter	Min	Max	Units
T135	Collision Detect Width (Note 1)	2		tcyc
T136	Delay from Collision		8	tcyc
T137	Jam Period		32	tcyc

Note 1: tcyc = transmit clock.

## 8.0 AC Timing Test Conditions

All specifications are valid only if the mandatory isolation is employed and all differential signals are taken to be at the AUI side of the pulse transformer.

Input Pulse Levels (TTL/CMOS)	GND to 3.0V
Input Rise and Fall Times (TTL/CMOS)	5 ns
Input and Output Reference Levels (TTL/CMOS)	1.5V
Input Pulse Levels (Diff.)	-350 mV to -1315 mV
Input and Output Reference Levels (Diff.)	50% Point of the Differential
TRI-STATE Reference Levels	Float ( $\Delta V$ ) $\pm 0.5V$

## Pin Capacitance

$T_A = 25^\circ C$ ,  $f = 1$  MHz

Symbol	Parameter	Typ	Units
$C_{IN}$	Input Capacitance	7	pF
$C_{OUT}$	Output Capacitance	7	pF

## DERATING FACTOR

Output timing is measured with a purely capacitive load of 50 pF. The following correction factor can be used for other loads:  $C_L \geq 50$  pF, add 0.05 ns/pF.

## AUI Transmit Test Load

Note: In the above diagram, the TX+ and TX- signals are taken from the AUI side of the isolation (pulse transformer). The pulse transformer used for all testing is a 100  $\mu H \pm 0.1\%$  Pulse Engineering PE64103.

## Output Load (See Figure below)

Note 1: 50 pF, includes scope and jig capacitance.

Note 2: S1 = Open for timing test for push pull outputs.

S1 =  $V_{CC}$  for  $V_{OL}$  test.

S1 = GND for  $V_{OH}$  test.

S1 =  $V_{CC}$  for High Impedance to active low and active low to High Impedance measurements.

S1 = GND for High Impedance to active high and active high to High Impedance measurements.

## DP83916 SONIC™-16 Systems-Oriented Network Interface Controller

### General Description

The SONIC™-16 (Systems-Oriented Network Interface Controller) is a second-generation Ethernet Controller designed to meet the demands of today's high-speed 16-bit systems. Its system interface operates with a high speed DMA that typically consumes less than 8% of the bus bandwidth. Selectable bus modes provide both big and little endian byte ordering and a clean interface to standard microprocessors. The linked-list buffer management system of SONIC-16 offers maximum flexibility in a variety of environments from PC-oriented adapters to high-speed motherboard designs. Furthermore, the SONIC-16 integrates a fully-compatible IEEE 802.3 Encoder/Decoder (ENDEC) allowing for a simple 2-chip solution for Ethernet when the SONIC-16 is paired with the DP8392 Coaxial Transceiver Interface.

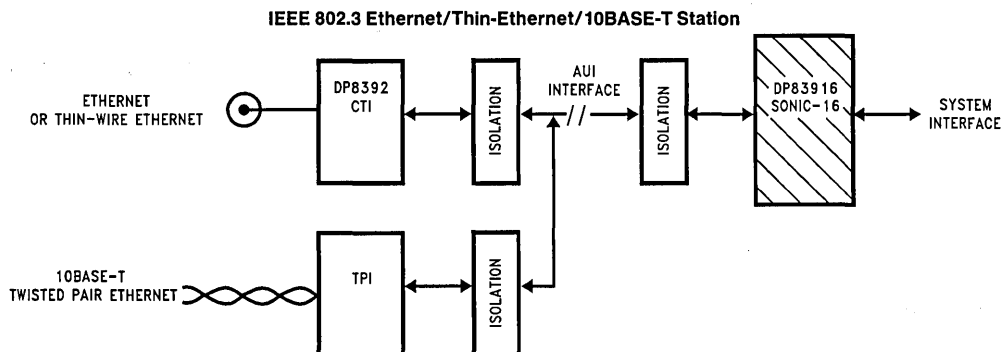

For increased performance, the SONIC-16 implements a unique buffer management scheme to efficiently process receive and transmit packets in system memory. No intermediate packet copy is necessary. The receive buffer management uses three areas in memory for (1) allocating additional resources, (2) indicating status information, and (3) buffering packet data. During reception, the SONIC-16 stores packets in the buffer area, then indicates receive status and control information in the descriptor area. The system allocates more memory resources to the SONIC-16 by adding descriptors to the memory resource area. The transmit buffer management uses two areas in memory:

one for indicating status and control information and the other for fetching packet data. The system can create a transmit queue allowing multiple packets to be transmitted from a single transmit command. The packet data can reside on any arbitrary byte boundary and can exist in several non-contiguous locations.

### Features

- 23-bit non-multiplexed address/16-bit data bus
- High-speed, interruptible DMA
- Linked-list buffer management maximizes flexibility
- Two independent 32-byte transmit and receive FIFOs
- Bus compatibility for all standard microprocessors
- Supports big and little endian formats
- Integrated IEEE 802.3 ENDEC
- Complete address filtering for up to 16 physical and/or multicast addresses
- 32-bit general-purpose timer
- Full-duplex loopback diagnostics
- Fabricated in low-power CMOS
- 132 PQFP package
- Full network management facilities support the IEEE 802.3 layer management standard
- Integrated support for bridge and repeater applications

# 1.0 Functional Description

The SONIC-16 (Figure 1-1) consists of an encoder/decoder (ENDEC) unit, media access control (MAC) unit, separate receive and transmit FIFOs, a system buffer management engine, and a user programmable system bus interface unit on a single chip. SONIC-16 is highly pipelined providing maximum system level performance. This section provides a functional overview of SONIC-16.

## 1.1 IEEE 802.3 ENDEC UNIT

The ENDEC (Encoder/Decoder) unit is the interface between the Ethernet transceiver and the MAC unit. It provides the Manchester data encoding and decoding functions for IEEE 802.3 Ethernet/Thin-Ethernet type local area networks. The ENDEC operations of SONIC-16 are identical to the DP83910A CMOS Serial Network Interface device. During transmission, the ENDEC unit combines non-return-zero (NRZ) data from the MAC section and clock pulses into Manchester data and sends the converted data differentially to the transceiver. Conversely, during reception, an analog PLL decodes the Manchester data to NRZ format and receive clock. The ENDEC unit is a functionally complete Manchester encoder/decoder incorporating a balanced driver and receiver, on-board crystal oscillator, collision signal translator, and a diagnostic loopback. The features include:

- Compatible with Ethernet I and II, IEEE 802.3 10BASE5 and 10BASE2
- 10Mb/s Manchester encoding/decoding with receive clock recovery
- Requires no precision components
- Loopback capability for diagnostics
- Externally selectable half or full step modes of operation at transmit output
- Squelch circuitry at the receive and collision inputs reject noise
- Connects to the transceiver (AUI) cable via external pulse transformer

## 1.1.1 ENDEC Operation

The primary function of the ENDEC unit (Figure 1-2) is to perform the encoding and decoding necessary for compatibility between the differential pair Manchester encoded data of the transceiver and the Non-Return-to-Zero (NRZ) serial data of the MAC unit data line. In addition to encoding and decoding the data stream, the ENDEC also supplies all the necessary special signals (e.g., collision detect, carrier sense, and clocks) to the MAC unit.

**Manchester Encoder and Differential Output Driver:** During transmission to the network, the ENDEC unit translates the NRZ serial data from the MAC unit into differential pair Manchester encoded data on the Coaxial Transceiver Interface (e.g., National's DP8392) transmit pair. To perform this operation the NRZ bit stream from the MAC unit is passed through the Manchester encoder block of the ENDEC unit. Once the bit stream is encoded, it is transmitted out differentially to the transmit differential pair through the transmit driver.

**Manchester Decoder:** During reception from the network, the differential receive data from the transceiver (e.g., the DP8392) is converted from Manchester encoded data into NRZ serial data and a receive clock, which are sent to the receive data and clock inputs of the MAC unit. To perform this operation the signal, once received by the differential receiver, is passed to the phase locked loop (PLL) decoder block. The PLL decodes the data and generates a data receive clock and a NRZ serial data stream to the MAC unit.

**Special Signals:** In addition to performing the Manchester encoding and decoding function, the ENDEC unit provides control and clocking signals to the MAC unit. The ENDEC sends a carrier sense (CRS) signal that indicates to the MAC unit that data is present on the network on the ENDEC's receive differential pair. The MAC unit is also provided with a collision detection signal (COL) that informs the MAC unit that a collision is taking place somewhere on the

TL/F/11722-3

1-737

## 1.0 Functional Description (Continued)

network. The ENDEC section detects this when its collision receiver detects a 10 MHz signal on the differential collision input pair. The ENDEC also provides both the receive and transmit clocks to the MAC unit. The transmit clock is one half of the oscillator input. The receive clock is extracted from the input data by the PLL.

**Oscillator:** The oscillator generates the 10 MHz transmit clock signal for network timing. The oscillator is controlled by a parallel resonant crystal or by an external clock (see section 6.1.3). The 20 MHz output of the oscillator is divided by 2 to generate the 10 MHz transmit clock (TXC) for the MAC section. The oscillator provides an internal clock signal for the encoding and decoding circuits.

The signals provided to the MAC unit from the on-chip ENDEC are also provided as outputs to the user.

**Loopback Functions:** The SONIC-16 provides three loopback modes. These modes allow loopback testing at the MAC, ENDEC and external transceiver level (see section 1.7 for details). It is important to note that when the SONIC-16 is transmitting, the transmitted packet will always be looped back by the external transceiver. The SONIC-16 takes advantage of this to monitor the transmitted packet. See the explanation of the Receive State Machine in section 1.2.1 for more information about monitoring transmitted packets.

### 1.1.2 Selecting An External ENDEC

An option is provided on SONIC-16 to disable the on-chip ENDEC unit and use an external ENDEC. The internal IEEE 802.3 ENDEC can be bypassed by connecting the EXT pin to V<sub>CC</sub> (EXT = 1). In this mode the MAC signals are redirected out from the chip, allowing an external ENDEC to be used. See section 5.2 for the alternate pin definitions.

### 1.2 MAC UNIT

The MAC (Media Access Control) unit performs the media access control functions for transmitting and receiving packets over Ethernet. During transmission, the MAC unit frames information from the transmit FIFO and supplies serialized data to the ENDEC unit. During reception, the incoming information from the ENDEC unit is deserialized, the frame checked for valid reception, and the data is transferred to the receive FIFO. Control and status registers on the SONIC-16 govern the operation of the MAC unit.

#### 1.2.1 MAC Receive Section

The receive section (*Figure 1-3*) controls the MAC receive operations during reception, loopback, and transmission. During reception, the deserializer goes active after detecting the 2-bit SFD (Start of Frame Delimiter) pattern (section 2.1). It then frames the incoming bits into octet boundaries

and transfers the data to the 32-byte receive FIFO. Concurrently the address comparator compares the Destination Address Field to the addresses stored in the chip's CAM address registers (Content Addressable Memory cells). If a match occurs, the deserializer passes the remainder of the packet to the receive FIFO. The packet is decapsulated when the carrier sense input pin (CRS) goes inactive. At the end of reception the receive section checks the following:

- Frame alignment errors
- CRC errors
- Length errors (runt packets)

The appropriate status is indicated in the Receive Control register (section 4.3.3). In loopback operations, the receive section operates the same as during normal reception.

During transmission, the receive section remains active to allow monitoring of the self-received packet. The CRC checker operates as normal, and the Source Address field is compared with the CAM address entries. Status of the CRC check and the source address comparison is indicated by the PMB bit in the Transmit Control register (section 4.3.4). No data is written to the receive FIFO during transmit operations.

The receive section consists of the following blocks detailed below.

**Receive State Machine (RSM):** The RSM insures the proper sequencing for normal reception and self-reception during transmission. When the network is inactive, the RSM remains in an idle state continually monitoring for network activity. If the network becomes active, the RSM allows the deserializer to write data into the receive FIFO. During this state, the following conditions may prevent the complete reception of the packet.

- FIFO Overflow—The receive FIFO has been completely filled before the SONIC-16 could buffer the data to memory.
- CAM Address Mismatch—The packet is rejected because of a mismatch between the destination address of the packet and the address in the CAM.
- Memory Resource Error—There are no more resources (buffers) available for buffering the incoming packets.
- Collision or Other Error—A collision occurred on the network or some other error, such as a CRC error, occurred (this is true if the SONIC-16 has been told to reject packets on a collision, or reject packets with errors).

If these conditions do not occur, the RSM processes the packet indicating the appropriate status in the Receive Control register.

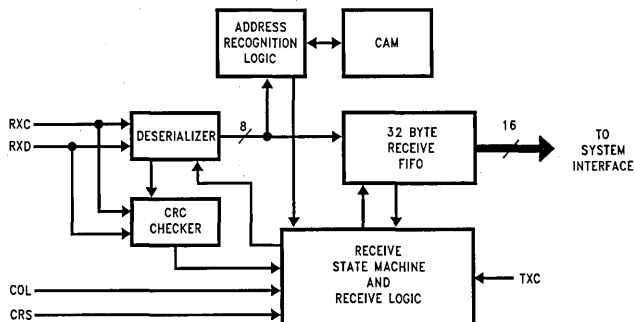

FIGURE 1-3. MAC Receiver

TL/F/11722-4

## 1.0 Functional Description (Continued)

During transmission of a packet from the SONIC-16, the external transceiver will always loop the packet back to the SONIC-16. The SONIC-16 will use this to monitor the packet as it is being transmitted. The CRC and source address of the looped back packet are checked with the CRC and source address that were transmitted. If they do not match, an error bit is set in the status of the transmitted packet (see Packet Monitored Bad, PBM, in the Transmit Control Register, section 4.3.4). Data is not written to the receive FIFO during this monitoring process unless Transceiver Loopback mode has been selected (see section 1.7).

**Receive Logic:** The receive logic contains the command, control, and status registers that govern the operations of the receive section. It generates the control signals for writing data to the receive FIFO, processes error signals obtained from the CRC checker and the deserializer, activates the "packet reject" signal to the RSM for rejecting packets, and posts the applicable status in the Receive Control register.

**Deserializer:** This section deserializes the serial input data stream and furnishes a byte clock for the address comparator and receive logic. It also synchronizes the CRC checker to begin operation (after SFD is detected), and checks for proper frame alignment with respect to CRS going inactive at the end of reception.

**Address Comparator:** The address comparator latches the Destination Address (during reception or loopback) or Source Address (during transmission) and determines whether the address matches one of the entries in the CAM (Content Addressable Memory).

**CRC Checker:** The CRC checker calculates the 4-byte Frame Check Sequence (FCS) field from the incoming data stream and compares it with the last 4-bytes of the received packet. The CRC checker is active for both normal reception and self-reception during transmission.

**Content Addressable Memory (CAM):** The CAM contains 16 user programmable entries and 1 pre-programmed Broadcast address entry for complete filtering of received packets. The CAM can be loaded with any combination of Physical and Multicast Addresses (section 2.2). See section 4.1 for the procedure on loading the CAM registers.

### 1.2.2 MAC Transmit Section

The transmit section (Figure 1-4) is responsible for reading data from the transmit FIFO and transmitting a serial data

stream onto the network in conformance with the IEEE 802.3 CSMA/CD standard. The Transmit Section consists of the following blocks.

**Transmit State Machine (TSM):** The TSM controls the functions of the serializer, preamble generator, and JAM generator. It determines the proper sequence of events that the transmitter follows under various network conditions. If no collision occurs, the transmitter prefixes a 62-bit preamble and 2-bit Start of Frame Delimiter (SFD) at the beginning of each packet, then sends the serialized data. At the end of the packet, an optional 4-byte CRC pattern is appended. If a collision occurs, the transmitter switches from transmitting data to sending a 4-byte Jam pattern to notify all nodes that a collision has occurred. Should the collision occur during the preamble, the transmitter waits for it to complete before jamming. After the transmission has completed, the transmitter writes status in the Transmit Control register (section 4.3.4).

**Protocol State Machine:** The protocol state machine assures that the SONIC-16 obeys the CSMA/CD protocol. Before transmitting, this state machine monitors the carrier sense and collision signals for network activity. If another node(s) is currently transmitting, the SONIC-16 defers until the network is quiet, then transmits after its Interframe Gap Timer (9.6  $\mu$ s) has expired. The Interframe Gap time is divided into two portions. During the first 6.4  $\mu$ s, network activity restarts the Interframe Gap timer. Beyond this time, however, network activity is ignored and the state machine waits the remaining 3.2  $\mu$ s before transmitting. If the SONIC-16 experiences a collision during a transmission, the SONIC-16 switches from transmitting data to a 4-byte JAM pattern (4 bytes of all 1's), before ceasing to transmit. The SONIC-16 then waits a random number of slot times (51.2  $\mu$ s) determined by the *Truncated Binary Exponential Backoff Algorithm* before reattempting another transmission. In this algorithm, the number of slot times to delay before the *n*th retransmission is chosen to be a random integer *r* in the range of:

$$0 \leq r \leq 2^k$$

$$\text{where } k = \min(n, 10)$$

If a collision occurs on the 16th transmit attempt, the SONIC-16 aborts transmitting the packet and reports an "Excessive Collisions" error in the Transmit Control register.

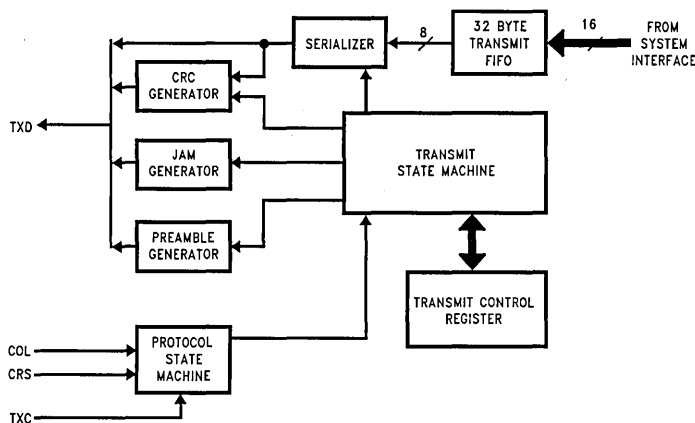

FIGURE 1-4. MAC Transmitter

TL/F/11722-5

### 1.0 Functional Description (Continued)

**Serializer:** After data has been written into the 32-byte transmit FIFO, the serializer reads byte wide data from the FIFO and sends a NRZ data stream to the Manchester encoder. The rate at which data is transmitted is determined by the transmit clock (TXC). The serialized data is transmitted after the SFD.

**Preamble Generator:** The preamble generator prefixes a 62-bit alternating "1,0" pattern and a 2-bit "1,1" SFD pattern at the beginning of each packet. This allows receiving nodes to synchronize to the incoming data. The preamble is always transmitted in its entirety even in the event of a collision. This assures that the minimum collision fragment is 96 bits (64 bits of normal preamble, and 4 bytes, or rather 32 bits, of the JAM pattern).

**CRC Generator:** The CRC generator calculates the 4-byte FCS field from the transmitted serial data stream. If enabled, the 4-byte FCS field is appended to the end of the transmitted packet (section 2.6).

**Jam Generator:** The Jam generator produces a 4-byte pattern of all 1's to assure that all nodes on the network sense the collision. When a collision occurs, the SONIC-16 stops transmitting data and enables the Jam generator. If a collision occurs during the preamble, the SONIC-16 finishes transmitting the preamble before enabling the Jam generator (see Preamble Generator above).

#### 1.3 BYTE ORDERING

The SONIC-16 will operate with 16-bit wide memory. The SONIC-16 provides both Little Endian and Big Endian byte-

ordering capability for compatibility with National/Intel or Motorola microprocessors respectively by selecting the proper level on the BMODE pin. The byte ordering is depicted as follows:

**Little Endian mode (BMODE = 0):** The byte orientation for received and transmitted data in the Receive Buffer Area (RBA) and Transmit Buffer Area (TBA) of system memory is as follows:

**Big Endian mode (BMODE = 1):** The byte orientation for received and transmitted data in the RBA and TBA is as follows:

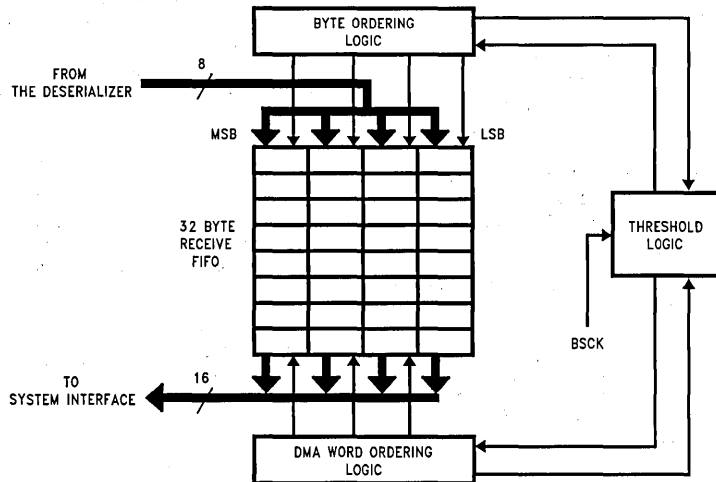

FIGURE 1-5. Receive FIFO

TL/F/11722-6

## 1.0 Functional Description (Continued)

### 1.4 FIFO AND CONTROL LOGIC

The SONIC-16 incorporates two independent 32-byte FIFOs for transferring data to/from the system interface and from/to the network. The FIFOs, providing temporary storage of data, free the host system from the real-time demands on the network.

The way in which the FIFOs are emptied and filled is controlled by the FIFO threshold values and the Block Mode Select bits (BMS, section 4.3.2). The threshold values determine how full or empty the FIFOs can be before the SONIC-16 will request the bus to get more data from memory or buffer more data to memory. When block mode is set, the number of bytes transferred is set by the threshold value. For example, if the threshold for the receive FIFO is 4 words, then the SONIC-16 will always transfer 4 words from the receive FIFO to memory. If empty/fill mode is set, however, the number of bytes transferred is the number required to fill the transmit FIFO or empty the receive FIFO. More specific information about how the threshold affects reception and transmission of packets is discussed in sections 1.4.1 and 1.4.2 below.

#### 1.4.1 Receive FIFO

To accommodate the different transfer rates, the receive FIFO (*Figure 1-5*) serves as a buffer between the 8-bit network (deserializer) interface and the 16-bit system interface. The FIFO is arranged as a 4-byte wide by 8 deep memory array (8 long words, or 32 bytes) controlled by three sections of logic. During reception, the Byte Ordering logic directs the byte stream from the deserializer into the FIFO using one of four write pointers. Depending on the selected byte-ordering mode, data is written either least significant byte first or most significant byte first to accommodate little or big endian byte-ordering formats respectively.

As data enters the FIFO, the Threshold Logic monitors the number of bytes written in from the deserializer. The programmable threshold (RFT1,0 in the Data Configuration Register) determines the number of words (or long words) written into the FIFO from the MAC unit before a DMA request for system memory occurs. When the threshold is reached, the Threshold Logic enables the Buffer Management Engine to read a programmed number of 16-bit words (depending upon the selected word width) from the FIFO and transfers them to the system interface (the system memory) using DMA. The threshold is reached when the number of bytes in the receive FIFO is greater than the value of the threshold. For example, if the threshold is 4 words (8 bytes), then the Threshold Logic will not cause the Buffer Management Engine to write to memory until there are more than 8 bytes in the FIFO.

The Buffer Management Engine reads either the upper or lower half (16 bits) of the FIFO. If, after the transfer is complete, the number of bytes in the FIFO is less than the threshold, then the SONIC-16 is done. This is always the case when the SONIC-16 is in empty/fill mode. If, however, for some reason (e.g. latency on the bus) the number of bytes in the FIFO is still greater than the threshold value, the Threshold Logic will cause the Buffer Management Engine to do a DMA request to write to memory again. This later case is usually only possible when the SONIC-16 is in block mode.

When in block mode, each time the SONIC-16 requests the bus, only a number of bytes equal to the threshold value will

be transferred. The Threshold Logic continues to monitor the number of bytes written in from the deserializer and enables the Buffer Management Engine every time the threshold has been reached. This process continues until the end of the packet.

Once the end of the packet has been reached, the serializer will fill out the last word if the last byte did not end on a word boundary. The fill byte will be 0FFh. Immediately after the last byte (or fill byte) in the FIFO, the received packets status will be written into the FIFO. The entire packet, including any fill bytes and the received packet status will be buffered to memory. When a packet is buffered to memory by the Buffer Management Engine, it is always taken from the FIFO in words and buffered to memory on word boundaries. Data from a packet cannot be buffered on odd byte boundaries (see Section 3.3). For more information on the receive packet buffering process, see Section 3.4.

#### 1.4.2 Transmit FIFO

Similar to the Receive FIFO, the Transmit FIFO (*Figure 1-6*) serves as a buffer between the 16-bit system interface and the network (serializer) interface. The Transmit FIFO is also arranged as a 4 byte by 8 deep memory array (8 long words or 32 bytes) controlled by three sections of logic. Before transmission can begin, the Buffer Management Engine fetches a programmed number of 16-bit words from memory and transfers them to the FIFO. The Buffer Management Engine writes either the upper or lower half (16 bits) into the FIFO.

The Threshold logic monitors the number of bytes as they are written into the FIFO. When the threshold has been reached, the Transmit Byte Ordering state machine begins reading bytes from the FIFO to produce a continuous byte stream for the serializer. The threshold is met when the number of bytes in the FIFO is greater than the value of the threshold. For example, if the transmit threshold is 4 words (8 bytes), the Transmit Byte Ordering state machine will not begin reading bytes from the FIFO until there are 9 or more bytes in the buffer. The Buffer Management Engine continues replenishing the FIFO until the end of the packet. It does this by making multiple DMA requests to the system interface. Whenever the number of bytes in the FIFO is equal to or less than the threshold value, the Buffer Management Engine will do a DMA request. If block mode is set, then after each request has been granted by the system, the Buffer Management Engine will transfer a number of bytes equal to the threshold value into the FIFO. If empty/fill mode is set, the FIFO will be completely filled in one DMA request.

Since data may be organized in big or little endian byte ordering format, the Transmit Byte Ordering state machine uses one of four read pointers to locate the proper byte within the 4 byte wide FIFO. It also determines the valid number of bytes in the FIFO. For packets which begin or end at odd bytes in the FIFO, the Buffer Management Engine writes extraneous bytes into the FIFO. The Transmit Byte Ordering state machine detects these bytes and only transfers the valid bytes to the serializer. The Buffer Management Engine can read data from memory on any byte boundary (see Section 3.3). See Section 3.5 for more information on transmit buffering.

## 1.0 Functional Description (Continued)

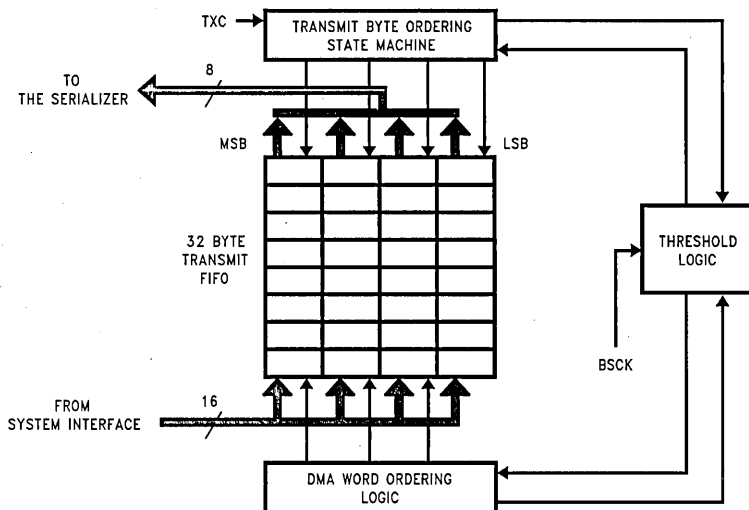

FIGURE 1-6. Transmit FIFO

TL/F/11722-7

### 1.5 STATUS AND CONFIGURATION REGISTERS

The SONIC-16 contains a set of status/control registers for conveying status and control information to/from the host system. The SONIC-16 uses these registers for loading commands generated from the system, indicating transmit and receive status, buffering data to/from memory, and providing interrupt control. Each register is 16 bits in length. See section 4.0 for a description of the registers.

### 1.6 BUS INTERFACE

The system interface (Figure 1-7) consists of the pins necessary for interfacing to a variety of buses. It includes the I/O drivers for the data and address lines, bus access control for standard microprocessors, ready logic for synchronous or asynchronous systems, slave access control, interrupt control, and shared-memory access control. The functional signal groups are shown in Figure 1-7. See section 5.0 for a complete description of the SONIC-16 bus interface.

### 1.7 LOOPBACK AND DIAGNOSTICS

The SONIC-16 furnishes three loopback modes for self-testing from the controller interface to the transceiver interface. The loopback function is provided to allow self-testing of the chip's internal transmit and receive operations. During loopback, transmitted packets are routed back to the receive section of the SONIC-16 where they are filtered by the address recognition logic and buffered to memory if accepted. Transmit and receive status and interrupts remain active during loopback. This means that when using loopback, it is as if the packet was transmitted and received by two separate chips that are connected to the same bus and memory.

**MAC Loopback:** Transmitted data is looped back at the MAC. Data is not sent from the MAC to either the internal ENDEC or an external ENDEC (the external ENDEC interface pins will not be driven), hence, data is not transmitted from the chip. Even though the ENDEC is not used in MAC loopback, the ENDEC clock (an oscillator or crystal for the internal ENDEC or TXC for an external ENDEC) must be driven. Network activity, such as a collision, does not affect

MAC loopback. CSMA/CD MAC protocol is not completely followed in MAC loopback.

**ENDEC Loopback:** Transmitted data is looped back at the ENDEC. If the internal ENDEC is used, data is switched from the transmit section of the ENDEC to the receive section (Figure 1-2). Data is not transmitted from the chip and the collision lines,  $CD\pm$ , are ignored, hence, network activity does not affect ENDEC loopback. The LBK signal from the MAC tells the internal ENDEC to go into loopback mode. If an external ENDEC is used, it should operate in loopback mode when the LBK signal is asserted. CSMA/CD MAC protocol is followed even though data is not transmitted from the chip.

**Transceiver Loopback:** Transmitted data is looped back at the external transceiver (which is always the case regardless of the SONIC-16's loopback mode). CSMA/CD MAC protocol is followed since data will be transmitted from the chip. This means that transceiver loopback is affected by network activity. The basic difference between Transceiver Loopback and normal, non-loopback, operations of the SONIC-16 is that in Transceiver Loopback, the SONIC-16 loads the receive FIFO and buffers the packet to memory. In normal operations, the SONIC-16 only monitors the packet that is looped back by the transceiver, but does not fill the receive FIFO and buffer the packet.

#### 1.7.1 Loopback Procedure

The following procedure describes the loopback operation.

1. Initialize the Transmit and Receive Area as described in Sections 3.4 and 3.5.
2. Load one of the CAM address registers (see Section 4.1), with the Destination Address of the packet if you are verifying the SONIC-16's address recognition capability.
3. Load one of the CAM address registers with the Source Address of the packet if it is different than the Destination Address to avoid getting a Packet Monitored Bad (PMB) error in the Transmit status (see Section 4.3.4).

### 1.0 Functional Description (Continued)

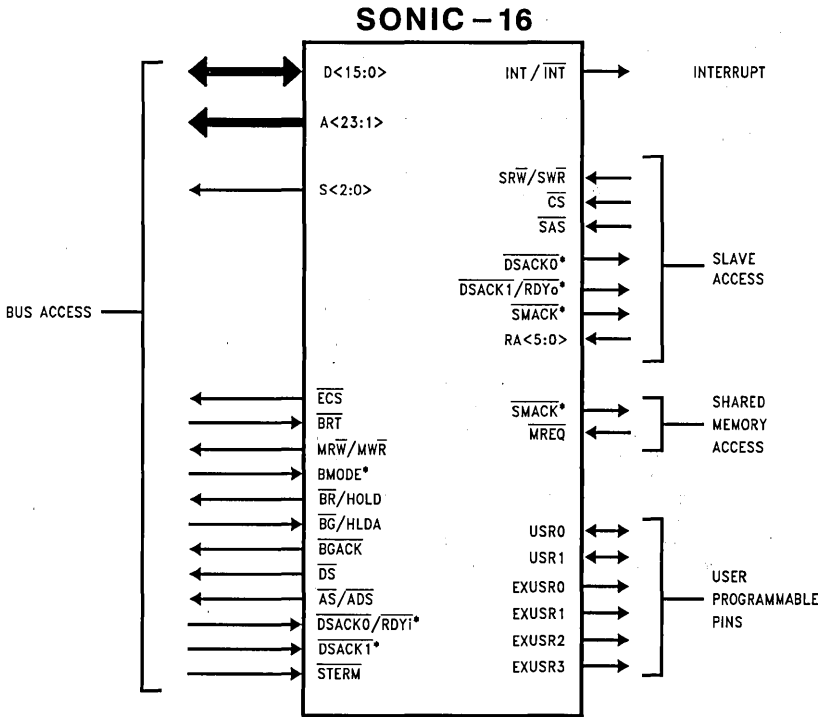

4. Program the Receive Control register with the desired receive filter and the loopback mode (LB1, LB0).
5. Issue the transmit command (TXP) and enable the receiver (RXEN) in the Command register.

The SONIC-16 completes the loopback operation after the packet has been completely received (or rejected if there is an address mismatch). The Transmit Control and Receive Control registers treat the loopback packet as in normal operation and indicate status accordingly. Interrupts are also generated if enabled in the Interrupt Mask register.

**Note:** For MAC Loopback, only one packet may be queued for proper operation. This restriction occurs because the transmit MAC section, which does not generate an Interframe Gap time (IFG) between transmitted packets, does not allow the receive MAC section to update receive status. There are no restrictions for the other loopback modes.

### 1.8 NETWORK MANAGEMENT FUNCTIONS

The SONIC-16 fully supports the Layer Management IEEE 802.3 standard to allow a node to monitor the overall performance of the network. These statistics are available on a per packet basis at the end of reception or transmission. In addition, the SONIC-16 provides three tally counters to tabulate CRC errors, Frame Alignment errors, and missed packets. Table 1-1 shows the statistics indicated by the SONIC-16.

TL/F/11722-8

\*Note: DSACK0,T are used for both Bus and Slave Access Control and are bidirectional. SMACK is used for both Slave access and shared memory access. The BMODE pin selects between National/Intel or Motorola type buses.

**FIGURE 1-7. SONIC-16 Interface Signals**

# 1.0 Functional Description (Continued)

TABLE 1-1. Network Management Statistics

Statistic	Register Used	Bits Used
Frames Transmitted OK	TCR (Note)	PTX
Single Collision Frames	(Note)	NC0-NC4
Multiple Collision Frames	(Note)	NC0-NC4
Collision Frames	(Note)	NC0-NC4
Frames with Deferred Transmissions	TCR (Note)	DEF
Late Collisions	TCR (Note)	OWC
Excessive Collisions	TCR (Note)	EXC
Excessive Deferral	TCR (Note)	EXD
Internal MAC Transmit Error	TCR (Note)	BCM, FU
Frames Received OK	RCR (Note)	PRX
Multicast Frames Received OK	RCR (Note)	MC
Broadcast Frames Received OK	RCR (Note)	BC
Frame Check Sequence Errors	CRCT RCR	All CRC
Alignment Errors	FAET RCR	All FAE
Frame Lost due to Internal MAC Receive Error	MPT ISR	All RFO

Note: The number of collisions and the contents of the Transmit Control register are posted in the TXpkt.status field (see section 3.5.1.2). The contents of the Receive Control register are posted in the RXpkt.status field (see section 3.4.3.1).

## 2.0 Transmit/Receive IEEE 802.3 Frame Format

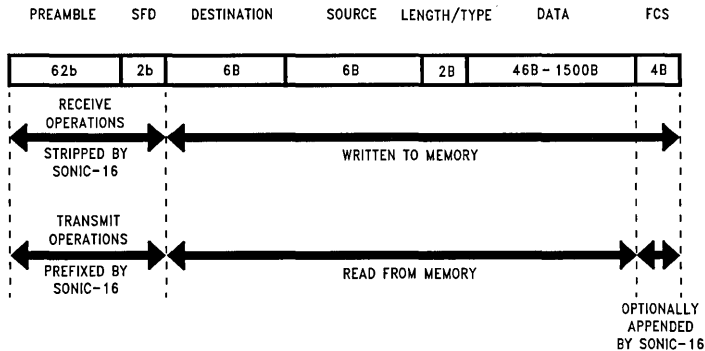

A standard IEEE 802.3 packet (Figure 2-1) consists of the following fields: preamble, Start of Frame Delimiter (SFD), destination address, source address, length, data and Frame Check Sequence (FCS). The typical format is shown in Figure 2-1. The packets are Manchester encoded and decoded by the ENDEC unit and transferred serially to/from the MAC unit using NRZ data with a clock. All fields are of fixed length except for the data field. The SONIC-16 generates and appends the preamble, SFD and FCS field during transmission. The Preamble and SFD fields are stripped during reception. (The CRC is passed through to buffer memory during reception.)

### 2.1 PREAMBLE AND START OF FRAME DELIMITER (SFD)

The Manchester encoded alternating 1,0 preamble field is used by the ENDEC to acquire bit synchronization with an incoming packet. When transmitted, each packet contains 62 bits of an alternating 1,0 preamble. Some of this preamble may be lost as the packet travels through the network. Byte alignment is performed when the Start of Frame Delimiter (SFD) pattern, consisting of two consecutive 1's, is detected.

### 2.2 DESTINATION ADDRESS

The destination address indicates the destination of the packet on the network and is used to filter unwanted pack-

Note: B = bytes  
b = bits

FIGURE 2-1. IEEE 802.3 Packet Structure

TL/F/11722-9

## 2.0 Transmit/Receive IEEE 802.3 Frame Format (Continued)

ets from reaching a node. There are three types of address formats supported by the SONIC-16: Physical, Multicast, and Broadcast.

**Physical Address:** The physical address is a unique address that corresponds only to a single node. All physical addresses have the LSB of the first byte of the address set to "0". These addresses are compared to the internally stored CAM (Content Addressable Memory) address entries. All bits in the destination address must match an entry in the CAM in order for the SONIC-16 to accept the packet.

**Multicast Address:** Multicast addresses, which have the LSB of the first byte of the address set to "1", are treated similarly as Physical addresses, i.e., they must match an entry in the CAM. This allows perfect filtering of Multicast packet's and eliminates the need for a hashing algorithm for mapping Multicast packets.

**Broadcast Address:** If the address consists of all 1's, it is a Broadcast address, indicating that the packet is intended for all nodes.

The SONIC-16 also provides a promiscuous mode which allows reception of all physical address packets. Physical, Multicast, Broadcast, and promiscuous address modes can be selected via the Receive Control register.

### 2.3 SOURCE ADDRESS

The source address is the physical address of the sending node. Source addresses cannot be multicast or broadcast addresses. This field must be passed to the SONIC-16's transmit buffer from the system software. During transmission, the SONIC-16 compares the Source address with its internal CAM address entries before monitoring the CRC of the self-received packet. If the source address of the packet transmitted does not match a value in the CAM, the packet monitored bad flag (PMB) will be set in the transmit status field of the transmit descriptor (see Sections 3.5.1.2 and 4.3.4). The SONIC-16 does not provide Source Address insertion. However, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. (See Section 3.5.1.)

### 2.4 LENGTH/TYPE FIELD

For IEEE 802.3 type packets, this field indicates the number of bytes that are contained in the data field of the packet. For Ethernet I and II networks, this field indicates the type of packet. The SONIC-16 does not operate on this field.

### 2.5 DATA FIELD

The data field has a variable octet length ranging from 46 to 1500 bytes as defined by the Ethernet specification. Messages longer than 1500 bytes need to be broken into multiple packets for IEEE 802.3 networks. Data fields shorter than 46 bytes require appending a pad to bring the complete frame length to 64 bytes. If the data field is padded, the number of valid bytes are indicated in the length field. The SONIC-16 does not append pad bytes for short packets during transmission, nor check for oversize packets during reception. However, the user's driver software can easily append the pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes (see Section 3.5.1). While the Ethernet specification defines the maximum number of bytes in the data field the SONIC-16 can transmit and receive packets up to 64k bytes.

### 2.6 FCS FIELD

The Frame Check Sequence (FCS) is a 32-bit CRC field calculated and appended to a packet during transmission to allow detection of error-free packets. During reception, an error-free packet results in a specific pattern in the CRC

generator. The AUTODIN II ( $X_{32} + X_{26} + X_{23} + X_{22} + X_{16} + X_{12} + X_{11} + X_{10} + X_8 + X_7 + X_5 + X_4 + X_2 + X_1 + 1$ ) polynomial is used for the CRC calculations. The SONIC-16 may optionally append the CRC sequence during transmission, and checks the CRC both during normal reception and self-reception during a transmission (see Section 1.2.1).

### 2.7 MAC (MEDIA ACCESS CONTROL) CONFORMANCE

The SONIC-16 is designed to be compliant to the IEEE 802.3 MAC Conformance specification. The SONIC-16 implements most of the MAC functions in silicon and provides hooks for the user software to handle the remaining functions. The MAC Conformance specifications are summarized in Table 2-1.

TABLE 2-1. MAC Conformance Specifications

Conformance Test Name	Support By		
	SONIC-16	User Driver Software	Notes
Minimum Frame Size	X		
Maximum Frame Size	X	X	1
Address Generation	X	X	2
Address Recognition	X		
Pad Length Generation	X	X	3
Start Of Frame Delimiter	X		
Length Field	X		
Preamble Generation	X		
Order of Bit Transmission	X		
Inconsistent Frame Length	X	X	1
Non-Integral Octet Count	X		
Incorrect Frame Check Sequence	X		
Frame Assembly	X		
FCS Generation and Insertion	X		
Carrier Deference	X		
Interframe Spacing	X

Collision Handling	X		
Collision Backoff and Retransmission	X		
FCS Validation	X		
Frame Disassembly	X		
Back-to-Back Frames	X		
Flow Control	X		
Attempt Limit	X		
Jam Size (after SFD)	X		
Jam Size (in Preamble)	X		

**Note 1:** The SONIC-16 provides the byte count of the entire packet in the RXpkt.byte\_count (see Section 3.4.3). The user's driver software may perform further filtering of the packet based upon the byte count.

**Note 2:** The SONIC-16 does not provide Source Address insertion; however, a transmit descriptor fragment, containing only the Source Address, may be created for each packet. See Section 3.5.1.

**Note 3:** The SONIC-16 does not provide Pad generation; however, the user's driver software can easily append the Pad by lengthening the TXpkt.pkt\_size field and TXpkt.frag\_size field(s) to at least 64 bytes. See Section 3.5.1.

### 3.0 Buffer Management

#### 3.1 BUFFER MANAGEMENT OVERVIEW

The SONIC-16's buffer management scheme is based on separate buffers and descriptors (*Figures 3-2 and 3-11*). Packets that are received or transmitted are placed in buffers called the Receive Buffer Area (RBA) and the Transmit Buffer Area (TBA). The system keeps track of packets in these buffers using the information in the Receive Descriptor Area (RDA) and the Transmit Descriptor Area (TDA). A single (TDA) points to a single TBA, but multiple RDAs can point to a single RBA (one RDA per packet in the buffer). The Receive Resource Area (RRA), which is another form of descriptor, is used to keep track of the actual buffer.

When packets are transmitted, the system sets up the packets in one or more TBAs with a TDA pointing to each TBA. There can only be one packet per TBA/TDA pair. A single packet, however, may be made up of several fragments of data dispersed in memory. There is one TDA pointing to each packet which specifies information about the packet's size, location in memory, number of fragments and status after transmission. The TDAs are linked together in a linked list. The system causes the SONIC-16 to transmit the packets by passing the first TDA to the SONIC-16 and issuing the transmit command.

Before a packet can be received, an RBA and RDA must be set up by the system. RDAs are made up as a linked list similar to TDAs. An RDA is not linked to a particular RBA, though. Instead, an RDA is linked specifically to a packet after it has been buffered into an RBA. More than one packet can be buffered into the same RBA, but each packet gets its own RDA. A received packet can not be scattered into fragments. The system only needs to tell the SONIC-16 where the first RDA and where the RBAs are. Since an RDA never specifically points to an RBA, the RRA is used to keep track of the RBAs. The RRA is a circular queue of pointers and buffer sizes (not a linked list). When the SONIC-16 receives a packet, it is buffered into a RBA and a RDA is written to so that it points to and describes the new packet. If the RBA does not have enough space to buffer the next packet, a new RBA is obtained from the RRA.

#### 3.2 DESCRIPTOR AREAS

Descriptors are the basis of the buffer management scheme used by the SONIC-16. A RDA points to a received packet within a RBA, a RRA points to a RBA and a TDA points to a TBA which contains a packet to be transmitted. The conventions and registers used to describe these descriptors are discussed in the next three sections.

##### 3.2.1 Naming Convention for Descriptors

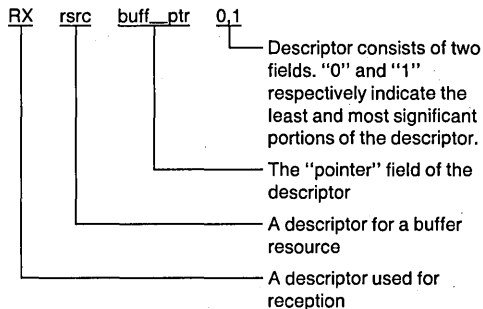

The fields which make up the descriptors are named in a consistent manner to assist in remembering the usage of each descriptor. Each descriptor name consists of three components in the following format.

[RX/TX][descriptor name].[field]

The first two capital letters indicate whether the descriptor is used for transmission (TX) or reception (RX), and is then followed by the descriptor name having one of two names.

rsrc = Resource descriptor  
 pkt = Packet descriptor

The last component consists of a field name to distinguish it from the other fields of a descriptor. The field name is separated from the descriptor name by a period ("."). An example of a descriptor is shown below.

##### 3.2.2 Abbreviations

The abbreviations in Table 3-1 are used to describe the SONIC-16 registers and data structures in memory. The "0" and "1" in the abbreviations indicate the least and most significant portions of the registers or descriptors. Table 3-1 lists the naming convention abbreviations for descriptors.

##### 3.2.3 Buffer Management Base Addresses

The SONIC-16 uses three areas in memory to store descriptor information: the Transmit Descriptor Area (TDA), Receive Descriptor Area (RDA), and the Receive Resource Area (RRA). The SONIC-16 accesses these areas by concatenating a 16-bit base address register with a 16-bit offset register. The base address register supplies a fixed upper 8 bits of address and the offset registers provide the lower 16 bits of address. The base address registers are the Upper Transmit Descriptor Address (UTDA), Upper Receive Descriptor Address (URDA), and the Upper Receive Resource Address (URRA) registers. The corresponding offset registers are shown below.

Upper Address Registers	Offset Registers
URRA	RSA, REA, RWP, RRP
URDA	CRDA
UTDA	CTDA

See Table 3-1 for definition of register mnemonics.

*Figure 3-1* shows an example of the Transmit Descriptor Area and the Receive Descriptor Area being located by the UTDA and URDA registers. The descriptor areas, RDA, TDA, and RRA are allowed to have the same base address. i.e., URRA=URDA=UTDA. Care, however, must be taken to prevent these areas from overwriting each other.

### 3.0 Buffer Management (Continued)

TABLE 3-1. Descriptor Abbreviations

TRANSMIT AND RECEIVE AREAS	
RRA	Receive Resource Area
RDA	Receive Descriptor Area
RBA	Receive Buffer Area
TDA	Transmit Descriptor Area
TBA	Transmit Buffer Area
BUFFER MANAGEMENT REGISTERS	
RSA	Resource Start Area Register
REA	Resource End Area Register
RRP	Resource Read Pointer Register
RWP	Resource Write Pointer Register
CRDA	Current Receive Descriptor Address Register
CRBA0,1	Current Receive Buffer Address Register
TCBA0,1	Temporary Current Buffer Address Register
RBWC0,1	Remaining Buffer Word Count Register
TRBWC0,1	Temporary Remaining Buffer Word Count Register
EOBC	End of Buffer Count Register
TPS	Transmit Packet Size Register
TSA0,1	Transmit Start Address Register
CTDA	Current Transmit Descriptor Address Register

BUFFER MANAGEMENT REGISTERS (Continued)	
TFC	Transmit Fragment Count Register
TFS	Transmit Fragment Size Register

### 3.0 Buffer Management (Continued)

#### 3.3 DESCRIPTOR DATA ALIGNMENT

All fields used by descriptors (RXpkt.xxx, RXrsrc.xxx, and TXpkt.xxx) are word quantities (16-bit) and must be aligned to word boundaries (A0=0). The Receive Buffer Area (RBA) must also be aligned to a word boundary. The fragments in the Transmit Buffer Area (TBA), however, may be aligned on any arbitrary byte boundary.

All descriptor areas follow little endian byte ordering, even when BMODE = 1.

#### 3.4 RECEIVE BUFFER MANAGEMENT

The Receive Buffer Management operates on three areas in memory into which data, status, and control information are written during reception (Figure 3-2). These three areas must be initialized (section 3.4.4) before enabling the receiver (setting the RXEN bit in the Command register). The receive resource area (RRA) contains descriptors that locate receive buffer areas in system memory. These descriptors are denoted by R1, R2, etc. in Figure 3-2. Packets (denoted by P1, P2, etc.) can then be buffered into the corresponding RBAs. Depending on the size of each buffer area and the size of the packet(s), multiple or single packets are buffered into each RBA. The receive descriptor area (RDA) contains status and control information for each packet (D1, D2, etc. in Figure 3-2) corresponding to each received packet (D1 goes with P1, D2 with P2, etc.).

When a packet arrives, the address recognition logic checks the address for a Physical, Multicast, or Broadcast match and if the packet is accepted, the SONIC-16 buffers the packet contiguously into the selected Receive Buffer Area (RBA). Because of the previous end-of-packet processing, the SONIC-16 assures that the complete packet is written into a single contiguous block. When the packet ends, the SONIC-16 writes the receive status, byte count, and location of the packet into the Receive Descriptor Area (RDA). The SONIC-16 then updates its pointers to locate the next available descriptor and checks the remaining words available in the RBA. If sufficient space remains, the SONIC-16 buffers the next packet immediately after the previous pack-

et. If the current buffer is out of space the SONIC-16 fetches a Resource descriptor from the Receive Resource Area (RRA) acquiring an additional buffer that has been previously allocated by the system.

#### 3.4.1 Receive Resource Area (RRA)

As buffer memory is consumed by the SONIC-16 for storing data, the Receive Resource Area (RRA) provides a mechanism that allows the system to allocate additional buffer space for the SONIC-16. The system loads this area with resource descriptors that the SONIC-16, in turn, reads as its current buffer space is used up. Each resource descriptor consists of a 23-bit buffer pointer locating the starting point of the RBA and a 32-bit Word Count that indicates the size of the buffer in words (2 bytes per word). The buffer pointer and word count are contiguously located using the format shown in Figure 3-3 with each component composed of 16-bit fields. The SONIC-16 stores this information internally and concatenates the corresponding fields to create 23- and 32-bit long words for the buffer pointer and word count.

The SONIC-16 organizes the RRA as a circular queue for efficient processing of descriptors. Four registers define the RRA. The first two, the Resource Start Area (RSA) and the Resource End Area (REA) registers, determine the starting and ending locations of the RRA, and the other two registers update the RRA. The system adds descriptors at the address specified by the Resource Write Pointer (RWP), and the SONIC-16 reads the next descriptor designated by the Resource Read Pointer (RRP). The RRP is advanced 4 words after the SONIC-16 finishes reading the RRA and automatically wraps around to the beginning of the RRA once the end has been reached. When a descriptor in the RRA is read, the RXrsrc.buf\_pt0,1 is loaded into the CRBA0,1 registers and the RXrsrc.buf\_wc0,1 is loaded into the RBWC0,1 registers.

The alignment of the RRA is confined to word boundaries (A0 is always zero).

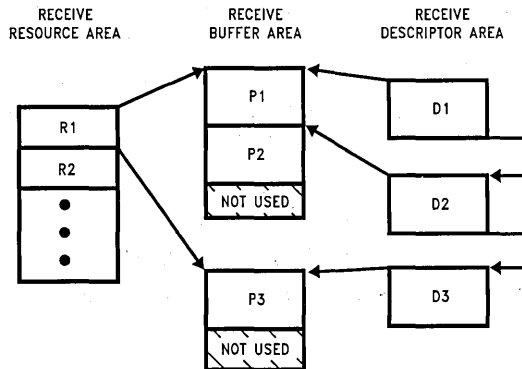

FIGURE 3-2. Overview of Receive Buffer Management

TL/F/11722-11

### 3.0 Buffer Management (Continued)

#### 3.4.2 Receive Buffer Area (RBA)

The SONIC-16 stores the actual data of a received packet in the RBA. The RBAs are designated by the resource descriptors in the RRA as described above. The `RXsrc.buf_wc0,1` fields of the RRA indicate the length of the RBA. When the SONIC-16 gets a RBA from the RRA, the `RXsrc.buf_wc0,1` values are loaded into the Remaining Buffer Word Count registers (`RBWC0,1`). These registers keep track of how much space (in words) is left in the buffer. When a packet is buffered in a RBA, it is buffered contiguously (the SONIC-16 will not scatter a packet into multiple buffers or fragments). Therefore, if there is not enough space left in a RBA after buffering a packet to buffer at least one more maximum sized packet (the maximum legal sized packet expected to be received from the network), a new buffer must be acquired. The End of Buffer Count (EOBC) register is used to tell the SONIC-16 the maximum packet size that the SONIC-16 will need to buffer.

##### 3.4.2.1 End of Buffer Count (EOBC)

The EOBC is a boundary in the RBA based from the bottom of the buffer. The value written into the EOBC is the maximum expected size (in words) of the network packet that the SONIC-16 will have to buffer. This word count creates a line in the RBA that, when crossed, causes the SONIC-16 to fetch a new RBA resource from the RRA.

**Note:** The EOBC is a word count, not a byte count.

##### 3.4.2.2 Buffering the Last Packet in an RBA

At the start of reception, the SONIC-16 stores the packet beginning at the Current Receive Buffer Address (`CRBA0,1`) and continues until the reception is complete. Concurrent with reception, the SONIC-16 decrements the Remaining Buffer Word Count (`RBWC0,1`) by one. At the end of reception, if the packet has crossed the EOBC boundary, the SONIC-16 knows that the next packet might not fit in the RBA. This check is done by comparing the `RBWC0,1` registers with the EOBC. If `RBWC0,1` is less than the EOBC (the last packet buffered has crossed the EOBC boundary), the SONIC-16 fetches the next resource descriptor in the RRA. If `RBWC0,1` is greater than or equal to the EOBC (the EOBC boundary has not been crossed) the next packet reception continues at the present location pointed to by `CRBA0,1` in the same RBA. *Figure 3-4* illustrates the SONIC-16's actions for (1)  $RBWC0,1 \geq EOBC$  and (2)  $RBWC0,1 < EOBC$ . See Section 3.4.4.4 for specific information about setting the EOBC.

**Note:** It is important that the EOBC boundary be "crossed." In other words, case #1 in *Figure 3-4* must exist before case #2 exists. If case #2 occurs without case #1 having occurred first, the test for  $RBWC0,1 < EOBC$  will not work properly and the SONIC-16 will not fetch a new buffer. The result of this will be a buffer overflow (RBAE in the Interrupt Status Register, section 4.3.6).

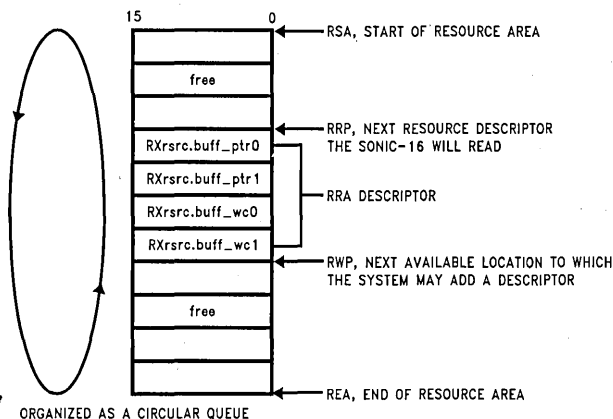

FIGURE 3-3. Receive Resource Area Format

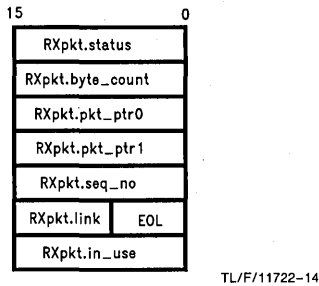

Case #1: SONIC-16 buffers next packet in same RBA.  
 Case #2: SONIC-16 detects an exhausted RBA and will buffer the next packet in another RBA.

FIGURE 3-4. Receive Buffer Area

### 3.0 Buffer Management (Continued)

#### 3.4.3 Receive Descriptor Area (RDA)

After the SONIC-16 buffers a packet to memory, it writes 5 words of status and control information into the RDA, reads the link field to the next receive descriptor and writes to the in use field of the current descriptor. Each receive descriptor consists of the following sections (*Figure 3-5*).

**FIGURE 3-5. Receive Descriptor Format**
